This strengthens HD's full-source evaluation bound to this precise quotient comparison. It needs an actual positive-mass sampled root; none is invented. For $k = 1$ full-order cancellation supplies positivity at any selected sampled root; for $k \geq 2$ the original convolution is positive everywhere. If Z_θ is empty, CR13 has zero limit but CR14 makes no relative-rate assertion.

For the fixed χ , the exceptional phases are finite. The completed phase quotient field is therefore zero almost everywhere for its actual phase measure, and its direct integral is zero. The exact source isometry over all phases, the finite quotient identity $J_N R_N = I$, CR11, CR12 and the exceptional positive quotient limit CR13 are all compatible through their displayed maps. No arithmetic class is declared absent before the specified completion. A retained split label is transported as $(\lambda, v) \mapsto (\lambda, fv)$; the zero comparison takes it to $(\lambda, 0)$, fixes τ , and does not identify that receiving zero with external absence.

80.0.6 Provenance and scope

Read in full before deriving this note: the owner HD1–9 source, SHA256 56c05d9be82fa356f82d71324f317f86325e761531767b57d4a085e91b7760fa; holonomy_completed_quotient_density_review_20260913.md; and holonomy_continuous_descent_review_20260913.tex. P53–58 and surrounding original-source definitions were read directly in their delivered research note. CR4–11 are proved here, not inferred from a numerical check. CR12–14 explicitly compose those results with the named existing phase maps.

This is a written argument, pending independent review. No new Lean, numerical arithmetic enclosure, publication, tensor- k estimate or claimed solution of the remaining arithmetic upper-bound problem accompanies it.

81 Complete independent proof of the original continuous relation completion

81.1 Independent review: original continuous relation completion

Date: 2026-09-13. Scope: CR1–14 in the parent's period_laplacian/CONTINUOUS_RELATION_COMPLETION.md, including the subsequently written CR12a–c pullback construction. This is a written mathematical review, not a numerical or Lean certificate. Only this new independent review directory is written. No source, owner, public, or remote artifact is edited. No new model examples are needed.

81.1.1 Disposition and the actual positivity issue

Accept CR1–11 and CR13–14 with the exact domains and positive-support maps specified there. Accept the revised unconditional CR12a–c and CR12. The original HCD2 assumption is a uniformly positive finite phase family; it is not, by itself, a proof of that assumption for every one-fold phase. Full-order cancellation proves positivity at a sampled selected root, not positivity of every sampled weight or invertibility of every finite one-fold source Gram. The pullback construction resolves that distinction without adding a hypothesis or choosing a new source norm.

For the actual source one can also prove, without uniform phase positivity, that every finite averaged pullback form is positive definite, and that these average forms decrease to zero. The full graph closure of the original class map is $H \times E$. Proofs and qualifications follow.

81.1.2 1. Continuous measure, density, and domains

Retain the original full-order packet h , tensor degree $k \geq 1$, $g = 2\xi$, $c = k/2$, $S(u) = c + iu$, and

$$w_h(u) = |(g/h)(1/2 + iu)|^2/(2\pi), m = w_h^{*k}, d\nu = m(u) du.$$

HD1 and P54 provide the positive exponential moments for this actual measure; P54 also provides the pointwise exponential bound needed for sampling. No mass normalization occurs: $\nu(\mathbb{R}) = \mu_h^k$. The quotient g/h is entire and nonzero after full-order removal. Its real-line zeros are isolated, so $w_h > 0$ almost everywhere. For $k \geq 2$, integrating the positive-almost-everywhere product in convolution proves $m(u) > 0$ for every real u . The inherited boundedness/integrability makes those convolution integrals finite. In every case ν is atomless and positive on every set of positive Lebesgue measure.

For either $\eta = \nu$ or $\eta = |\chi(S)|^2\nu$, a smaller positive exponential exponent absorbs the fixed polynomial factor. Every polynomial is in $L^2(\eta)$. With inner product $\int \bar{f} g d\eta$, orthogonality of f to all S -polynomials gives zero moments of $\sigma = \bar{f} \eta$ in u , since $u = (S - c)/i$ is invertible. Cauchy–Schwarz supplies the exponentially weighted finite variation needed in CR4. Hence $F(z) = \int \exp(izu) d\sigma(u)$ is holomorphic in the stated strip; dominated differentiation on each smaller strip is valid for every order. All derivatives at zero vanish. The identity theorem gives $F = 0$ on the strip.

The Gaussian uniqueness argument in CR4–5 has the correct Fourier signs: $\gamma_t(x - u)$ contributes $\exp(-i\xi x) \exp(i\xi u)$, so its integral against σ is zero. Finite variation permits Fubini; compactly supported continuous test functions are uniformly approximated by their Gaussian convolutions. Thus $\sigma = 0$, hence $f = 0$ almost everywhere. This proves both polynomial-density assertions without a moment-problem uniqueness hypothesis being silently added.

Put $H = L^2(\nu)$ and $H_\chi = L^2(|\chi(S)|^2\nu)$. The map

$$U_\chi : H_\chi \longrightarrow H, f \longmapsto \chi(S)f$$

is a linear onto isometry. The inverse $v/\chi(S)$ belongs to H_χ because its weighted squared norm is exactly $\|v\|_H^2$. The finitely many real zeros of $\chi(S)$ have zero ν -mass; inverse values there are irrelevant to both equivalence classes. This is not an assertion that unweighted multiplication by χ is bounded $H \longrightarrow H$. Its weighted domain is essential and is exactly the inherited norm of its relation image, so it does not replace the source metric.

Density in H_χ and this onto isometry prove $\text{closure}_H(\chi\mathbb{C}[S]) = H$. Completing the two terms of the inclusion complex $[\chi\mathbb{C}[S] \longrightarrow \mathbb{C}[S]]$ in their inherited H norms therefore gives $[H \xrightarrow{I} H]$, whose degree-minus-one contraction is I . The original algebraic quotient $E = \mathbb{C}[S]/(\chi)$ maps to its zero completed quotient with kernel all of E . In particular completion does not identify the original algebraic quotient with zero before the stated map.

81.1.3 2. The same finite canonical forms and the full graph

For $N \geq q - 1$, multiplication by the literal nonzero χ is injective on P_{N-q} and has image $B_N = \ker J_N$. At $N = q - 1$ this is the zero relation space. Polynomial evaluation in H is injective because a nonzero polynomial has only finitely many real-line zeros and the density is positive almost everywhere. Thus every finite original M_N is positive definite.

Let $s : E \rightarrow P_{q-1}$ be the fixed remainder section and let Π_N be orthogonal projection in the actual H norm onto B_N . Then

$$R_N = (I - \Pi_N)s, J_N R_N = I_E, G_N = R_N^* R_N.$$

The adjoint in this Gram uses the fixed coefficient inner product on E and the actual H inner product. Every lift is $sx + b$, $b \in B_N$; orthogonal decomposition gives unique minimality. In coefficient coordinates the unique minimizer is exactly

$$G_N = (J_N M_N^{-1} J_N^*)^{-1}, R_N = M_N^{-1} J_N^* G_N.$$

All inverses here are legitimate: $M_N > 0$ and J_N is onto. No phase positivity enters these continuous-source formulas.

The B_N increase and have dense union. Therefore $\Pi_N \rightarrow I_H$ strongly. Applying this to the finitely many fixed columns of s gives $R_N \rightarrow 0$ in the operator norm from any fixed finite norm on E to H , and hence $G_N \rightarrow 0$ in every fixed coordinate matrix norm. The minimum decreases when relations are enlarged, proving $G_N \downarrow 0$ in Loewner order. Each finite G_N remains positive definite, and $\det G_N \rightarrow 0$ since $q \geq 1$. No cutoff or tensor-degree rate follows.

For every $x \in E$, $(R_N x, J R_N x) \rightarrow (0, x)$. Thus the closure of graph J contains $\{0\} \times E$. It also contains (p, Jp) for every polynomial p , and is a closed linear subspace. Adding $(0, x - Jp)$ shows it contains (p, x) for every polynomial p and every x . Polynomial density now proves the exact stronger assertion

$$\text{closure}(\text{graph}(J : \mathbb{C}[S] \subset H \rightarrow E)) = H \times E.$$

This is full nonclosability, not just an unbounded-evaluation example. It is compatible with $J_N R_N = I_E$ at every finite cutoff. Under every fixed invertible coefficient change $x = Wx'$, the exact maps become $G'_N = W^* G_N W$, $R'_N = R_N W$, $J'_N = W^{-1} J_N$; all claims persist.

81.1.4 3. Unconditional finite phase pullback, including singular phases

Fix the original $L > 0$, put $u_n(\theta) = (2\pi n + \theta)/L$, and retain $\nu_n(\theta) = (2\pi/L)m(u_n(\theta))$. Let

$$I_\theta = \{n : \nu_n(\theta) > 0\}, H_\theta = \ell^2(I_\theta, \nu_\theta), T_\theta P = (P(c + iu_n(\theta)))_{n \in I_\theta}.$$

The pointwise exponential estimate P54/CQ5 and its lattice sum CQ6 prove every finite polynomial evaluation is in this original Hilbert space, including when $k = 1$. Zero-weight coordinates are null classes, never inverted evaluation functionals. Define

$$Q_{N,\theta} = T_\theta(P_N)/T_\theta(B_N)$$

with the quotient norm inherited from H_θ . Both images are finite-dimensional and closed, whether or not T_θ is injective. The map

$$\rho_{N,\theta} : E \rightarrow Q_{N,\theta}, [P] \mapsto [T_\theta P]$$

is well defined and onto. Its exact kernel is

$$\ker \rho_{N,\theta} = J_N(\ker(T_\theta|_{P_N})).$$

Indeed $T_\theta P = T_\theta b$, for some $b \in B_N$, exactly when $P - b$ is a sampling-null polynomial with the same class. Conversely such a null representative maps to zero. The unique pullback form is

$$x^* G_{N,\theta} x = \min_{b \in B_N} \|T_\theta(sx + b)\|^2.$$

The minimum exists because it is distance to a closed finite-dimensional relation image. Its minimizing observed vector is unique, although a minimizing coefficient polynomial need not be. Its radical is the exact displayed kernel. If $M_{N,\theta} > 0$, this is precisely the usual positive canonical Gram

$(J_N M_{N,\theta}^{-1} J_N^*)^{-1}$. At a singular phase that inverse expression is not asserted.

For each fixed x , the minimum equals the infimum over a countable dense set of complex rational relation coefficients. The norm at each such coefficient is measurable in θ , so the infimum is measurable; polarization makes all matrix entries measurable. Testing the particular original lift $R_N x$ and unfolding the literal phase measure gives

$$\begin{aligned} & \int x^* G_{N,\theta} x \frac{d\theta}{2\pi} \\ & \leq \int \|T_\theta R_N x\|^2 \frac{d\theta}{2\pi} \\ & = \int_{\mathbb{R}} |R_N x(c + iu)|^2 m(u) du = x^* G_N x. \end{aligned}$$

The normalization is exact: $(2\pi/L) d\theta/(2\pi) = du$ on each lattice interval. The integrals are finite. Off-diagonal entries are integrable by the positive-form inequality $|G_{ij}| \leq \sqrt{G_{ii}G_{jj}}$ and Cauchy-Schwarz in the actual phase measure. Thus for every original $k \geq 1$ and every $N \geq q - 1$, without universal phase invertibility,

$$\begin{aligned} 0 & \leq \overline{G}_N := \int G_{N,\theta} \frac{d\theta}{2\pi} \leq G_N, \\ D_N & := G_N - \overline{G}_N \geq 0. \end{aligned}$$

81.1.5 Exact relation-gap version without coefficient inverse assumptions

Let $\Pi_{N,\theta}$ be orthogonal projection in H_θ onto $T_\theta(B_N)$. Since $T_\theta R_N x$ and $T_\theta s x$ differ by that relation image, the minimizing observed lift is $(I - \Pi_{N,\theta})T_\theta R_N x$. Orthogonal decomposition gives

$$x^* D_N x = \int \|\Pi_{N,\theta} T_\theta R_N x\|^2 \frac{d\theta}{2\pi}.$$

This is an exact positive original-relation norm at every phase; it specializes to HCD13 on the admitted positive family. For an explicit measurable coefficient formula only, let B contain the literal relation columns, $F_\theta = B^* M_{N,\theta} B$, and $d_\theta = B^* M_{N,\theta} R_N$. Then the projected relation is $T_\theta B F_\theta^+ d_\theta$, where $+$ is the finite Moore–Penrose pseudoinverse. Here d_θ lies in the range of F_θ : a vector in $\ker F_\theta$ gives the zero observed relation and hence pairs to zero with $T_\theta R_N$. Thus this expression is precisely the projection, not a modified quotient. Pseudoinverse is Borel measurable, for example as the limit of $(F_\theta^2 + \epsilon I)^{-1} F_\theta$. Its observed squared norm is bounded by that of $T_\theta R_N$, so the integral exists even if the chosen coefficient representative is not uniformly bounded. At $B_N = 0$ the projection is zero and $D_N = 0$.

The mean-zero coefficient contraction and coefficientwise averaging of arbitrary fields in HCD5–16 still use the HCD2 uniform-equivalence hypothesis. The unconditional argument above does not silently extend those stronger coefficient-field assertions beyond their stated domain.

81.1.6 What is unconditional about one-fold positivity

For $k = 1$, the zeros of the actual nonzero entire g/h on the sampled vertical line form a discrete, hence countable, set. Their phases modulo 2π form a countable set. Outside it every lattice weight is positive; a nonzero polynomial cannot vanish at all the infinitely many distinct sample points. Therefore $M_{N,\theta} > 0$ for almost every phase, simultaneously for all finite N . For $k \geq 2$ the same statement holds at every phase by everywhere-positive convolution.

Consequently, for every nonzero fixed x , $x^* G_{N,\theta} x > 0$ almost everywhere and its integral is positive. This proves the additional actual-source statement

$$\overline{G}_N > 0 \text{ at every finite cutoff, and } \overline{G}_N \downarrow 0.$$

Monotonicity follows phasewise by enlarging relations; the limit follows from $\overline{G}_N \leq G_N$. Also $0 \leq D_N \leq G_N$ implies $D_N \rightarrow 0$. No monotonicity of D_N , no zero limit for $G_N^{-1} D_N$, and no uniform positive lower bound in θ is inferred. In particular positivity almost everywhere does not supply the HCD2 uniform lower constant.

81.1.7 4. Fixed-phase limits, full primary kernels, and surviving masses

The exponential sampled moment proof applies on I_θ , and also after multiplying the measure by $|\chi|^2$. Thus the sampled polynomial vectors are dense. The image of multiplication by χ is exactly the closed subspace vanishing at

$$Z_\theta = \{n \in I_\theta : \chi(c + iu_n(\theta)) = 0\}.$$

Division by χ on the complementary positive atoms proves the reverse inclusion isometrically in the weighted domain. Restriction to Z_θ is the orthogonal quotient map, with squared norm $\sum_{n \in Z_\theta} \nu_n(\theta) |v_n|^2$. No weight or phase is removed.

Increasing finite relation images have union equal to the evaluated polynomial relation space. Their distances therefore decrease to distance to its closure, including singular finite phase Grams. For every class x , this proves

$$x^* G_{N,\theta} x \downarrow \sum_{n \in Z_\theta} \nu_n(\theta) |x(S_n(\theta))|^2.$$

Polarization gives the matrix limit CR13 in the same fixed coefficient frame. Let p_θ be the square-free product of the displayed roots. The exact limiting radical is $(p_\theta)/(\chi)$. In a sampled primary block $\mathbb{C}[\epsilon]/(\epsilon^r)$, only the constant coefficient is received and the full ideal $(\epsilon)/(\epsilon^r)$ stays in the kernel. Every unsampled primary block stays entirely in the kernel. This uses the full original χ ; it does not replace its multiplicities by a reduced polynomial upstream.

At $k = 1$, the original cyclic minimal polynomial has ideal $(\chi) = (h)$. If a_h is the original leading coefficient, $\chi = h/a_h$ identifies the monic ideal generator, without replacing the density $|g/h|^2/(2\pi)$. For an actual selected root ρ of complete order r , write $h = (S - \rho)^r h_0$, with the unchanged $h_0(\rho) \neq 0$. Then

$$(g/h)(\rho) = g^{(r)}(\rho)/(r! h_0(\rho)) \neq 0,$$

$$\nu_n(\theta) = |g^{(r)}(\rho)|^2/(L(r!)^2 |h_0(\rho)|^2) > 0$$

whenever $S_n(\theta) = \rho$. Thus no sampled root of the actual one-fold χ loses its receiving line to a zero weight. This does not say that every phase samples such a root or that every other atom has positive weight. It is the exact narrower positivity needed for CR14.

If a displayed sampled root exists, take the original unit class $x = 1$ (or any class evaluating to one there). Since $G_{N,\theta} \geq K_\theta$, its numerator is at least the retained positive mass. Its continuous denominator is positive at every finite cutoff and tends to zero by CR11. This proves the quotient ratio in CR14 tends to infinity. If Z_θ is empty there is no such lower bound and no relative rate is asserted. No sampled root is invented.

Only finitely many phases can sample a root of the fixed χ : each root on $\text{Re } S = c$ specifies its unique phase $L \text{Im } \rho \bmod 2\pi$. The completed quotient field is therefore zero almost everywhere. Its measurable realization is the range in ordinary $\ell^2(\mathbb{Z})$ of the diagonal projection with entries $\mathbf{1}_{\nu_n(\theta) > 0} \mathbf{1}_{\chi(S_n(\theta))=0}$. Its direct integral is the zero Hilbert space, and the induced map from the whole original E has kernel E . Individual exceptional weighted fibres are not erased pointwise. The retained marked map is $(\text{label}, v) \mapsto (\text{label}, 0)$, with $\tau \mapsto \tau$; represented zero is not external absence.

81.1.8 5. Read scope and provenance pins

Read completely: the original and revised root note; the current HD source; the completed-phase density review; the continuous-descent review; and the complete delivered periodized-source research note. Source SHA-256 pins:

Key source proof locations are HD1–5 and HD6–10; HCD2 for the uniform phase assumption, HCD9–16 for its positive-family gap formulas, HCD17–29 for sampled support, completion and marked maps; CQ4–8 for actual exponential sampled tails, CQ14–22 for the quotient and primary kernel, CQ23–25 for exact one-fold root masses, CQ26–29 for the direct integral; and P8–10, P26a–b, P53–58 in the delivered note.

This review makes no evaluated arithmetic enclosure, uniform source or tensor-degree estimate, public-publication, or proof-assistant claim.

82 Arithmetic determinant transport on the original tau complex

This calculation retains the arithmetic coefficient complex over the absolute pointed base $\mathbf{F}_{1,\tau} = \{\tau, 1\}$. It computes the signed arithmetic/reference determinant term on the original finite theta source. The new formulas are a complete first and second variation, an exact four-window projection trace, and a quantitative bound in terms of the actual common source Gram. No arithmetic source multiplier is assumed bounded above or bounded away from zero.

82.1 Original objects and the fixed comparison

The retained tau-base construction has the four-point chart $+, - < \eta < \sigma$ and the coefficient sheaf $\mathcal{T}$ with $(\mathcal{T}_+, \mathcal{T}_-, \mathcal{T}_\eta, \mathcal{T}_\sigma) = (V, V, \mathcal{B}, 0)$. Its two nonzero restrictions are Θ and $J\Theta = \Theta\mathcal{F}$. The actual projective resolution gives

$$A_\tau(\mathcal{T}) = [V \oplus V \xrightarrow{\Theta(\phi-\hat{\psi})} \mathcal{B}], \quad H^1 A_\tau(\mathcal{T}) = Q = \mathcal{B}/\Theta V. \quad (\text{AT1})$$

These are the fixed source objects of the original Tau Base note, equations (18)–(25), supplied in the source closure. The tensor resolution in its equations (46)–(48) retains the original differential signs and identifies its top cohomology with $Q^{\otimes k}$. The operation here uses that pushforward, with its arithmetic classes. Its separately computed restriction to σ remains an available comparison; it is not substituted for (AT1).

Fix an original actual packet h of full zero orders of $g = 2\xi$, and a positive integer k . Retain the full tensor-sum operator, its original cyclic annihilator $\chi = \chi_{h,k}$ of degree $q \geq 1$, and $E = \mathbb{C}[S]/(\chi)$ in the increasing-power remainder frame. The original construction supplies

$$\mathcal{V}P = P(D_1 + \cdots + D_k)F_h^{\otimes k}, \quad J^{(k)}\mathcal{V}P = \eta_{h,k}J_N P, \quad \eta_{h,k}[P] = v_h^{\otimes k}P(A_h^{(k)})1, \quad (\text{AT2})$$

where $v_h = j_h(g/h)$ is the full invertible Taylor unit, J_N is literal remainder modulo χ , and $\eta_{h,k} : E \hookrightarrow E_h^{\otimes k}$ is the original injective full-jet observation, $E_h = \mathbb{C}[s]/(h)$. The original section $\sigma_h : E_h \hookrightarrow Q$ gives the separate arithmetic cohomology injection and equality

$$q^{(k)}\mathcal{V}P = \sigma_h^{\otimes k}\eta_{h,k}J_N P, \quad \sigma_h^{\otimes k}\eta_{h,k} : E \hookrightarrow Q^{\otimes k}. \quad (\text{AT2a})$$

The supplied arithmetic-input and cyclic-sum proofs construct these maps; all operations below keep them fixed. In particular the sum coordinate is $S = k/2 + iu$, with no division by k .

For $N \geq q - 1$, set $\mathcal{P}_N = \mathbb{C}[S]_{\leq N}$, $\mathcal{P}_{-1} = 0$, and let $B_N : \mathcal{P}_{N-q} \rightarrow \mathcal{P}_N$ be multiplication by the literal monic χ . Write $s_N : E \rightarrow \mathcal{P}_N$ for the degree-less-than- q remainder section. Polynomial division proves

$$0 \longrightarrow \mathcal{P}_{N-q} \xrightarrow{B_N} \mathcal{P}_N \xrightarrow{J_N} E \longrightarrow 0, \quad J_N s_N = I_E. \quad (\text{AT3})$$

The arithmetic norm has density $m_1(u) = m_{h,k}(u) = w_h^{*k}(u)$, $w_h(u) = |(g/h)(1/2 + iu)|^2/(2\pi)$. The retained Gamma reference has density

$$m_0(u) = r_{1/4,k}(u) = \frac{(\sqrt{2\pi})^k}{c_{k/4}} \frac{|\Gamma(k/4 + iu/2)|^2}{2\pi}, \quad c_a = 2^{1-2a}\Gamma(2a). \quad (\text{AT4})$$

Its mass is $(2\pi)^{k/2}$; the arithmetic mass is the original μ_h^k . The source proofs included with this calculation establish finite moments of every degree and positivity almost everywhere for both densities. The calculation below only integrates polynomials against these two actual measures and their sum. It needs no estimate on the pointwise ratio m_1/m_0 .

For $0 \leq t \leq 1$ define, in the unchanged coefficient frame,

$$\begin{aligned} m_t &= (1-t)m_0 + tm_1, \quad \Delta m = m_1 - m_0, \quad v_N(u) = (1, S(u), \dots, S(u)^N), \\ M_N(t) &= \int v_N(u)^* v_N(u) m_t(u) du, \quad \Delta M_N = M_N(1) - M_N(0), \\ H_N(t) &= B_N^* M_N(t) B_N. \end{aligned} \quad (\text{AT5})$$

Every $M_N(t)$ is positive definite: a nonzero polynomial has finitely many real zeros, and m_t is positive almost everywhere. B_N is injective, so $H_N(t)$ is positive definite on its actual relation domain. When $N = q - 1$, that domain is zero; its determinant is one, its unique endomorphism is its inverse, and all compositions through that domain are zero. The real parameter t interpolates norms on (AT3); it changes neither the absolute base nor a cochain map.

The reference density in (AT4) is exactly the density denoted $r_{1/4}^{*k}$ in SP: with the retained convolution constant $c_a = 2^{1-2a}\Gamma(2a)$ one has

$$c_{1/4} = \sqrt{2\pi}, \quad r_{1/4}^{*k}(u) = \frac{c_{1/4}^k}{c_{k/4}} \frac{|\Gamma(k/4 + iu/2)|^2}{2\pi} = m_0(u). \quad (\text{AT4a})$$

The original Gamma convolution identity therefore identifies all moments and the mass $(2\pi)^{k/2}$, without a mass adjustment. Writing $x = t$ and $y = u$, the precise coefficient arrow to the common-source notation of SP is $B_N^{\text{SP}} = I_N B_N^{\text{AT}}$, from $\mathcal{P}_{N-q}$ to $H = \mathcal{P}_{2q}$. Consequently

$$(B_N^{\text{SP}})^* M_* B_N^{\text{SP}} = B_N^* M_N B_N, \quad Q_N^{\text{SP}} = I_N B_N H_N^{-1} B_N^* I_N^* M_* = Q_N. \quad (\text{AT4b})$$

These identities follow from $M_N = I_N^* M_* I_N$. They include the zero relation domain, where all compositions are zero.

82.2 Canonical sections, determinant lines and full variations

Theorem 82.1. *On the fixed exact sequence (AT3), its least-norm section and quotient Gram are*

$$\begin{aligned} R_N(t) &= s_N - B_N H_N(t)^{-1} B_N^* M_N(t) s_N, \\ J_N R_N(t) &= I_E, \quad B_N^* M_N(t) R_N(t) = 0, \\ G_N(t) &= R_N(t)^* M_N(t) R_N(t) = (J_N M_N(t)^{-1} J_N^*)^{-1}, \\ V_N(t) &:= \det G_N(t) = \frac{\det M_N(t)}{\det H_N(t)}. \end{aligned} \quad (\text{AT6})$$

In the original polynomial frame the exact first and second variations are

$$\begin{aligned}\dot{R}_N &= -B_N H_N^{-1} B_N^* \Delta M_N R_N, & \dot{G}_N &= R_N^* \Delta M_N R_N, \\ \ddot{G}_N &= -2R_N^* \Delta M_N B_N H_N^{-1} B_N^* \Delta M_N R_N \preceq 0.\end{aligned}\tag{AT7}$$

The exact logarithmic variation, with both trace terms retained, is

$$\begin{aligned}\frac{d}{dt} \log V_N &= \text{Tr}(M_N^{-1} \Delta M_N) - \text{Tr}(H_N^{-1} B_N^* \Delta M_N B_N) \\ &= \text{Tr}(G_N^{-1} R_N^* \Delta M_N R_N).\end{aligned}\tag{AT8}$$

Its second derivative is

$$\begin{aligned}\frac{d^2}{dt^2} \log V_N &= -2 \text{Tr}(G_N^{-1} R_N^* \Delta M_N B_N H_N^{-1} B_N^* \Delta M_N R_N) \\ &\quad - \text{Tr}(G_N^{-1} \dot{G}_N G_N^{-1} \dot{G}_N) \leq 0.\end{aligned}\tag{AT9}$$

Proof. Every lift of $x \in E$ is $s_N x + B_N y$. Expanding its squared norm and completing its finite quadratic expression gives the unique minimizer $y = -H_N^{-1} B_N^* M_N s_N$. This proves the first two lines of (AT6). For the inverse expression, every polynomial vector p decomposes as $B_N y + R_N J_N p$. Orthogonality therefore gives $R_N^* M_N p = G_N J_N p$ for every p . Taking adjoints yields $M_N R_N = J_N^* G_N$. Substituting this into $J_N R_N = I_E$ gives $(J_N M_N^{-1} J_N^*) G_N = I_E$, which proves the inverse expression.

The determinant calculation preserves orientation. Put $r = N - q + 1$ and $L_N = [B_N \ s_N]$. In the ordered monomial bases, $[s_N \ B_N]$ has determinant one, since χ is monic and the lower diagonal block is triangular with diagonal one. Thus $\det L_N = (-1)^{qr}$. The upper-left block of $L_N^* M_N L_N$ is H_N , and its Schur complement is G_N . Consequently $\det H_N \det G_N = |(-1)^{qr}|^2 \det M_N = \det M_N$. Equivalently the map

$$\begin{aligned}\det \mathcal{P}_{N-q} \otimes \det E &\longrightarrow \det \mathcal{P}_N, \\ (y_1 \wedge \cdots \wedge y_r) \otimes (x_1 \wedge \cdots \wedge x_q) &\longmapsto B_N y_1 \wedge \cdots \wedge B_N y_r \wedge s_N x_1 \wedge \cdots \wedge s_N x_q\end{aligned}\tag{AT10}$$

is the fixed determinant-line isomorphism. Replacing any lift by a relation does not change its wedge. Orthogonal lifts give the product metric just computed. This proves the determinant identity including the empty relation space, without changing any scalar mass.

Differentiate $J_N R_N = I$; then $\dot{R}_N$ lies in $\text{im } B_N$. Differentiating $B_N^* M_N R_N = 0$ determines its unique coefficient and proves the first identity of (AT7). On differentiating $R_N^* M_N R_N$, the two terms involving $\dot{R}_N$ vanish by that orthogonality. A second differentiation gives the two equal negative terms in (AT7), since ΔM_N is Hermitian. This proves the claimed second derivative and its sign. Applying the finite determinant derivative to (AT6) gives the first equality of (AT8); applying it to G_N gives the second. One more derivative gives (AT9). The first trace there is the squared Hilbert–Schmidt norm of $H_N^{-1/2} B_N^* \Delta M_N R_N G_N^{-1/2}$; the second is the squared Hilbert–Schmidt norm of $G_N^{-1/2} \dot{G}_N G_N^{-1/2}$. These identities establish their signs and retain the original forms. All inverse matrices are smooth on a neighborhood of the compact interval $[0, 1]$, by positivity and continuity. No infinite-dimensional inverse has been used. $\square$

The derivative $\dot{R}_N$ in (AT7) is a literal polynomial relation. Applying the original $\mathcal{V}$ in (AT2) therefore retains its original theta primitive and sends its arithmetic class to zero; $J^{(k)} \mathcal{V} R_N(t) = \eta_{h,k}$ for every t . At each nonempty original support label A , the cochain identities lift by $(A, P) \mapsto (A, fP)$, while $\tau \mapsto \tau$. Thus a relation-valued derivative has a supported zero class at label A . Its source vector and its full nonnegative energy in (AT7)–(AT9) remain present. These formulas compute their contribution rather than deleting it after taking cohomology.

82.3 The signed four-endpoint term on one retained source

Let $N_* = 2q$. Every space in (AT3) for the four endpoints sits in $\mathcal{P}_{N_*}$ by its actual coefficient inclusion. Give this common space the form $M_*(t) = M_{N_*}(t)$. Write $P_N(t)$ for its orthogonal projection onto $\mathcal{P}_N$, and $Q_N(t)$ for its orthogonal projection onto the relation subspace $\mathcal{R}_N = \chi\mathcal{P}_{N-q}$. The latter is zero at $N = q - 1$. For the coefficient inclusion $I_N : \mathcal{P}_N \hookrightarrow \mathcal{P}_{N_*}$, the formulas, with their domains retained, are

$$P_N = I_N M_N^{-1} I_N^* M_*, \quad Q_N = I_N B_N H_N^{-1} B_N^* I_N^* M_*, \quad C(t) = M_*(t)^{-1} \Delta M_*. \quad (\text{AT11})$$

Both P_N and Q_N are $M_*(t)$ -self-adjoint idempotents with their displayed images, verified by substitution. Since $\mathcal{R}_N \subset \mathcal{P}_N$, $P_N Q_N = Q_N P_N = Q_N$. Their difference is the orthogonal projection onto the finite canonical quotient section and has trace q . Cyclicity of finite matrix trace in (AT11) proves the exact common-source version of (AT8):

$$\frac{d}{dt} \log V_N(t) = \text{Tr}((P_N(t) - Q_N(t))C(t)). \quad (\text{AT12})$$

Put $i_0 = q - 1$, $i_1 = q$, $j_0 = 2q - 1$, and $j_1 = 2q$. Define the two positive operators

$$\begin{aligned} U(t) &= (Q_{j_0} - Q_{i_0}) + (Q_{j_1} - Q_{i_1}), \\ W(t) &= (P_{j_0} - P_{i_0}) + (P_{j_1} - P_{i_1}). \end{aligned} \quad (\text{AT13})$$

Each difference in this display is an orthogonal projection, because the two spaces in its pair are nested in the same Hilbert space. Each has rank q . The sums need not be projections and are not asserted to be orthogonal sums; they are positive operators with $\text{Tr } U = \text{Tr } W = 2q$.

Write

$$\begin{aligned} \mathcal{B}(t) &= \log \frac{V_{i_0}(t)V_{i_1}(t)}{V_{j_0}(t)V_{j_1}(t)}, \quad T_N = V_N(1)/V_N(0), \\ \Delta \mathcal{B} &= \mathcal{B}(1) - \mathcal{B}(0) = \log \frac{T_{q-1}T_q}{T_{2q-1}T_{2q}}. \end{aligned} \quad (\text{AT14})$$

Subtracting the four exact formulas (AT12), with their original signs, and integrating gives

$$\Delta \mathcal{B} = \int_0^1 \text{Tr}((U(t) - W(t))C(t)) dt. \quad (\text{AT15})$$

This is the actual arithmetic correction in the audit's formula (54). It compares the two added relation windows with the two added polynomial windows. Concavity of each individual $\log V_N(t)$ in (AT9) does not assign a sign to their signed combination in (AT15); that combination has now been computed.

There is also an exact pointwise integral, using no division by the arithmetic density. Define

$$\begin{aligned} k_N(t, u) &= v_N(u)M_N(t)^{-1}v_N(u)^*, \\ r_N(t, u) &= |\chi(S(u))|^2 v_{N-q}(u)H_N(t)^{-1}v_{N-q}(u)^*, \\ d_N(t, u) &= k_N(t, u) - r_N(t, u), \quad r_{q-1}(t, u) = 0, \\ d_N(t, u) &= v_N(u)R_N(t)G_N(t)^{-1}R_N(t)^*v_N(u)^* \geq 0. \end{aligned} \quad (\text{AT16})$$

The last equality follows by writing the orthogonal splitting of M_N^{-1} as $B_N H_N^{-1} B_N^* + R_N G_N^{-1} R_N^*$; multiplying by M_N and evaluating on $\text{im } B_N \oplus \text{im } R_N$ proves that inverse identity. In particular $\int d_N(t, u)m_t(u) du = q$. Consequently (AT8) also reads

$$\frac{d}{dt} \log V_N(t) = \int d_N(t, u) \Delta m(u) du, \quad \Delta \mathcal{B} = \int_0^1 \int (d_{i_0} + d_{i_1} - d_{j_0} - d_{j_1})(t, u) \Delta m(u) du dt. \quad (\text{AT17})$$

All coefficients of these fixed-degree polynomials in u and $\bar{S}(u)$ are bounded for $t \in [0, 1]$. Since $|\Delta m| \leq m_0 + m_1$ and these measures have the required finite moments, absolute integrability proves the exchange of integrals. This remains valid at every zero of m_1 .

82.4 The full spectral and actual-overlap bound for the correction

Let $n = 2q + 1$ and let $b_1 \leq \dots \leq b_n$ be all eigenvalues of $D_* = M_*(0)^{-1}M_*(1)$ in its original $M_*(0)$ inner product. This operator is positive because $v^*M_*(0)D_*v = v^*M_*(1)v > 0$ for $v \neq 0$. Retain $\kappa_* = b_n/b_1$ and put

$$\begin{aligned} c_j(t) &= \frac{b_j - 1}{1 - t + tb_j}, & d(t) &= c_n(t) - c_1(t), \\ \mathcal{L}_q(D_*) &= \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}, \\ S_{AW}(t) &= c_{q+2}(t) - c_q(t) + 2 \sum_{j=1}^{q-1} (c_{2q+2-j}(t) - c_j(t)), \\ s(t) &= \dim(\text{ran } U(t) \cap \text{ran } W(t)), \\ S_{SP}(t) &= \frac{d(t)}{2} \min \left\{ 4q - 2s(t), \sqrt{(2q+1)(8q-4-2\text{Tr}(U(t)W(t)))} \right\}, \\ \mathcal{J}_{h,k} &= \int_0^1 \min\{S_{AW}(t), S_{SP}(t)\} dt. \end{aligned}$$

(AT18a)

An empty sum for $q = 1$ is zero. Every quantity uses the unchanged common source $H = \mathcal{P}_{2q}$ and the actual relation maps in (AT11). The complete spectra and $\mathcal{L}_q$ bound were proved in AW7 and AW13–AW16; the actual overlap terms were proved in SP8–SP10. Their full proofs are propagated here to the original endpoint estimate, so neither calculation is replaced by a reference.

The exact trace norm and the centered Hilbert–Schmidt estimate are also retained before taking a minimum. On this same source define

$$\begin{aligned} S_{\text{tr}}(t) &= \frac{d(t)}{2} \|U(t) - W(t)\|_1, \\ \Sigma(t) &= \text{Tr}(C(t)^2) - \frac{(\text{Tr } C(t))^2}{2q+1}, \\ S_{\text{HS}}(t) &= \sqrt{\Sigma(t) \text{Tr}((U(t) - W(t))^2)}. \end{aligned}$$

(AT18c)

The trace-norm inequality follows by subtracting the midpoint of the extreme eigenvalues from the metric derivative, since the trace of the signed projection difference is zero. In an orthonormal eigenbasis of that difference, every diagonal derivative entry is bounded in modulus by half the spectral diameter; summing with the absolute eigenvalues proves the assertion. For the other bound subtract the trace mean $\text{Tr}(C(t))I/(2q+1)$ instead. The square of its Hilbert–Schmidt norm in the unchanged source metric is exactly $\Sigma(t)$. Hilbert–Schmidt Cauchy–Schwarz with the signed difference proves that its trace pairing is bounded by $S_{\text{HS}}(t)$. Positivity of both factors under the square root follows from their self-adjointness. Thus both functions bound the same absolute signed derivative on general positive source forms; the angle term below still uses the specified moment measures. These are RMT10a–10b and ISM25–26 through the already proved original coefficient and projection maps.

The original-moment angle calculation supplies a further simultaneous bound at this same claim

site. Put $a_q = 2q - 1$ and

$$\begin{aligned} A_{h,k}(t) &= a_q \sqrt{1 - e^{-B(t)/a_q}} d(t), \\ \mathcal{J}_{h,k}^{(5)} &= \int_0^1 \min\{S_{AW}(t), S_{Tr}(t), S_{SP}(t), S_{HS}(t), A_{h,k}(t)\} dt, \\ \mathcal{I}_{h,k} &= \int_0^1 \min \left\{ d(t), \frac{S_{AW}(t)}{a_q \sqrt{1 - e^{-B(t)/a_q}}}, \frac{S_{SP}(t)}{a_q \sqrt{1 - e^{-B(t)/a_q}}}, \right. \\ &\quad \left. \frac{S_{Tr}(t)}{a_q \sqrt{1 - e^{-B(t)/a_q}}}, \frac{S_{HS}(t)}{a_q \sqrt{1 - e^{-B(t)/a_q}}} \right\} dt. \end{aligned} \quad (\text{AT18b})$$

These specialize RMT1–RMT18 through $a_{\text{RMT}} = a_q$, $x = t$, $C_x = C(t)$ and $(U_x, W_x) = (U(t), W(t))$. The density and relation arrows were proved in (AT4a)–(AT4b), so every source moment and original cohomology map agrees. This application uses the actual moment measures (AT4)–(AT5). It does not impose moment structure on an arbitrary positive coefficient Gram.

Theorem 82.2. *The exact correction on the original finite source satisfies*

$$|\Delta \mathcal{B}| \leq \mathcal{J}_{h,k}^{(5)} \leq \mathcal{J}_{h,k} \leq \mathcal{L}_q(D_*) \leq (2q - 1) \log \kappa_*. \quad (\text{AT18})$$

Moreover $\mathcal{J}_{h,k} \leq \int_0^1 S_{SP}(t) dt$. The original Gamma and arithmetic endpoint quantities consequently obey

$$\max\{\mathcal{B}_{h,k}^\Gamma - \mathcal{J}_{h,k}^{(5)}, \mathcal{B}_{h,k}^\Gamma + j_{\ell_N} - e_{\ell_N}\} \leq \mathcal{B}_{h,k}^{\text{ar}} \leq \min\{\mathcal{B}_{h,k}^\Gamma + \mathcal{J}_{h,k}^{(5)}, \mathcal{B}_{h,k}^\Gamma + j_{\ell_N} + e_{\ell_N}\}. \quad (\text{AT19})$$

Here the constructed j_{ℓ_N}, e_{ℓ_N} are defined and proved in (AT19ba)–(AT19bc) below.

Proof. The relation flag $\chi \mathcal{P}_0 \subset \chi \mathcal{P}_{q-1} \subset \chi \mathcal{P}_q \subset H$ has dimensions $1, q, q+1, 2q+1$. On its successive orthogonal pieces the operator $U = Q_{2q-1} + Q_{2q} - Q_q$ has values $1, 2, 1, 0$ with multiplicities $1, q-1, 1, q$. On the orthogonal pieces of $\mathcal{P}_{q-1} \subset \mathcal{P}_q \subset \mathcal{P}_{2q-1} \subset H$, W has values $0, 1, 2, 1$ with multiplicities $q, 1, q-1, 1$. Nested orthogonal projections act as identity or zero on these pieces, which proves the assertions including $q = 1$. In particular

$$\begin{aligned} \text{rank } U &= \text{rank } W = q + 1, \quad \text{Tr } U = \text{Tr } W = 2q, \quad \text{Tr } U^2 = \text{Tr } W^2 = 4q - 2, \\ A &= U - W, \quad \text{Tr } A = 0, \quad \text{Tr } A^2 = 8q - 4 - 2 \text{Tr}(UW). \end{aligned} \quad (\text{AT20a})$$

Thus the equal mass $2q$ is an operator trace, and its multiplicity-two subspace of dimension $q - 1$ is retained in each rank calculation.

The identity $M_* C = \Delta M_* = \Delta M_*^*$ proves that C is self-adjoint in $M_*(t)$. The exact factorization $M_*(t) = M_*(0)((1-t)I + tD_*)$ gives $C = ((1-t)I + tD_*)^{-1}(D_* - I)$. A basis of $M_*(0)$ -orthonormal eigenvectors of D_* remains orthogonal in $M_*(t)$, with positive squared lengths $1 - t + tb_j$, proving that the displayed $c_j(t)$ are its eigenvalues. Differentiation in b_j gives $(1 - t + tb_j)^{-2} > 0$, so they retain their order.

For any $M_*(t)$ -orthogonal projection P of rank r , choose an orthonormal eigenbasis e_j of C . Its diagonal values $a_j = \langle e_j, P e_j \rangle$ lie in $[0, 1]$ and sum to r . Thus $\text{Tr}(PC) = \sum_j c_j a_j$ lies between the sum of the smallest r and the sum of the largest r eigenvalues: moving a fixed amount of mass from a smaller coefficient to a larger coefficient increases the sum, until these two extrema are obtained. This also proves the assertion when there are ties. Either $Z = U$ or $Z = W$ is the sum of its range projection of rank $q + 1$ and its eigenvalue-two projection of rank $q - 1$. Applying the just-proved inequality gives

$$\sum_{j=1}^{q+1} c_j + \sum_{j=1}^{q-1} c_j \leq \text{Tr}(ZC) \leq \sum_{j=q+1}^{2q+1} c_j + \sum_{j=q+3}^{2q+1} c_j. \quad (\text{AT20b})$$

Subtracting the extrema for the two original operators, retaining both sums before their common middle term cancels, proves $|\operatorname{Tr}(AC)| \leq S_{\text{AW}}(t)$.

Both ranges have dimension $q + 1$ in dimension $2q + 1$; hence $s(t) \geq 1$. Let E_L be the orthogonal projection onto their intersection. Each of U, W dominates its range projection, since its nonzero eigenvalues are 1, 2; that projection dominates E_L . Therefore $U - E_L, W - E_L$ are positive, of trace $2q - s(t)$, and

$$\|A\|_1 \leq 4q - 2s(t), \quad \|A\|_1 \leq \sqrt{(2q + 1) \operatorname{Tr} A^2}. \quad (\text{AT20c})$$

The first inequality is the trace-norm triangle inequality applied to their difference. The second is Cauchy-Schwarz on all $2q + 1$ real eigenvalues of A . Subtracting the midpoint $a = (c_1 + c_n)/2$ from C leaves $\operatorname{Tr}(AC)$ unchanged by $\operatorname{Tr} A = 0$. In an orthonormal eigenbasis f_j of A with eigenvalues α_j , $|\operatorname{Tr}(A(C - aI))| \leq \sum_j |\alpha_j| |\langle f_j, (C - aI)f_j \rangle| \leq d(t) \|A\|_1/2$. Together with (AT20a)–(AT20c), this proves the full pointwise bound

$$|\operatorname{Tr}((U - W)C)| \leq \min\{S_{\text{AW}}(t), S_{\text{SP}}(t)\}. \quad (\text{AT20})$$

No pairwise commutation of U, W, C has been used. The Gram inverses and projectors are smooth on the compact interval; their ranks and intersection dimensions are Borel, since ranks are specified by vanishing and nonvanishing minors. All terms are bounded, hence the displayed minimum is integrable. Integrating (AT20) in (AT15) gives $|\Delta\mathcal{B}| \leq \mathcal{J}_{h,k}$ for these two positive forms, even without moment structure. On the actual measures, RMT11 retains the two full q -angle lists of the crossed pairs $(q - 1, 2q)$ and $(q, 2q - 1)$, including the designated zero angle, and proves $|\mathcal{B}'| \leq A_{h,k}$. Its strict positivity proof applies here: if $\mathcal{B} = 0$, the first pair has identical minimum sections, putting 1 in the orthogonal complement of $\chi\mathcal{P}_q$. The polynomial $\chi^{\#k}(S) = \sum_j \bar{\chi}_j(k - S)^j$ then gives $0 = \int \chi\chi^{\#k} dm_t = \int |\chi|^2 dm_t$, contradicting the positive original Gram of χ . Thus $\mathcal{B}(t) > 0$. RMT11 follows from its complete original angle proof and concavity of $\sqrt{1 - e^{-z}}$ on the retained a_q -entry scalar list. Applying all five inequalities to this same derivative proves $|\Delta\mathcal{B}| \leq \mathcal{J}_{h,k}^{(5)} \leq \mathcal{J}_{h,k}$. Compactness and the positive continuous $\mathcal{B}$ make every denominator in (AT18b) nonzero and bounded away from zero.

For each retained relative eigenvalue,

$$\int_0^1 c_j(t) dt = \log b_j, \quad \int_0^1 d(t) dt = \log(b_n/b_1) = \log \kappa_*. \quad (\text{AT21})$$

This follows by differentiating $\log(1 - t + tb_j)$; it includes $b_j = 1$, whose integrand is zero. Thus $\int S_{\text{AW}} = \mathcal{L}_q(D_*)$ and $\mathcal{J}_{h,k} \leq \int S_{\text{SP}}$. Each ratio in $\mathcal{L}_q$ is at most κ_* ; the retained total coefficient is $1 + 2(q - 1) = 2q - 1$. This proves all inequalities. Finally the absolute branches of (AT19) follow by applying both signs of (AT18), and its constructed signed branches follow from (AT19bb) proved below, to the exact equality $\mathcal{B}_{h,k}^{\text{ar}} = \mathcal{B}_{h,k}^{\Gamma} + \Delta\mathcal{B}$. $\square$

For every integer $\ell_N \geq 0$ the constructed signed approximation is applied on these exact end-point forms as well. Here $\mathbf{M}_z = M_*(t)|_{t=z}$, $\mathbf{C}_z = C(t)|_{t=z}$, $\mathbf{A}_z = (U(t) - W(t))|_{t=z}$, and $\mathbf{D} = D_*$. Thus the RMT/ISM coefficient map is the identity with $x_{\text{RMT}} = z = t$, and its $\mathcal{B}$ is (AT14). Write $\mathbf{D} = (\mathbf{M}_0)^{-1}\mathbf{M}_1$, with its complete ordered positive eigenvalues $b_1, \dots, b_{2q+1}$, and let $\mathbf{A}_z$ be this same signed projection difference. Define

$$\begin{aligned} \alpha_z^\circ &= \frac{2(1 - z) + z(b_1 + b_{2q+1})}{2}, & H_z^\circ &= I - \frac{(1 - z)I + z\mathbf{D}}{\alpha_z^\circ}, \\ C_z^{[\ell_N]} &= (\alpha_z^\circ)^{-1} \sum_{r=0}^{\ell_N} (H_z^\circ)^r (\mathbf{D} - I), & R_z^{[\ell_N]} &= (H_z^\circ)^{\ell_N+1} \mathbf{C}_z, \\ E_z^{[\ell_N]} &= R_z^{[\ell_N]} - \frac{\operatorname{Tr} R_z^{[\ell_N]}}{2q + 1} I. \end{aligned} \quad (\text{AT19ba})$$

The symbols $\alpha_z^\circ, H_z^\circ$ preserve every original source parameter and relation map; ℓ_N is only the finite series truncation. Multiplication of the finite geometric sum gives $C_z - C_z^{[\ell_N]} = R_z^{[\ell_N]}$. All factors are real functions of the positive relative operator D , hence self-adjoint in the original $M_z = M_0((1 - z)I + zD)$ metric. Since $\text{Tr } A_z = 0$, the derivative of the same four-volume function is its signed center $\text{Tr}(C_z^{[\ell_N]} A_z)$ plus $\text{Tr}(E_z^{[\ell_N]} A_z)$. Consequently

$$\begin{aligned} j_{\ell_N} &= \int_0^1 \text{Tr}(C_z^{[\ell_N]} A_z) dz, \\ e_{\ell_N} &= \int_0^1 \sqrt{\text{Tr}((E_z^{[\ell_N]})^2) \text{Tr}(A_z^2)} dz, \\ j_{\ell_N} - e_{\ell_N} &\leq \mathcal{B}(1) - \mathcal{B}(0) \leq j_{\ell_N} + e_{\ell_N}. \end{aligned} \tag{AT19bb}$$

For this block $\mathcal{B}$ denotes precisely the four-volume function identified above. The signed inequalities follow by Hilbert–Schmidt Cauchy–Schwarz in that unchanged metric and integration of the exact derivative. The full residual calculation ISM29–37, equivalently RMT19–21, uses $\vartheta = (b_{2q+1} - b_1)/(b_{2q+1} + b_1) < 1$ and $K_D = \sum_j (|b_j - 1|/\min\{1, b_j\})^2$ to prove

$$0 \leq e_{\ell_N} \leq \vartheta^{\ell_N+1} \sqrt{K_D(8q - 6)} \longrightarrow 0. \tag{AT19bc}$$

Indeed every eigenvalue of H_z° has modulus at most ϑ , centering the residual subtracts a nonnegative square from its squared Hilbert–Schmidt norm, and $\text{Tr}(A_z^2) \leq 8q - 6$ by the full flag spectra and the common range. This proves the bound with all eigenvalue multiplicities retained. The displayed integrals are exact; a numerical evaluation must retain its own integration error. Intersecting this proved signed interval with the already proved absolute and nonlinear intervals supplies the additional endpoint entries below, for every specified ℓ_N .

The same actual-moment calculation also propagates to the nonlinear endpoint coordinate. Set $\mathcal{H}_{a_q}(B) = 2 \text{arcosh}(e^{B/(2a_q)})$ and $H_0 = \mathcal{H}_{a_q}(\mathcal{B}_{h,k}^\Gamma)$. Its exact derivative is $\mathcal{H}_{a_q}'(B) = 1/(a_q \sqrt{1 - e^{-B/a_q}})$ and its continuous inverse is $2a_q \log \cosh(z/2)$ for $z \geq 0$. The positivity just proved permits the chain rule throughout this fixed path. Dividing the five derivative bounds by their positive factor and integrating gives $|\mathcal{H}_{a_q}(\mathcal{B}_{h,k}^{\text{ar}}) - H_0| \leq \mathcal{I}_{h,k} \leq \log \kappa_*$. Consequently the existing interval (AT19) has the simultaneous strengthening

$$\begin{aligned} \mathcal{B}_{h,k}^{\text{ar}} &\geq \max \left\{ 0, \mathcal{B}_{h,k}^\Gamma - \mathcal{J}_{h,k}^{(5)}, 2a_q \log \cosh \frac{\max\{0, H_0 - \mathcal{I}_{h,k}\}}{2}, \mathcal{B}_{h,k}^\Gamma + j_{\ell_N} - e_{\ell_N} \right\}, \\ \mathcal{B}_{h,k}^{\text{ar}} &\leq \min \left\{ \mathcal{B}_{h,k}^\Gamma + \mathcal{J}_{h,k}^{(5)}, 2a_q \log \cosh \frac{H_0 + \mathcal{I}_{h,k}}{2}, \mathcal{B}_{h,k}^\Gamma + j_{\ell_N} + e_{\ell_N} \right\}. \end{aligned} \tag{AT19a}$$

The inverse and nonlinear branches are RMT16–RMT18; the signed branches are RMT19–RMT22 and the full local calculation (AT19bb), on the forms already specified in AT; the scalar continuous value at zero bounds an actual strictly positive endpoint.

When $M_*(1) = cM_*(0)$, every $b_j = c$, so $d = 0$ and $\mathcal{J}_{h,k} = 0$. The original quotient determinants are $(1 - t + tc)^q V_N(0)$, whose four factors cancel exactly in (AT14). This retains both original masses. For an invertible coefficient arrow $F : H' \rightarrow H$, let $M'_* = F^* M_* F$ and transport every subspace by F^{-1} . The projector formula gives $P'_N = F^{-1} P_N F$, $Q'_N = F^{-1} Q_N F$, $D'_* = F^{-1} D_* F$, and $C' = F^{-1} C F$. Their spectra, intersection dimensions, $\text{Tr}(UW)$, the signed trace and $\mathcal{J}_{h,k}$ consequently agree under this exact map.

For the original reflection-stable quartet with displacement $\delta > 0$ and multiplicity m , retain $q = [1 + k(m - 1)](k + 1)^2$. Its supplied Gamma theorem gives $\mathcal{B}_{h,k}^\Gamma \geq 4q \log(\delta k / (2\sqrt{5}))$. Applying (AT19)

with its actual sign proves

$$\begin{aligned}
\mathcal{B}_{h,k}^{\text{ar}} &\geq 4q \log\left(\frac{\delta k}{2\sqrt{5}}\right) - \mathcal{J}_{h,k}^{(5)} \\
&\geq 4q \log\left(\frac{\delta k}{2\sqrt{5}}\right) - \mathcal{L}_q(D_*) \\
&\geq 4q \log\left(\frac{\delta k}{2\sqrt{5}}\right) - (2q-1) \log \kappa_*, \\
\log \kappa_* &\geq \frac{4q \log(\delta k/(2\sqrt{5})) - \mathcal{B}_{h,k}^{\text{ar}}}{2q-1}.
\end{aligned} \tag{AT22}$$

The signed branch also yields $\mathcal{B}_{h,k}^{\text{ar}} \geq 4q \log(\delta k/(2\sqrt{5})) + j_{\ell_N} - e_{\ell_N}$: substitute the same Gamma lower bound into $\mathcal{B}_{h,k}^{\text{ar}} \geq \mathcal{B}_{h,k}^{\Gamma} + j_{\ell_N} - e_{\ell_N}$. This branch and (AT22) are both retained by their maximum. The last denominator is positive for every $q \geq 1$. This is the same actual packet application, with its earlier necessary condition updated to the stronger proved finite control. No existence of such a quartet or uniform growth bound is assumed. The full signed formulas (AT15)–(AT17), all source primitives and the retained cohomology observations remain the objects whose moments and actual overlaps enter the bound.

82.5 Source dependencies and precise status

The complete retained Tau Base note supplies (AT1), its tensor pushforward, right adjoint and supported maps. The original arithmetic-input and cyclic-sum proofs supply (AT2), full packet units and the theta primitives. The Gamma/source-density notes supply the actual measures and finite moments in (AT4)–(AT5). The new Deligne-bound note supplies the full quartet Gamma lower bound used only in (AT22). Each is preserved in the accompanying source closure, with its actual edition and hash.

The new proved calculations here are (AT6)–(AT21) on those unchanged input objects, and their substitution (AT22). They give an analytic calculation on the canonical finite complex mapping to $A_{\tau,k}(\mathcal{T}^{\boxtimes k})$. They neither replace that pushforward by a generic stalk nor deduce a verdict about the entire tau-based program from an auxiliary model.

83 Exact identification of the retained AT extraction hash

This additive record identifies the processing frame of a retained metadata hash. The entire accepted AT proof source and reader, including the original preamble and all 23 equation tags, remain unchanged.

83.0.1 The exact identified value

The value in the sealed evidence/BODY_EXTRACTION.json field `pre_layout_reader_body_sha256` is 42b97470bfe0f67e0a0247e5cefc95609c487b8ff20c275457aeabc02b7b706. It identifies the complete final *post-layout* reader body in LF encoding, with 17149 bytes. Replacing each CRLF in the 17558-byte accepted reader by LF gives this value exactly. The retained field name and its explanatory note name the wrong processing stage. The four exact frames are:

Complete body frame	Bytes	SHA-256
pre layout LF	17113	5ccb346f20b37ea30a40491a9c6ec84e7121869816efbb08107ae8f64cc9116
pre layout CRLF	17520	3ed5d0dbedbcffdaa8949a4dc6108e99546acd3023c32c4785388860a5d1815

post layout LF	17149	42b97470bfe0f67e0a0247e5cefc95609c487b8ff20c275457aeebc02b7b706
post layout CRLF	17558	9fa19a509edf91f5aa0a9cb4762485449196d0b1ff521f2445f791fa3290cc75

83.0.2 Complete forward and inverse reconstruction

Read the pinned original source, extraction record and ten-entry layout record. The exact original body begins with the 13-byte sequence whose base64 representation is `ClxtYWtldGl0bGUKCg==`. Remove exactly that title prefix; no proof prose is removed. The remaining complete LF body has 17113 bytes. Replacing each LF by CRLF gives its 17520-byte CRLF representation.

Apply all ten ordered old/new pairs from the sealed layout map. In the CRLF representation, convert every LF in both sides of each pair to CRLF. Each old payload occurs exactly once at its recorded byte span. The final LF and CRLF results are the complete final bodies identified above. The full payloads, source spans and before/after hashes for every step are retained in `CLARIFICATION.json`.

For the inverse, start with the accepted CRLF reader and reverse all ten pairs in reverse order, replacing each unique new payload by the complete old payload. This recovers the entire pre-layout CRLF body. Replace each CRLF by LF and restore the exact removed title prefix. Then concatenate the original preamble, the literal begin-document boundary, the restored complete body, the literal end-document boundary and the original postamble. The result is every byte of the pinned original source, whose SHA-256 is `24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae`. The JSON record gives exact zero-based byte intervals and hashes for all five original-file components, and retains the complete original preamble and postamble literally. The source itself retains every proof paragraph.

83.0.3 Complete byte-verification program

The following standard-library program checks the five sealed input pins, the exact source spans and every intermediate hash in both representations, the ten reverse transformations and all original-file components. It writes no source file, imports no mathematical program and performs no document build. Invoke it with `--artifact-root` naming the sealed artifact directory. Its complete JSON recipe accompanies this file.

```

84 Exact relation-window spectral transport on the original tau complex

This calculation continues arithmetic determinant transport on its original finite source over the absolute tau base. It computes the full spectra of the two retained window operators, constructs an isometry intertwining them in the actual source metric, and strengthens the signed determinant bound. The source measures, their masses, the cyclic polynomial, the Taylor unit, and the cohomology observation remain fixed.

84.1 The original source and its four windows

Use a full actual packet h for $g = 2\xi$, an integer $k \geq 1$, and the original cyclic polynomial $\chi = \chi_{h,k}$ of degree $q \geq 1$. Let $E = \mathbb{C}[S]/(\chi)$, $E_h = \mathbb{C}[s]/(h)$, and $v_h = j_h(g/h) \in E_h^\times$. The original tensor-sum observation is

$$\eta : E \hookrightarrow E_h^{\otimes k}, \quad \eta[P] = v_h^{\otimes k} P(A_h^{(k)})1. \quad (\text{AW1})$$

The original section $\sigma_h : E_h \hookrightarrow Q = \mathcal{B}/\Theta V$ gives the separate injection $\sigma_h^{\otimes k} \eta : E \hookrightarrow Q^{\otimes k}$. Here $Q^{\otimes k}$ is the top cohomology of the original tensor pushforward over $\mathbf{F}_{1,\tau} = \{\tau, 1\}$; the one-factor complex is $[V \oplus V \xrightarrow{\Theta(\phi-\psi)} \mathcal{B}]$. The complete Tau Base and cyclic source proofs accompany the preceding arithmetic determinant transport calculation (AT).

For $N \geq q - 1$, retain the increasing-power spaces and maps

$$0 \longrightarrow \mathcal{P}_{N-q} \xrightarrow{B_N = \times \chi} \mathcal{P}_N \xrightarrow{J_N} E \longrightarrow 0, \quad \mathcal{P}_{-1} = 0. \quad (\text{AW2})$$

The common source is $H = \mathcal{P}_{2q}$, of dimension $n = 2q + 1$. Its original coordinate on the integration line is $S = k/2 + iu$. Set $v_N(u) = (1, S(u), \dots, S(u)^N)$ and retain the two densities

$$\begin{aligned} m_1(u) &= w_h^{*k}(u), & w_h(u) &= \frac{|(g/h)(1/2 + iu)|^2}{2\pi}, \\ m_0(u) &= \frac{(\sqrt{2\pi})^k}{c_{k/4}} \frac{|\Gamma(k/4 + iu/2)|^2}{2\pi}, & c_a &= 2^{1-2a}\Gamma(2a). \end{aligned} \quad (\text{AW3})$$

Their actual masses are μ_h^k and $(2\pi)^{k/2}$. For the real parameter $0 \leq t \leq 1$, put $m_t = (1-t)m_0 + tm_1$, $M_N(t) = \int v_N^* v_N m_t$, and $M(t) = M_{2q}(t)$. The source density proofs give all finite moments and positivity almost everywhere, so all these finite Grams are positive definite. We use the original form $\langle x, y \rangle_t = x^* M(t) y$ on H .

Let $P_N(t)$ be the orthogonal projection onto $\mathcal{P}_N \subset H$, and $Q_N(t)$ the projection onto $\chi\mathcal{P}_{N-q} \subset H$. Set $Q_{q-1} = 0$. For the coefficient inclusion $I_N : \mathcal{P}_N \rightarrow H$, their fully typed coefficient formulas are

$$\begin{aligned} P_N &= I_N M_N^{-1} I_N^* M, \\ Q_N &= I_N B_N (B_N^* M_N B_N)^{-1} B_N^* I_N^* M. \end{aligned} \quad (\text{AW4})$$

The zero relation domain at $N = q - 1$ contributes the zero operator. Let $G_N(t)$ be the minimum-lift Gram on E from (AW2) and $V_N(t) = \det G_N(t)$. Retain

$$\begin{aligned} \mathcal{B}(t) &= \log \frac{V_{q-1}(t) V_q(t)}{V_{2q-1}(t) V_{2q}(t)}, \\ C(t) &= M(t)^{-1} (M(1) - M(0)), \\ U(t) &= (Q_{2q-1} - Q_{q-1}) + (Q_{2q} - Q_q), \\ W(t) &= (P_{2q-1} - P_{q-1}) + (P_{2q} - P_q). \end{aligned} \quad (\text{AW5})$$

The AT proof, included in full, establishes $V_N = \det M_N / \det(B_N^* M_N B_N)$ with the original orientation $(-1)^{q(N-q+1)}$, and

$$\Delta \mathcal{B} = \mathcal{B}(1) - \mathcal{B}(0) = \int_0^1 \text{Tr}((U(t) - W(t))C(t)) dt. \quad (\text{AW6})$$

Thus the following computation evaluates the operators in the already proved signed arithmetic correction.

84.2 Full spectra and an explicit source isometry

Theorem 84.1. *In the original $M(t)$ metric, both $U(t)$ and $W(t)$ have spectrum*

$$0 \text{ with multiplicity } q, \quad 1 \text{ with multiplicity } 2, \quad 2 \text{ with multiplicity } q - 1. \quad (\text{AW7})$$

The last multiplicity is zero when $q = 1$. There is an explicitly constructed smooth $M(t)$ -unitary $T(t) : H \rightarrow H$ such that $U(t) = T(t)W(t)T(t)^{-1}$.

Proof. Every subspace in either of the following flags is the literal displayed polynomial subspace, with its original coefficient inclusion. For the relation flag use

$$F_0 = \chi\mathcal{P}_0 \subset F_1 = \chi\mathcal{P}_{q-1} \subset F_2 = \chi\mathcal{P}_q \subset H. \quad (\text{AW8})$$

Their dimensions are 1, q , $q+1$, since multiplication by χ is injective. When $q = 1$, $F_0 = F_1$ is retained as that equality. Projections of nested subspaces commute and their products equal the projection of the smaller subspace: each larger space is the orthogonal direct sum of the smaller space and its orthogonal complement within the larger space. On the original orthogonal decomposition $F_0 \oplus (F_1 \cap F_0^\perp) \oplus (F_2 \cap F_1^\perp) \oplus F_2^\perp$, the operator $U = Q_{F_1} + Q_{F_2} - Q_{F_0}$ acts respectively by 1, 2, 1, 0. The dimensions are respectively 1, $q - 1$, 1, q .

For W use $\mathcal{P}_{q-1} \subset \mathcal{P}_q \subset \mathcal{P}_{2q-1} \subset \mathcal{P}_{2q} = H$. On the four corresponding orthogonal pieces, W acts by 0, 1, 2, 1, with dimensions q , 1, $q - 1$, 1. This proves (AW7), including the repeated middle subspaces at $q = 1$.

For an explicit intertwiner retain every Gram factor as follows. For any specified ordered independent list $z_0, \dots, z_d$, apply the recursion

$$y_j = z_j - \sum_{i < j} e_i \langle e_i, z_j \rangle_t, \quad a_j = (y_j^* M(t) y_j)^{1/2} > 0, \quad e_j = y_j / a_j. \quad (\text{AW9})$$

The positive real square root fixes its phase. No source density or mass is changed; each a_j is the norm in the original form. Independence proves $y_j \neq 0$ at every step, so this recursion is defined and smooth on the entire parameter interval.

First use $z_j = S^j$, $0 \leq j \leq 2q$, obtaining $p_0, \dots, p_{2q}$. Next use $z_j = \chi S^j$, $0 \leq j \leq q$, obtaining $r_0, \dots, r_q$. These lie in the successive relation spaces in (AW8). Finally let $R_{2q}(t) : E \rightarrow H$ be the original minimum section from AT6 and apply (AW9) to $R_{2q}(t)[1], \dots, R_{2q}(t)[S^{q-1}]$, obtaining $c_0, \dots, c_{q-1}$. The relation orthogonality in AT6 puts this entire list in $F_2^\perp$. Since $J_{2q}R_{2q} = I_E$, the list is independent and spans that q -dimensional complement.

Define T on the first orthonormal basis by

$$\begin{aligned} Tp_j &= c_j & (0 \leq j \leq q-1), \\ Tp_q &= r_0, & Tp_{2q} &= r_q, \\ Tp_{q+j} &= r_j & (1 \leq j \leq q-1). \end{aligned} \tag{AW10}$$

The middle range is empty for $q = 1$, with p_q and p_{2q} still distinct. The target list is an orthonormal basis. Thus this linear map is invertible and $T^*MT = M$. The spectral actions already calculated agree on each indicated basis vector, proving $UT = TW$. The recursion, the smooth minimum section and the positive norms prove the asserted smoothness. This completes the construction. $\square$

The exact isometry gives a commutator form of the signed integrand:

$$\text{Tr}((U - W)C) = \text{Tr}(WT^{-1}[C, T]), \quad [C, T] = CT - TC. \tag{AW11}$$

Indeed cyclicity moves T in $\text{Tr}(TWT^{-1}C)$ to the right, and subtraction then gives the displayed product. This T is an isometry of the original source; its cohomology observation is computed, rather than silently assigned an intertwining property. The unchanged arithmetic observation $\mathcal{O} = \sigma_h^{\otimes k} \eta J_{2q} : H \rightarrow Q^{\otimes k}$ satisfies

$$\mathcal{O}T = \sigma_h^{\otimes k} \eta J_{2q} T, \quad \mathcal{O}T - \mathcal{O} = \sigma_h^{\otimes k} \eta J_{2q} (T - I), \quad \ker(\mathcal{O}T) = T^{-1}F_2. \tag{AW12}$$

The last identity follows from both injections in (AW1) and $\ker J_{2q} = F_2$. By (AW10), $T^{-1}F_2$ is exactly $\text{span}\{p_q, \dots, p_{2q}\} = \mathcal{P}_{q-1}^\perp$ in H . At any fixed nonempty support label A , lift every displayed linear map by $(A, x) \mapsto (A, fx)$ and send τ to τ . Consequently the supported-zero inverse image of the lifted $\mathcal{O}T$ at A is the full set $\{A\} \times \mathcal{P}_{q-1}^\perp$. The Taylor unit in (AW1) and the defect in (AW12) remain present.

84.3 The spectral bound with every eigenvalue retained

Let $b_1 \leq \dots \leq b_n$ be all eigenvalues, counted with multiplicity, of $D = M(0)^{-1}M(1)$ on its original $M(0)$ Hilbert space. All are positive. Define

$$\mathcal{L}_q(D) = \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}, \quad \kappa(D) = b_n/b_1. \tag{AW13}$$

For $q = 1$ the sum is empty and $\mathcal{L}_1(D) = \log(b_3/b_1)$.

Retain also the actual polynomial-space overlap. At each t , let $s(t) = \dim(\text{ran } U \cap \text{ran } W)$ and $d(t) = c_n(t) - c_1(t)$. With the actual $c_j(t)$ of (AW17), set

$$\begin{aligned} S_{\text{AW}}(t) &= c_{q+2} - c_q + 2 \sum_{j=1}^{q-1} (c_{2q+2-j} - c_j), \\ S_{\text{SP}}(t) &= \frac{d(t)}{2} \min \left\{ 4q - 2s(t), \sqrt{(2q+1)(8q-4-2\text{Tr}(UW))} \right\}, \\ \mathcal{J}_{h,k} &= \int_0^1 \min \{ S_{\text{AW}}(t), S_{\text{SP}}(t) \} dt. \end{aligned} \tag{AW13a}$$

The overlap refinement from SP8–SP10 is transported to this earlier calculation by the exact arrows $x = t, y = u, B_N^{\text{SP}} = I_N B_N^{\text{AW}}$. Indeed $M_N = I_N^* M I_N$ gives $(B_N^{\text{SP}})^* M B_N^{\text{SP}} = B_N^* M_N B_N$, so its projectors are precisely (AW4), and $(\mathcal{R}^{\text{SP}}, \mathcal{P}^{\text{SP}}, T^{\text{SP}}) = (U, W, C)$. The original Gamma densities agree because $r_{1/4}^{*k} = c_{1/4}^k r_{k/4} / c_{k/4}$ with $c_{1/4} = \sqrt{2\pi}$, exactly (AW3). The arithmetic densities already coincide as w_h^{*k} . Thus this comparison preserves the moments, masses, polynomial coefficients and all four endpoint signs.

The exact trace norm and the centered Hilbert–Schmidt estimate are also retained before taking a minimum. On this same source define

$$\begin{aligned} S_{\text{tr}}(t) &= \frac{d(t)}{2} \|U(t) - W(t)\|_1, \\ \Sigma(t) &= \text{Tr}(C(t)^2) - \frac{(\text{Tr } C(t))^2}{2q+1}, \\ S_{\text{HS}}(t) &= \sqrt{\Sigma(t) \text{Tr}((U(t) - W(t))^2)}. \end{aligned} \tag{AW13c}$$

The trace-norm inequality follows by subtracting the midpoint of the extreme eigenvalues from the metric derivative, since the trace of the signed projection difference is zero. In an orthonormal eigenbasis of that difference, every diagonal derivative entry is bounded in modulus by half the spectral diameter; summing with the absolute eigenvalues proves the assertion. For the other bound subtract the trace mean $\text{Tr}(C(t))I/(2q+1)$ instead. The square of its Hilbert–Schmidt norm in the unchanged source metric is exactly $\Sigma(t)$. Hilbert–Schmidt Cauchy–Schwarz with the signed difference proves that its trace pairing is bounded by $S_{\text{HS}}(t)$. Positivity of both factors under the square root follows from their self-adjointness. Thus both functions bound the same absolute signed derivative on general positive source forms; the angle term below still uses the specified moment measures. These are RMT10a–10b and ISM25–26 through the already proved original coefficient and projection maps.

The original-moment angle calculation supplies a further simultaneous bound at this same claim site. Put $a_q = 2q - 1$ and

$$\begin{aligned} A_{h,k}(t) &= a_q \sqrt{1 - e^{-\mathcal{B}(t)/a_q}} d(t), \\ \mathcal{J}_{h,k}^{(5)} &= \int_0^1 \min\{S_{\text{AW}}(t), S_{\text{tr}}(t), S_{\text{SP}}(t), S_{\text{HS}}(t), A_{h,k}(t)\} dt, \\ \mathcal{I}_{h,k} &= \int_0^1 \min \left\{ d(t), \frac{S_{\text{AW}}(t)}{a_q \sqrt{1 - e^{-\mathcal{B}(t)/a_q}}}, \frac{S_{\text{SP}}(t)}{a_q \sqrt{1 - e^{-\mathcal{B}(t)/a_q}}}, \right. \\ &\quad \left. \frac{S_{\text{tr}}(t)}{a_q \sqrt{1 - e^{-\mathcal{B}(t)/a_q}}}, \frac{S_{\text{HS}}(t)}{a_q \sqrt{1 - e^{-\mathcal{B}(t)/a_q}}} \right\} dt. \end{aligned} \tag{AW13b}$$

These specialize RMT1–RMT18 through $a_{\text{RMT}} = a_q, x = t, C_x = C(t)$ and $(U_x, W_x) = (U(t), W(t))$. The density and relation arrows were proved in (AW3)–(AW4) and (AW13a), so every source moment and original cohomology map agrees. This application uses the actual moment measures (AW3). It does not impose moment structure on an arbitrary positive coefficient Gram.

Theorem 84.2. *On the unchanged arithmetic source,*

$$|\Delta \mathcal{B}| \leq \mathcal{J}_{h,k}^{(5)} \leq \mathcal{J}_{h,k} \leq \mathcal{L}_q(D) \leq (2q - 1) \log \kappa(D). \tag{AW14}$$

The previously proved coefficient $2q - 1$ and full relative-spectrum bound are retained. The pointwise minimum additionally preserves the actual polynomial-space overlap, and is at most $\int_0^1 S_{\text{SP}}(t) dt$.

Proof. We first prove the needed finite spectral trace inequality. Let C be self-adjoint in a finite Hilbert space with eigenvalues $c_1 \leq \dots \leq c_n$. If P is an orthogonal projection of rank r , let e_j be an orthonormal eigenbasis of C and $d_j = \langle e_j, P e_j \rangle$. Then $0 \leq d_j \leq 1$ and $\sum_j d_j = r$, since $d_j = \|P e_j\|^2$

and $\text{Tr } P = r$. Thus $\text{Tr}(PC) = \sum_j c_j d_j$. Its upper bound by $\sum_{j=n-r+1}^n c_j$ follows by subtracting the two expressions: the mass $\sum_{j \leq n-r} d_j$ equals $\sum_{j > n-r} (1 - d_j)$, and every coefficient in the latter group is at least every coefficient in the former. Pairing the same nonnegative mass, or bounding both groups by c_{n-r+1} , proves the inequality. Applying this argument to $-C$ proves the lower bound $\sum_{j=1}^r c_j$. This proof includes repeated eigenvalues and the ranks zero and n .

For an operator Z with spectrum (AW7), its spectral projection A_Z onto eigenvalues 1, 2 has rank $q + 1$, and its spectral projection B_Z onto eigenvalue 2 has rank $q - 1$. The exact decomposition is $Z = A_Z + B_Z$. Applying the proved projection bounds gives

$$\sum_{j=1}^{q+1} c_j + \sum_{j=1}^{q-1} c_j \leq \text{Tr}(ZC) \leq \sum_{j=q+1}^{2q+1} c_j + \sum_{j=q+3}^{2q+1} c_j. \quad (\text{AW15})$$

Each bound is attained for an abstract operator of this spectrum by assigning its eigenspaces to the appropriate eigenvectors of C . This attainment statement is only about the displayed spectral constraint; it assigns no freely chosen orientation to the actual polynomial relation spaces. Both U and W satisfy (AW15). Subtract their bounds and cancel the common c_{q+1} term only after writing both complete sums:

$$|\text{Tr}((U - W)C)| \leq c_{q+2} - c_q + 2 \sum_{j=1}^{q-1} (c_{2q+2-j} - c_j). \quad (\text{AW16})$$

No mutual commutation of U, W, C is used.

The range dimensions in (AW7) give $s(t) \geq 1$. Let E_L be the orthogonal projector onto their intersection. Each $Z = U, W$ is at least its range projection, since its nonzero eigenvalues are 1, 2, and therefore $Z - E_L$ is positive of trace $2q - s(t)$. Writing $A = U - W = (U - E_L) - (W - E_L)$ proves

$$\|A\|_1 \leq 4q - 2s(t), \quad \text{Tr } A = 0, \quad \text{Tr } A^2 = 8q - 4 - 2 \text{Tr}(UW), \quad \|A\|_1 \leq \sqrt{(2q + 1) \text{Tr } A^2}. \quad (\text{AW16a})$$

The square identity uses $\text{Tr } U^2 = \text{Tr } W^2 = 4q - 2$ and cyclicity. The last inequality is Cauchy-Schwarz on every real eigenvalue of the self-adjoint A . Subtracting $(c_1 + c_n)I/2$ from C does not change its trace pairing with A . In an orthonormal eigenbasis of A , that pairing is bounded in absolute value by $d(t)\|A\|_1/2$. This proves $|\text{Tr}((U - W)C)| \leq S_{\text{SP}}(t)$ in addition to (AW16), and hence bounds it by their pointwise minimum. Smooth positive Grams give bounded continuous eigenvalues and overlaps; $s(t)$ is Borel because its rank strata are specified by matrix minors. Therefore the minimum is integrable. The signed identity (AW6) now proves $|\Delta\mathcal{B}| \leq \mathcal{J}_{h,k}$ and $\mathcal{J}_{h,k} \leq \int S_{\text{SP}}$. For the original moment path, the exact original-source identification above also applies RMT11-RMT12: its full crossed angle lists give $|\mathcal{B}'| \leq A_{h,k}$, and $\mathcal{B} > 0$ follows because otherwise $1 \perp \chi \mathcal{P}_q$ would force $\int |\chi|^2 m_t = 0$ by the reflected polynomial $\chi^{\#k}(S) = \sum_j \bar{\chi}_j(k - S)^j$. Taking the pointwise minimum of this additional proved inequality with (AW16), (AW16a), and both complete bounds in (AW13c) gives $|\Delta\mathcal{B}| \leq \mathcal{J}_{h,k}^{(5)}$. The complete proof of the original angle estimate and its exact chain-rule continuation is retained in EP and RMT; it uses AW's earlier projection identities, not the final claim (AW14).

For the actual interpolated metric, $C(t) = ((1-t)I + tD)^{-1}(D - I)$, so its eigenvalues in increasing order are

$$c_j(t) = \frac{b_j - 1}{1 - t + tb_j}. \quad (\text{AW17})$$

The denominator is positive and the derivative with respect to b_j is $(1 - t + tb_j)^{-2} > 0$. Thus the ordering is valid for the entire closed interval. Each $c_j(t)$ is the derivative of $\log(1 - t + tb_j)$ and has integral $\log b_j$. Integrating (AW16) proves $\mathcal{J}_{h,k} \leq \mathcal{L}_q(D)$; the preceding pointwise-minimum argument proves the first inequality of (AW14). Every ratio in (AW13) lies between 1 and b_n/b_1 , so retaining its coefficient gives $1 + 2(q - 1) = 2q - 1$ times $\log \kappa(D)$ for the second bound. This proves the theorem for all $q \geq 1$. $\square$

All bounds retain the literal source masses. If $M(1) = cM(0)$, every $b_j = c$, so (AW13) is zero. Directly each original quotient determinant is multiplied at time t by $(1-t+tc)^q$, and the four displayed factors in (AW5) cancel. For a fixed invertible source-coordinate arrow F , the transported forms are $M' = F^*MF$, all subspaces have their F^{-1} images, and $D' = F^{-1}DF$. Hence the eigenvalues, (AW6) and (AW13) are unchanged under this explicit map.

For every integer $\ell_N \geq 0$ the constructed signed approximation is applied on these exact endpoint forms as well. Here $M_z = M(t)|_{t=z}$, $C_z = C(t)|_{t=z}$ and $A_z = (U(t) - W(t))|_{t=z}$, with $D = D$. The exact RMT/ISM source arrow is the identity, and $\mathcal{B}$ is the function (AW5). Write $D = (M_0)^{-1}M_1$, with its complete ordered positive eigenvalues $b_1, \dots, b_{2q+1}$, and let A_z be this same signed projection difference. Define

$$\begin{aligned} \alpha_z^\circ &= \frac{2(1-z) + z(b_1 + b_{2q+1})}{2}, & H_z^\circ &= I - \frac{(1-z)I + zD}{\alpha_z^\circ}, \\ C_z^{[\ell_N]} &= (\alpha_z^\circ)^{-1} \sum_{r=0}^{\ell_N} (H_z^\circ)^r (D - I), & R_z^{[\ell_N]} &= (H_z^\circ)^{\ell_N+1} C_z, \\ E_z^{[\ell_N]} &= R_z^{[\ell_N]} - \frac{\text{Tr } R_z^{[\ell_N]}}{2q+1} I. \end{aligned} \tag{AW17aa}$$

The symbols $\alpha_z^\circ, H_z^\circ$ preserve every original source parameter and relation map; ℓ_N is only the finite series truncation. Multiplication of the finite geometric sum gives $C_z - C_z^{[\ell_N]} = R_z^{[\ell_N]}$. All factors are real functions of the positive relative operator D , hence self-adjoint in the original $M_z = M_0((1-z)I + zD)$ metric. Since $\text{Tr } A_z = 0$, the derivative of the same four-volume function is its signed center $\text{Tr}(C_z^{[\ell_N]} A_z)$ plus $\text{Tr}(E_z^{[\ell_N]} A_z)$. Consequently

$$\begin{aligned} j_{\ell_N} &= \int_0^1 \text{Tr}(C_z^{[\ell_N]} A_z) dz, \\ e_{\ell_N} &= \int_0^1 \sqrt{\text{Tr}((E_z^{[\ell_N]})^2) \text{Tr}(A_z^2)} dz, \\ j_{\ell_N} - e_{\ell_N} &\leq \mathcal{B}(1) - \mathcal{B}(0) \leq j_{\ell_N} + e_{\ell_N}. \end{aligned} \tag{AW17ab}$$

For this block $\mathcal{B}$ denotes precisely the four-volume function identified above. The signed inequalities follow by Hilbert–Schmidt Cauchy–Schwarz in that unchanged metric and integration of the exact derivative. The full residual calculation ISM29–37, equivalently RMT19–21, uses $\vartheta = (b_{2q+1} - b_1)/(b_{2q+1} + b_1) < 1$ and $K_D = \sum_j (|b_j - 1|/\min\{1, b_j\})^2$ to prove

$$0 \leq e_{\ell_N} \leq \vartheta^{\ell_N+1} \sqrt{K_D(8q-6)} \longrightarrow 0. \tag{AW17ac}$$

Indeed every eigenvalue of H_z° has modulus at most ϑ , centering the residual subtracts a nonnegative square from its squared Hilbert–Schmidt norm, and $\text{Tr}(A_z^2) \leq 8q - 6$ by the full flag spectra and the common range. This proves the bound with all eigenvalue multiplicities retained. The displayed integrals are exact; a numerical evaluation must retain its own integration error. Intersecting this proved signed interval with the already proved absolute and nonlinear intervals supplies the additional endpoint entries below, for every specified ℓ_N .

The original quartet Gamma theorem, when applied to the actual full quartet packet with displacement $\delta > 0$ and common order m , retains $q = [1 + k(m-1)](k+1)^2$ and gives

$$\mathcal{B}_{h,k}^{\text{ar}} \geq 4q \log\left(\frac{\delta k}{2\sqrt{5}}\right) + \max\{-\mathcal{J}_{h,k}^{(5)}, j_{\ell_N} - e_{\ell_N}\}. \tag{AW18}$$

This substitutes the complete supplied Gamma theorem into the lower branches of (AW14) and the constructed signed inequality (AW17ab), then takes their maximum. It retains the stronger actual overlap bound, and also implies the earlier lower bounds with $-\mathcal{L}_q(D)$ and $-(2q-1) \log \kappa(D)$ respectively. It proves no uniform estimate for the eigenvalues b_j , and asserts no existence of an off-line packet. The new computed objects are the exact window spectra, their source isometry, its arithmetic observation and commutator, and the strengthened finite bound.

85 The one-dimensional quotient: exact angle and nonlinear transport

When $q = 1$, the same four endpoints are 0, 1, 1, 2. Their middle factors cancel in the specified ratio, leaving $\mathcal{B}(t) = \log(V_0(t)/V_2(t))$ with both original masses still present. Write $\chi = S - a$. The actual operators now are $U = Q_2$ and $W = I - P_0$. If $\mathcal{N} = (\chi\mathcal{P}_1)^\perp$ and $P_{\mathcal{N}} = I - Q_2$, then $U - W = P_0 - P_{\mathcal{N}}$. Both projections have rank one.

Let $e = 1 \in H$, $z = R_2(t)[1]$, and retain their actual norms $\langle e, e \rangle_t = V_0(t)$ and $\langle z, z \rangle_t = V_2(t)$. The source splitting gives $z = P_{\mathcal{N}}e$, since $J_2e = 1$. Thus $\langle e, z \rangle_t = V_2(t)$, and the angle between the two lines has the exact value

$$\cos^2 \theta(t) = \frac{|\langle e, z \rangle_t|^2}{\langle e, e \rangle_t \langle z, z \rangle_t} = \frac{V_2(t)}{V_0(t)} = e^{-\mathcal{B}(t)}. \quad (\text{AW19})$$

Both Grams are positive, so the cosine is positive. It is strictly less than one for the actual measure (AW3). Otherwise $e \in \mathcal{N}$, implying $\int \chi(S)m_t = 0$ and $\int S\chi(S)m_t = 0$. On the unchanged line $\bar{S} = k - S$, and consequently $|\chi(S)|^2 = ((k - \bar{a}) - S)\chi(S)$. The two equalities would force $\int |\chi(S)|^2 m_t = 0$, contrary to the positive Gram of this nonzero polynomial. Hence $0 < \theta(t) < \pi/2$ and $\mathcal{B}(t) > 0$ on the whole closed interval.

For completeness, take the unit vector $p = e/\sqrt{V_0}$ and write $z/\sqrt{V_2} = \cos \theta p + \sin \theta r$, where r is the resulting unit vector orthogonal to p . The phase is already fixed since $\langle e, z \rangle_t = V_2 > 0$. In this orthonormal pair the exact difference of projections is

$$(P_0 - P_{\mathcal{N}})|_{\text{span}(p,r)} = \begin{pmatrix} \sin^2 \theta & -\sin \theta \cos \theta \\ -\sin \theta \cos \theta & -\sin^2 \theta \end{pmatrix}. \quad (\text{AW20})$$

Its trace is zero and its determinant is $-\sin^2 \theta$. It vanishes on the remaining one-dimensional orthogonal complement. Thus its full eigenvalues are $\sin \theta, 0, -\sin \theta$. Applying the proved rank-one spectral trace bounds to its positive and negative eigenprojections yields

$$|\dot{\mathcal{B}}(t)| \leq \sqrt{1 - e^{-\mathcal{B}(t)}} (c_3(t) - c_1(t)). \quad (\text{AW21})$$

This retains the actual alignment of the two lines.

The function $\Phi(B) = 2 \operatorname{arcosh}(e^{B/2})$ for $B > 0$ has derivative $\Phi'(B) = 1/\sqrt{1 - e^{-B}}$, by differentiating the inverse of the hyperbolic cosine on its positive branch. The preceding strict positivity on the compact interval justifies its smooth composition with $\mathcal{B}(t)$. Divide (AW21) by its positive square-root factor. The four independent generic inequalities (AW16), (AW16a), and the trace-norm and Hilbert–Schmidt inequalities (AW13c) can all be divided by that same factor because $q = 1$ gives $a_q = 1$ and $\mathcal{B} > 0$. Their pointwise minimum integrates to $\mathcal{I}_{h,k}$ in (AW13b); integration of (AW17) bounds it by $\log(b_3/b_1)$. The exact nonlinear endpoint bound is

$$\left| 2 \operatorname{arcosh}(e^{B(1)/2}) - 2 \operatorname{arcosh}(e^{B(0)/2}) \right| \leq \mathcal{I}_{h,k} \leq \log(b_3/b_1). \quad (\text{AW22})$$

Combining (AW22) with the signed interval (AW17ab), with the original values $A_0 = \operatorname{arcosh}(e^{B(0)/2})$ and $L = \mathcal{I}_{h,k}/2 \leq \frac{1}{2} \log(b_3/b_1)$, monotonicity of $2 \log \cosh A$ for $A \geq 0$ gives

$$\begin{aligned} \mathcal{B}(1) &\geq \max\{2 \log \cosh(\max\{0, A_0 - L\}), \mathcal{B}(0) + j_{\ell_N} - e_{\ell_N}\}, \\ \mathcal{B}(1) &\leq \min\{2 \log \cosh(A_0 + L), \mathcal{B}(0) + j_{\ell_N} + e_{\ell_N}\}. \end{aligned} \quad (\text{AW23})$$

This last lower bound can be zero although the actual $\mathcal{B}(1)$ is strictly positive, as proved above. Every step concerns the original $q = 1$ quotient and its degree-two source. No extension of that dimension restriction to a quartet quotient is asserted.

85.1 Complete proof dependencies

The complete AT calculation accompanies this note, together with its 29 complete source dependencies and independent proof review. Those sources prove the original pushforward, tensor signs, full Taylor-unit injections, theta primitive, positive arithmetic and Gamma moments, and the quartet application. Every new assertion (AW7)–(AW23) is proved above on those unchanged finite objects. A separate independent review supplies the spectral calculation and its edge-case checks.

86 Complete arithmetic cohomology over the tau-base

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

86.0.1 Arithmetic cohomology over the τ -base

86.0.2 Scope and result

This note changes the geometric base of the existing arithmetic theta model to a one-point absolute base with distinguished absorbing element τ . It does **not** start with a variety over a finite field and then relabel its coefficients.

The main calculation is the right adjoint to the actual global-section functor on this τ -based model. A projective resolution computes the arithmetic cohomology; a dual injective complex computes its right-adjoint object. These are then linked to the existing finite Mellin-jet quotients, including the full nilpotent jets and the original e/τ distinction.

This is an algebraic, finite-chart realization. No assertion is made that the chart model is an arithmetic scheme, that its topology already supplies all prime correspondences, that the right-adjoint object is an involutive Verdier duality on every sheaf, or that the calculation proves a weight estimate. Each operation used below has its stated category. In particular the algebraic dual is not an assertion about the continuous dual of the Schwartz quotient.

The supplied SplitZero results are the source for the scalar operations, support fibres and transports. The new constructions and proofs below are calculations in this note; they have not been Lean-formalized.

86.0.3 1. An actual base whose structural zero is τ

Let

$$\mathbf{F}_{1,\tau} = \{\tau, 1\}$$

be the pointed multiplicative monoid with identity 1 and absorbing element τ . As a blueprint, its only additional zero relation is that the empty sum represents τ . No additive equation $1 + 1 = 1$ is imposed. Its spectrum $\mathfrak{b}_\tau$ has the one prime $\{\tau\}$.

For every nonzero commutative ring R , retain

$$G(R) = \{\tau\} \sqcup \{r^\bullet : r \in R\}, \quad e_R = 0_R^\bullet. \quad (\text{TauBase 1})$$

Let B_R be its associated blueprint: the original multiplicative pointed monoid, with all its original finite additive relations. In particular retain $[\tau] = 0$, in agreement with the presentation correction in the supplied formalization note. There is a blueprint morphism

$$\mathcal{J}_R : \mathbf{F}_{1,\tau} \longrightarrow B_R, \quad \tau \mapsto \tau, \quad 1 \mapsto 1_R^\bullet. \quad (\text{TauBase 2})$$

On spectra it gives a genuine structural morphism

$$a_R : \operatorname{Spec} B_R \longrightarrow \mathfrak{b}_\tau. \quad (\text{TauBase 3})$$

Every prime has inverse image $\{\tau\}$ under (2). Thus every arithmetic point lies over the single base point, by a specific inverse-image operation on prime ideals.

The arithmetic quotient stays attached:

$$p_R : G(R) \longrightarrow R, \quad p_R(\tau) = 0_R, \quad p_R(r^\bullet) = r. \quad (\text{TauBase 4})$$

For a domain,

$$P_\tau = \{\tau\}, \quad P_0 = \{\tau, e_R\}, \quad \operatorname{Spec} R \xrightarrow{i_R} \operatorname{Spec}_{\text{sr}} G(R), \quad \mathfrak{p} \mapsto \mathfrak{p} \sqcup \{\tau\}. \quad (\text{TauBase 5})$$

Here $i_R(\operatorname{Spec} R) = V(e_R) = \overline{\{P_0\}}$. These maps carry the source's infinite quotient when $R = \mathbb{Z}$. They do not assign an additional finite norm to either bottom ideal.

There is a second, different-direction morphism in the same diagram:

$$\operatorname{Spec} \mathbb{B} \xrightarrow{\operatorname{Spec} \chi_R} \operatorname{Spec}_{\text{sr}} G(R) \xrightarrow{a_R} \mathfrak{b}_\tau, \quad \chi_R(\tau) = 0, \quad \chi_R(r^\bullet) = 1. \quad (\text{TauBase 6})$$

The first arrow lands at P_τ . The original localization calculation is

$$G(R)[e_R^{-1}] \cong \mathbb{B}. \quad (\text{TauBase 7})$$

Indeed invertibility and $e_R^2 = e_R$ force $e_R = 1$, and $e_R r^\bullet = e_R$ then forces every supported scalar to equal 1. External absence remains distinct. We use (3), not localization (7), for the change of base. The arithmetic structure and its quotient remain upstream of (6).

For $R = \mathbb{Z}$, the source's infinite target is retained in the square

$$\begin{array}{ccc} G(\mathbb{Z}) & \xrightarrow{G(j)} & G(\mathbb{C}) \\ p_{\mathbb{Z}} \downarrow & & \downarrow p_{\mathbb{C}} \\ \mathbb{Z} & \hookrightarrow & \mathbb{C}. \end{array} \quad (\text{TauBase 8})$$

Here $j : \mathbb{Z} \hookrightarrow \mathbb{C}$ is the specified unital embedding, and $G(j)$ is its split lift.

86.0.4 2. The arithmetic theta chart space over that base

Fix $E = \mathbb{C}$. Let P be the four-point poset

$$+ < \eta < \sigma, \quad - < \eta < \sigma, \quad (\text{TauBase 9})$$

with $+$ and $-$ incomparable. Give P the upper-set topology. Its proper nonempty opens are

$$\{\sigma\}, \quad \{\eta, \sigma\}, \quad \{+, \eta, \sigma\}, \quad \{-, \eta, \sigma\}.$$

The structural sheaf $\mathcal{S}$ has value $G(E)$ on every open containing an arithmetic chart point and value $\mathbb{B}$ on $\{\sigma\}$. Restriction to σ is χ_E ; other nontrivial restrictions are identities. Compatible supported local amplitudes glue, and compatibility at σ distinguishes an absent family from a supported one. This proves the sheaf assertion directly.

Together with (2), this defines a space with a sheaf of blueprints over $\mathfrak{b}_\tau$. There is also the explicit structural morphism to $\operatorname{Spec}_{\text{sr}} G(E)$, sending $+, -, \eta$ to P_0 and σ to P_τ , followed by the morphism induced by $G(j)$ to $\operatorname{Spec}_{\text{sr}} G(\mathbb{Z})$. On arithmetic stalks its map is $G(\mathbb{Q}) \rightarrow G(E)$; at σ it is $\mathbb{B} \rightarrow \mathbb{B}$. Thus the infinite quotient is still in a commuting structural diagram. This particular chart model maps to the arithmetic generic point; its finite-prime geometry is not being claimed to cover the closed prime fibres. Arithmetic prime information in the present realization enters through the theta map and its Euler/explicit formula, not through extra chart points invented here.

The coefficient spaces are exactly

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi \text{ even}, \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx, \quad (\text{TauBase 10})$$

and

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^k F(x)| < \infty \text{ for every } b \in \mathbb{Z}, k \geq 0\}. \quad (\text{TauBase 11})$$

Define

$$\Theta\phi(x) = \sum_{n \in \mathbb{Z} \setminus \{0\}} \phi(nx), \quad JF(x) = x^{-1}F(1/x). \quad (\text{TauBase 12})$$

The retained Poisson identity gives

$$J\Theta\psi = \Theta\widehat{\psi}. \quad (\text{TauBase 13})$$

The arithmetic coefficient sheaf is the covariant diagram

$$\mathcal{T}_+ = V, \quad \mathcal{T}_- = V, \quad \mathcal{T}_\eta = \mathcal{B}, \quad \mathcal{T}_\sigma = 0, \quad r_+ = \Theta, \quad r_- = J\Theta = \Theta\mathcal{F}. \quad (\text{TauBase 14})$$

This use of a zero vector space at σ will not identify the supported zero with τ . It is reconstructed as the support skeleton in the next paragraph.

All original two-leg support faces Set $L = \mathcal{P}(\{+, -\})$. For nonempty $A \subseteq \{+, -\}$, define a sheaf $\mathcal{T}_A$ by

$$(\mathcal{T}_A)_+ = \begin{cases} V & + \in A \\ 0 & + \notin A, \end{cases} \quad (\mathcal{T}_A)_- = \begin{cases} V & - \in A \\ 0 & - \notin A, \end{cases} \quad (\mathcal{T}_A)_\eta = \mathcal{B}, \quad (\mathcal{T}_A)_\sigma = 0. \quad (\text{TauBase 15})$$

The nonzero restriction maps are those in (14); put $\mathcal{T}_\emptyset = 0$. Transports for $A \subseteq A'$ are coordinate inclusions at $+$ and $-$ and the identity at η . These form a strict diagram.

Reconstruct the supplied SplitZero semimodule sheaf

$$\widetilde{\mathcal{T}} = \{\tau\} \sqcup \bigsqcup_{A \neq \emptyset} \{A\} \times \mathcal{T}_A. \quad (\text{TauBase 16})$$

At σ its stalk is the semilattice L , with Boolean scalar action. At an arithmetic chart the scalar action is by $G(E)$. Restrictions to σ are semilinear along χ_E . In particular $e_E(A, v) = (A, 0)$, which restricts to A at σ , while τ restricts to the empty label. The original distinction is present at the new base boundary.

The additive module in degree zero is exactly the original two-leg carrier $(V^\tau)^2$: a missing leg is absent, and a supported zero in that leg is present. Formula (15) records a missing leg as a zero coefficient space **with its separate mask A retained**. Thus no new support is inserted into the original missing leg.

86.0.5 3. Compute global cohomology over the τ -base

We now use the explicitly declared linear-fibre category

$$\mathcal{A} = \text{Fun}(P, \text{Vect}_E).$$

This is a realization category of the marked blueprint space, not an asserted category of étale sheaves on a new arithmetic scheme. Its passage to the original supported sheaves is (15)–(16), with kernels and quotients reconstructed fibrewise.

For $x \in P$, let P_x be the projective diagram

$$P_x(y) = \begin{cases} E & x \leq y \\ 0 & \text{otherwise.} \end{cases} \quad \text{Hom}_{\mathcal{A}}(P_x, F) = F_x. \quad (\text{TauBase 17})$$

The constant diagram $\mathbf{E}$ has the exact projective resolution

$$0 \longrightarrow P_\eta \xrightarrow{v \mapsto (v, -v)} P_+ \oplus P_- \xrightarrow{(u, v) \mapsto u+v} \mathbf{E} \longrightarrow 0. \quad (\text{TauBase 18})$$

At $+$ and $-$ the last map is identity. At η and σ it is addition with kernel the displayed anti-diagonal. This checks every stalk and every arrow.

Consequently the base pushforward is

$$\mathbf{A}_\tau(F) := R\Gamma(P, F) \simeq [F_+ \oplus F_- \xrightarrow{r_+ - r_-} F_\eta], \quad \text{degrees } 0, 1. \quad (\text{TauBase 19})$$

This is global cohomology over the base point, rather than restriction to the added generic point. The typed comparison to the latter is

$$\text{res}_\sigma : \mathbf{A}_\tau(F) \longrightarrow F_\sigma[0]. \quad (\text{TauBase 20})$$

Two chain representatives of (20) in degree zero are $(x, y) \mapsto r_{+\sigma}x$ and $(x, y) \mapsto r_{-\sigma}y$. Their difference is

$$r_{\eta\sigma}(r_+x - r_-y),$$

so they are chain homotopic, with homotopy $r_{\eta\sigma} : F_\eta \rightarrow F_\sigma$. Thus (20) is canonical in the derived category. On the actual joint arithmetic sheaf,

$$\mathbf{A}_\tau(\mathcal{T}) = [V \oplus V \xrightarrow{\Theta(\phi - \widehat{\psi})} \mathcal{B}], \quad (\text{TauBase 21})$$

$$H^0 \mathbf{A}_\tau(\mathcal{T}) \cong V, \quad \psi \mapsto (\widehat{\psi}, \psi), \quad H^1 \mathbf{A}_\tau(\mathcal{T}) = Q := \mathcal{B}/\Theta V. \quad (\text{TauBase 22})$$

Injectivity of Θ follows from its Mellin transform on $\Re s > 1$, the nonvanishing Euler product there, and Mellin uniqueness. This is the existing source proof, not an assumption about zeros in the critical strip.

The actual supported differential is

$$\widetilde{d}(\phi, \psi) = (A, \Theta p(\phi) - J\Theta p(\psi)), \quad (\text{TauBase 23})$$

where A is the set of present legs; the absent pair maps to τ . Its cohomology uses

$$Z_{\text{sp}}^i = \text{Eq}(d, \epsilon d), \quad H_{\text{sp}}^i = \text{coeq}(b, \epsilon b), \quad \epsilon(x) = ex. \quad (\text{TauBase 24})$$

For every nonempty A , $H^1(\mathcal{T}_A) = Q$. For a single-leg A , $H^0 = 0$; for the joint A , $H^0 = V$. Therefore

$$\widetilde{H}_\tau^1 = \{\tau\} \sqcup \bigsqcup_{A \neq \emptyset} \{A\} \times Q. \quad (\text{TauBase 25})$$

Restriction (20) sends each of these arithmetic classes to the supported zero at its own label in the σ skeleton. Their global cohomology classes in (25) remain present. This is the exact answer to what remains when all geometric points lie over the τ -base.

86.0.6 4. Compute the right adjoint on this base

Deligne defines a dualizing object through a right adjoint and then proves weight bounds. Here we compute the right adjoint to our stated functor (19), rather than importing a dualizing complex from a finite-field variety.

For $x \in P$ and a vector space W , define

$$I_x(W)(y) = \begin{cases} W & y \leq x \\ 0 & \text{otherwise.} \end{cases} \quad \text{Hom}_{\mathcal{A}}(F, I_x(W)) = \text{Hom}_E(F_x, W). \quad (\text{TauBase 26})$$

Because evaluation at x is exact and W is an injective E -module, $I_x(W)$ is injective. The right-adjoint object is

$$\boxed{K_\tau(W) = [I_\eta(W) \xrightarrow{(+\text{res}, -\text{res})} I_+(W) \oplus I_-(W)], \quad \text{degrees } -1, 0.} \quad (\text{TauBase 27})$$

For every sheaf F ,

$$\begin{aligned} R\text{Hom}_A(F, K_\tau(W)) &= [\text{Hom}(F_\eta, W) \longrightarrow \text{Hom}(F_+, W) \oplus \text{Hom}(F_-, W)] \\ &\cong R\text{Hom}_E(A_\tau(F), W). \end{aligned} \quad (\text{TauBase 28})$$

The differential is $\ell \mapsto (\ell r_+, -\ell r_-)$. This proves the adjunction, with its signs. For a bounded complex W , totalize the same formula with its original differential.

Let $S_\eta W$ denote the diagram with W at η and zero at the other three points. Calculation of the four stalk complexes gives

$$K_\tau(W)_+ = [W \xrightarrow{1} W], \quad K_\tau(W)_- = [W \xrightarrow{-1} W], \quad K_\tau(W)_\eta = W[1], \quad K_\tau(W)_\sigma = 0. \quad (\text{TauBase 29})$$

Thus

$$\boxed{K_\tau(W) \simeq S_\eta W[1].} \quad (\text{TauBase 30})$$

The symbol $[1]$ means W is in cohomological degree -1 . It is obtained from (18) and (27). The functor is a right adjoint to $R\Gamma$ on this model; no assertion that it is the extraordinary pullback for an unconstructed proper arithmetic morphism is made. In particular, an involutive local Verdier duality or a finite-field purity theorem has not been obtained just from (28).

Apply (27) componentwise to support diagrams. Every zero coefficient stalk reconstructs as its labelled zero, including at σ . Dual transports are actual precomposition maps

$$\rho_{AB}^\vee : \text{Hom}(H_B, W) \longrightarrow \text{Hom}(H_A, W), \quad \ell \mapsto \ell \rho_{AB}. \quad (\text{TauBase 31})$$

They therefore have index category L^{op} ; the label arrows have not been reversed without retaining the precomposition operation.

86.0.7 5. Retain the actual characteristic-zero arithmetic action

For a positive real a , use

$$U_a F(x) = F(x/a), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}. \quad (\text{TauBase 32})$$

Then

$$\mathcal{M}U_a F(s) = a^s \mathcal{M}F(s), \quad \widehat{U_a \phi} = a U_{1/a} \widehat{\phi}. \quad (\text{TauBase 33})$$

The action on the two source charts is consequently

$$(\phi, \psi) \mapsto (U_a \phi, a U_{1/a} \psi), \quad F \mapsto U_a F \text{ at } \eta. \quad (\text{TauBase 34})$$

Using the same U_a on both source charts would fail the required intertwining. Direct calculation gives

$$U_a J = a J U_{1/a}, \quad d(U_a \phi, a U_{1/a} \psi) = U_a d(\phi, \psi). \quad (\text{TauBase 35})$$

It fixes every support mask. At σ it fixes the support skeleton. The new base remains the same point; the induced action on its pushforward remains the arithmetic action (33).

The source's moment map gives the two coefficient lines

$$\mathcal{L}_0 = E \text{ with action } 1, \quad \mathcal{L}_1 = E \text{ with action } a, \quad m(\phi) = (\phi(0), \int_{\mathbb{R}} \phi(x) dx), \quad (\text{TauBase 36})$$

$$mU_a = \text{diag}(1, a)m.$$

Both choices $K_\tau(\mathcal{L}_0)$ and $K_\tau(\mathcal{L}_1)$ exist. The latter produces, on dual functionals, the action

$$(U_a \ell)(v) = a \ell(U_a^{-1} v). \quad (\text{TauBase 37})$$

The factor a is carried from the actual second moment representation. It is not set to one or inferred from the cardinality of a base point.

86.0.8 6. An actual morphism from arithmetic cohomology to its τ -base dual

Put $g = 2\xi$. Retain a finite reflection-stable set Z of actual zeros, with actual multiplicities. Define

$$A_Z = \bigoplus_{\rho \in Z} \mathcal{O}_\rho / (g), \quad (J_Z F)_\rho = \sum_{j < m_\rho} \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} z_\rho^j. \quad (\text{TauBase 38})$$

The source identity $\mathcal{M}\Theta\phi = gH_\phi$, with H_ϕ entire, proves that the maps

$$\mathcal{T} \longrightarrow S_\eta A_Z, \quad 0 \text{ on } +, -, \sigma, \quad J_Z \text{ on } \eta, \quad (\text{TauBase 39})$$

are a sheaf morphism. Applying A_τ gives precisely the already-specified map $Q \rightarrow A_Z$ in degree one. This finite jet map is onto; the source proof is independence of the finite family $e^{\rho y} y^j / j!$ on any nonempty interval, followed by a compactly supported smooth right inverse.

On A_Z , the scaling action is

$$U_a|_\rho = a^\rho \sum_{j < m_\rho} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho z^j = z^{j+1}. \quad (\text{TauBase 40})$$

Using the reflected germ map

$$f^\dagger(s) = \overline{f(1-\bar{s})}, \quad \sum c_j z_{i_\rho}^j \mapsto \sum (-1)^j \bar{c}_j z_\rho^j, \quad (\text{TauBase 41})$$

retain the perfect finite residue pairing

$$R_Z(f, h) = \sum_{\rho \in Z} \text{Res}_\rho \frac{f^\dagger(s)h(s)}{g(s)} ds. \quad (\text{TauBase 42})$$

It has $R_Z(U_a f, U_a h) = a R_Z(f, h)$. Its raw skew-Hermitian orientation is retained; no multiplication by a phase is inserted to call it positive.

Precomposing the dual map of (39) with (42) gives an explicit injective linear morphism from the conjugate finite packet:

$$\boxed{\overline{A_Z} \longrightarrow H^{-1} R \text{Hom}_{\mathcal{A}}(\mathcal{T}, K_\tau(\mathcal{L}_1)), \quad \bar{f} \longmapsto \left([F] \longmapsto \sum_{\rho \in Z} \text{Res}_\rho \frac{f^\dagger(s) \mathcal{M}F(s)}{g(s)} ds \right)}. \quad (\text{TauBase 43})$$

The target is canonically $\text{Hom}_E(Q, \mathcal{L}_1)$ by (28). Well-definedness follows because replacing F by $F + \Theta\phi$ adds the holomorphic residue expression $f^\dagger H_\phi$. Injectivity follows from the surjectivity of J_Z and perfectness of (42). Formula (37) and covariance of (42) prove equivariance.

Thus the duality here is a morphism **to the right-adjoint object computed on the τ -base**, not merely a pairing written separately from a cohomological model.

The trace contraction is the specified endomorphism

$$J_g : A_Z \rightarrow A_Z, \quad [h] \mapsto [g'h], \quad (\text{TauBase 44})$$

$$R_Z(f, J_g h) = \sum_{\rho} m_{\rho} \overline{f(1 - \bar{\rho})} h(\rho) = \text{Tr}(M_{f^{\dagger}h}|A_Z). \quad (\text{TauBase 45})$$

At a zero of order m , write the actual $g = u(z)z^m$. Then $g' \equiv mu(z)z^{m-1} \pmod{z^m}$. The radical of (45) consists of the jets with zero residue value. They map to e under the original internal quotient, while (42) retains their full pairing before that observation.

All maps in (38)–(45) lift to supported fibres. At label A the map is $(A, [F]) \mapsto (A, J_Z F)$. A zero functional obtained in (43) or (45) is the supported zero functional at that label, not τ . For inclusions of admitted source labels the resulting squares commute, and the dual arrows are the precomposition arrows (31).

86.0.9 7. The tensor-amplification operation on the changed base

For the joint arithmetic fibre, take products of the actual chart space P over the underlying point of $\mathfrak{b}_{\tau}$, and external products of its coefficient sheaf. This is the ordinary product of the declared finite topological models with external coefficient tensors. It is not a claim that its structure-sheaf product has already been identified with the schematic square of the full arithmetic space.

The projective resolution for P^r is the external tensor product of (18). Its differential on homogeneous factors is

$$d(x_1 \otimes \cdots \otimes x_r) = \sum_{j=1}^r (-1)^{\sum_{k < j} |x_k|} x_1 \otimes \cdots \otimes dx_j \otimes \cdots \otimes x_r. \quad (\text{TauBase 46})$$

Because the tensor product is over the field E , this yields the explicit Künneth map and, at the top degree,

$$\boxed{H^r \mathbf{A}_{\tau, r}(\mathcal{T}^{\boxtimes r}) \cong Q^{\boxtimes_{E^r}}.} \quad (\text{TauBase 47})$$

Indeed the numerator of top cohomology is $\mathcal{B}^{\boxtimes r}$; its relations are the sum of all subspaces obtained by putting ΘV in at least one factor. The quotient is exactly the displayed tensor quotient. The joint-support evaluation is a stated functor from the full retained support diagram. Other original support fibres are not removed; their cochain complexes and transports remain in that diagram.

The top-degree kernel relation is again quotiented internally in its supported scalar fibre. Pure external absence is absorbing. A supported tensor whose amplitude becomes a tensor relation maps to the supported zero of that tensor fibre. We do not identify a coefficient external tensor with the Cartesian product of support labels; such a tensor has its specified absorbing basepoint and balancing relations.

The dual right-adjoint object on the product is computed from the dual tensor resolution:

$$K_{\tau, r}(W) \simeq S_{(\eta, \dots, \eta)} W[r]. \quad (\text{TauBase 48})$$

For $r = 2$, the degree -2 term and both degree -1 terms occur in that resolution with the signs from (46). The shift $[2]$ is obtained by this actual product calculation, not inserted into (30).

For a residue-value eigenvector at an actual zero ρ , the action in (47) on its r -fold tensor is

$$a^{r\rho}. \quad (\text{TauBase 49})$$

In particular the exact modulus defect relative to r copies of $\mathcal{L}_1^{1/2}$, expressed without rescaling the action, is

$$\log \frac{|a^{r\rho}|^2}{a^r} = r(2\Re \rho - 1) \log a \quad (a > 1). \quad (\text{TauBase 50})$$

This performs the amplification operation on the actual arithmetic spectral quotient over the new base. It does not prove a bound on the left-hand side. Deligne's geometric upper estimate is additional information in his setting; it has not been derived for (47).

86.0.10 8. What a map to the base does, and what deleting a spectral packet does

The structural map (3) sends every point to the base point. The derived pushforward (19) carries its coefficient relations and arithmetic operators along with it. Restriction (20), by contrast, has value the support skeleton on our sheaf. These are two explicitly compared operations on the same model.

For clarity about the proposed “exceptions land in τ ,” let W and W' be ordinary vector spaces and use their single-active-fibre split lifts. If a $G(E)$ -linear map

$$f : W^\tau \rightarrow (W')^\tau$$

sends one supported vector v to τ , then it sends every supported vector to τ . Proof: $f(0_W^\bullet) = f(ev) = ef(v) = \tau$. For every w , $ef(w) = f(ew) = \tau$. In $(W')^\tau$, the only element whose e -multiple is τ is τ itself. This result is for this specified target; it is not asserted for arbitrary semimodules with a nontrivial bottom group fibre.

A labelled projection can delete a whole packet while retaining other labels, but it has a calculable cohomological contribution. For a reflection-stable finite set Z split into C and B , the actual projection is

$$A_Z \twoheadrightarrow A_C, \quad \ker = A_B. \quad (\text{TauBase 51})$$

The difference of convolution traces is

$$\text{Tr}(H_h|A_Z) - \text{Tr}(H_h|A_C) = \sum_{\rho \in B} m_\rho \mathcal{M}h(\rho). \quad (\text{TauBase 52})$$

This is nonzero for some admissible compactly supported smooth h whenever B is nonempty, by finite Mellin interpolation. Its split value for that test is a supported nonzero number. The cone of the projection $A_Z[-1] \rightarrow A_C[-1]$ has $H^0 = A_B$; that is the precise cohomological trace lost by deletion.

Consequently a structural projection of the entire geometry to the τ -base does not delete a packet. A packet deletion is (51), with the separate kernel and trace (52). Establishing that all actual exceptional contributions are absent requires this kernel or its full trace contribution to vanish by arithmetic geometry, not merely by relabelling its support.

86.0.11 9. Result and next mathematically defined target

The completed construction in this note is

$$\tilde{\mathcal{T}} \text{ over } \mathfrak{b}_\tau \xrightarrow{A_\tau} \tilde{H}_\tau^1 \xrightarrow{J_Z} A_Z^\tau,$$

with the computed adjoint object $K_\tau(\mathcal{L}_1)$, the dual morphism (43), the trace contraction (45), and all tensor powers (47). It is a characteristic-zero scaling calculation, not a purity calculation on a finite-field curve.

The arithmetic quotient $G(\mathbb{Z}) \rightarrow \mathbb{Z}$ is kept in the structural map (8). The current theta chart model sees its generic arithmetic image; a global prime-sensitive geometric realization with a Lefschetz theorem and two-sided weight estimates is not obtained from this finite chart topology alone. The specific remaining quantity in this model is the tensor-growth defect (50), or equivalently the sign of the full trace pairing (45) after its global arithmetic realization. Neither is set to zero in the note.

The new work is the actual change of base, the computed right adjoint, and the cohomological placement of the finite arithmetic duality maps on that base. It narrows the task to a property of these explicit objects rather than repeating the assertion that a shared support should imply purity.

86.0.12 Sources read for this calculation

1. `globalization_note.tex`: lines 432–563 (localizations and stalks), 673–751 (contracted monoid algebra and blueprint remark). The separate supplied Lean-summary note provides the correction `[tau]=0` and the implemented support-fibre operations. Those source results are not claimed as new.
2. Retained `Split_Support_Actual_Comparison/CONTINUATION.tex`: test spaces, Fourier and theta maps, the arithmetic quotient and finite jet realization. This is an earlier research derivation, not an independent verification of every global statement in its package.

3. The supplied French Weil II TeX excerpts, original §6.2.1–6.2.7 and §3.3: the right-adjoint definition of a dualizing complex, opposite dual-weight bounds, proper pushforward, and the arithmetic-base twist/degree equation. The excerpts’ historical-transcription status remains recorded. Reading these windows is not a claim to read or audit the whole paper in this turn.
4. O. Lorscheid, *The geometry of blueprints. Part I* (arXiv:1103.1745): external framework for the declared blueprint base. The finite-chart model and adjoint calculation above are proved here; they are not attributed to that paper.

86.0.13 Checks

The accompanying executable checks finite instances of the stated poset resolution, dual complex, internal support differential, action compatibility, tensor differentials and trace deletion. They use explicit exceptions rather than optimizable assert statements. They are regression checks of these identities, not a formal proof of RH, of Deligne’s theorem, or of a global arithmetic realization.

87 Complete Gamma-reference lower bound and arithmetic determinant comparison

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

This is an all-degree written proof. No fresh Lean execution, complete Deligne scan audit, interval certification of arithmetic moments, or remote publication is claimed by this review. The purity/operator branch is being audited separately.

87.0.3 1. Literal norms and their coordinate map

The complete Beta/Fourier calculation in the appended proof derives, for $a > 0$,

$$r_a(x) = \frac{|\Gamma(a + ix/2)|^2}{2\pi}, \quad c_a = 2^{1-2a}\Gamma(2a), \quad \int e^{iyx} r_a(x) dx = c_a (\cosh y)^{-2a}. \quad (\text{GR1})$$

In particular c_a is the original mass. The literal substitution $t = e^{2y}$ in the Beta integral gives the factor 2^{1-2a} . Exponential moments exist for $|\theta| < \pi/2$, and the same calculation gives $c_a (\cos \theta)^{-2a}$. Fourier uniqueness for finite measures then gives

$$r_a^{*k}(x) = \frac{c_a^k}{c_{ka}} r_{ka}(x). \quad (\text{GR2})$$

The coordinate is the original sum $x = x_1 + \cdots + x_k$. At $a = 1/4$, $c_{1/4} = \sqrt{2\pi}$, so the mass is $(2\pi)^{k/2}$.

The printed generating function, with branches equal to one at zero, is

$$F_a(z, x) = (1 - iz)^{-a+ix/2} (1 + iz)^{-a-ix/2} = \sum_{n \geq 0} b_n^{(a)}(x) \frac{z^n}{n!}. \quad (\text{GR3})$$

For real small z , it is $(1 + z^2)^{-a} \exp(x \arctan z)$. Thus $b_1 = x$, with the positive sign. The appended proof shows

$$\int F_a(z, x) F_a(w, x) r_a(x) dx = c_a (1 - zw)^{-2a}. \quad (\text{GR4})$$

All coefficient extractions are justified by exponential moments on a larger neighborhood. Thus the real, monic polynomials have orthogonal norms $c_a n! (2a)_n$. Their recurrence follows from $(1 + z^2) \partial_z F_a = (x - 2az) F_a$:

$$b_{n+1}^{(a)} = x b_n^{(a)} - n(n + 2a - 1) b_{n-1}^{(a)}, \quad b_0 = 1, \quad b_1 = x. \quad (\text{GR5})$$

Keep $S = k/2 + ix$ and define

$$p_n(S) = i^n b_n^{(k/4)} ((S - k/2)/i). \quad (\text{GR6})$$

The leading coefficient is $i^n i^{-n} = 1$. On the integration line the factor i^n has squared modulus one. Substituting in GR5 and using $i^2 = -1$ gives, with the actual original Gamma sum measure,

$$\begin{aligned}\omega_{k,n}^\Gamma &= \int |p_n(k/2 + ix)|^2 r_{1/4}^{*k}(x) dx = (2\pi)^{k/2} n! (k/2)_n, \\ Sp_n &= p_{n+1} + \frac{k}{2} p_n - n(n + k/2 - 1) p_{n-1}.\end{aligned}\tag{GR7}$$

At $n = 0$ the last term is absent. Thus delivered (28), (29), and (35) have the correct masses, monic convention, and negative recurrence sign.

87.0.4 2. The complete cyclic polynomial for every multiplicity

Write

$$h_*(S) = \prod_{\epsilon, \eta \in \{\pm 1\}} (S - 1/2 - \epsilon/4 - i\eta).\tag{GR8}$$

For $Z = S - 1/2$, multiplying conjugate factors gives $h_* = Z^4 + (15/8)Z^2 + 289/256$. It is monic, real, and fixed by $S \mapsto 1 - S$.

Fix integers $m \geq 1, k \geq 1$. Consider the full tensor algebra of k copies of $\mathbb{C}[S]/(h_*^m)$, the sum multiplication operator, and cyclic vector $1^{\otimes k}$. Chinese remainders decompose each factor into four local algebras $\mathbb{C}[n]/(n^m)$. Every tensor occupation therefore has local algebra

$$\mathbb{C}[n_1, \dots, n_k]/(n_1^m, \dots, n_k^m)$$

and sum operator equal to its center plus $n_1 + \dots + n_k$. Its power of degree $k(m-1) + 1$ vanishes because every monomial then has some exponent at least m . Its power of degree $k(m-1)$ is exactly

$$\frac{(k(m-1))!}{((m-1)!)^k} \prod_{j=1}^k n_j^{m-1} \neq 0.\tag{GR9}$$

For $m = 1$ this is the zeroth power 1, giving the same length-one result. The coefficient is nonzero in characteristic zero. The cyclic vector projects to the unit in every local algebra, so this full nilpotency length also occurs in its cyclic minimal polynomial.

For margins $0 \leq a, b \leq k$, the center is

$$\lambda_{a,b} = k/2 + (2a - k)/4 + i(2b - k).\tag{GR10}$$

All margin pairs occur. Indeed, $t = \max(0, a + b - k)$ gives nonnegative occupations $t, a - t, b - t, k - a - b + t$, with total k and the required two margins. Distinct margins have distinct centers because both coordinate coefficients are nonzero. Repeated occurrences of the same center take the maximum of their identical nilpotency lengths in the minimal polynomial, not their sum. Therefore exactly

$$\ell_k = 1 + k(m-1), \quad \chi_k(S) = \prod_{a,b=0}^k (S - \lambda_{a,b})^{\ell_k}, \quad q_k = \ell_k(k+1)^2\tag{GR11}$$

is the cyclic minimal polynomial. Each primary summand in $\mathbb{C}[S]/(\chi_k)$ has dimension and block length ℓ_k . This proves delivered (30), including all $m > 1$.

87.0.5 3. Canonical quotient metric and the complete boundary identity

Fix k, m and abbreviate $q = q_k, \chi = \chi_k, c = k/2$. Use the ordered remainder basis $1, S, \dots, S^{q-1}$ of $E = \mathbb{C}[S]/(\chi)$, and let $A : E \rightarrow E$ be multiplication by S . Write $b_n = [p_n]_\chi$.

For $N \geq q - 1$, the first q monic remainder columns are a basis. In the source basis $p_0, \dots, p_N$, the source Gram is $O_N = \text{diag}(\omega_0, \dots, \omega_N)$, and the remainder matrix is $J_N = [b_0 \cdots b_N]$. Hence

$$K_N = J_N O_N^{-1} J_N^* = \sum_{n=0}^N \frac{b_n b_n^*}{\omega_n} > 0. \quad (\text{GR12})$$

The coefficient matrix of the canonical minimum section is

$$C_N = O_N^{-1} J_N^* K_N^{-1}. \quad (\text{GR13})$$

One has $J_N C_N = I_E$. If $z \in \ker J_N$, then $z^* O_N C_N v = z^* J_N^* K_N^{-1} v = 0$. Every other representative is $C_N v + z$, whose squared norm is $\|C_N v\|^2 + \|z\|^2$. Thus the actual minimum quotient Gram and volume are

$$G_N = K_N^{-1}, \quad V_N = \det G_N > 0. \quad (\text{GR14})$$

Put $\alpha_n = n(n + k/2 - 1)$. GR7 gives $\omega_n/\omega_{n-1} = \alpha_n$, and reduction gives $Ab_n = b_{n+1} + cb_n - \alpha_n b_{n-1}$. Substitution in $AK_N + K_N A^* - kK_N$ cancels each interior pair: the term $(b_{n+1}b_n^* + b_n b_{n+1}^*)/\omega_n$ is cancelled by the next negative term because $\alpha_{n+1}/\omega_{n+1} = 1/\omega_n$. No lower term occurs at zero. Therefore

$$AK_N + K_N A^* - kK_N = \frac{b_{N+1}b_N^* + b_N b_{N+1}^*}{\omega_N}. \quad (\text{GR15})$$

Multiplication by G_N on both sides gives

$$W_N := A^* G_N + G_N A - kG_N = G_N \frac{b_{N+1}b_N^* + b_N b_{N+1}^*}{\omega_N} G_N. \quad (\text{GR16})$$

Thus $H_N = G_N^{-1} W_N$ is self-adjoint in the original G_N inner product and has rank at most two. Its trace is $2\Re \text{Tr } A - kq = 0$: reflection $(a, b) \leftrightarrow (k - a, b)$ pairs real parts with sum k , retaining equal full multiplicities. Its possible nonzero eigenvalues are $+\epsilon_N, -\epsilon_N$, with $\epsilon_N \geq 0$.

To preserve the whole complex cross term, apply the exact isometry $G_N^{1/2} : (E, G_N) \rightarrow (\mathbb{C}^q, I)$. Put $u = G_N^{1/2} b_N, v = G_N^{1/2} b_{N+1}$, and $z_N = u^* v = b_N^* G_N b_{N+1}$. The conjugated matrix is $(vu^* + uv^*)/\omega_N$. Its zero trace says $\Re z_N = 0$. Direct multiplication gives trace of its square equal to

$$\frac{2\|u\|^2\|v\|^2 + 2\Re(z_N^2)}{\omega_N^2} = \frac{2(\|u\|^2\|v\|^2 - |z_N|^2)}{\omega_N^2}.$$

This trace is also $2\epsilon_N^2$, including the zero-rank case. Consequently

$$\epsilon_N^2 = \frac{(b_N^* G_N b_N)(b_{N+1}^* G_N b_{N+1}) - |z_N|^2}{\omega_N^2}. \quad (\text{GR17})$$

The isometry does not assign a different metric to either source. The phase term remains present before every ensuing inequality.

87.0.6 4. The reflected generalized trace and its exact count

Let $E_{>} \subset E$ be the sum of all primary spaces with $\Re \lambda > k/2$, retaining every power in GR11. It is A -invariant. Let $P_{>}$ be its G_N -orthogonal projection. In $E_{>} \oplus E_{>}^{\perp G_N}$, the lower-left block of A vanishes. Taking the first diagonal block of $A^{\dagger G_N} + A - kI$ proves

$$\text{Tr}(P_{>} H_N) = 2\Re \text{Tr}(A|_{E_{>}}) - k \dim E_{>}. \quad (\text{GR18})$$

If $\epsilon_N > 0$, choose unit eigenvectors u_+, u_- at its two nonzero eigenvalues. Its spectral expansion gives $\text{Tr}(P_{>} H_N) = \epsilon_N \|P_{>} u_+\|^2 - \epsilon_N \|P_{>} u_-\|^2 \leq \epsilon_N$. If $\epsilon_N = 0$, the same trace is zero. This uses the actual orthogonal projection and does not silently identify it with a generally nonorthogonal algebraic spectral projector.

The exact count is

$$\sum_{a > k/2} (2a - k) = \left\lfloor \frac{(k+1)^2}{4} \right\rfloor. \quad (\text{GR19})$$

For $k = 2r$ it is $2 + 4 + \cdots + 2r = r(r+1)$; for $k = 2r+1$ it is $1 + 3 + \cdots + (2r+1) = (r+1)^2$. There are $k+1$ choices of imaginary margin and multiplicity ℓ_k at each center. Thus

$$L_k := \text{Tr}(P_{>} \mathbf{H}_N) = \frac{1}{2} \ell_k (k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor \leq \epsilon_N. \quad (\text{GR20})$$

The two parity formulas also prove $\lfloor (k+1)^2/4 \rfloor \geq k(k+1)/4$, so

$$L_k \geq kq_k/8 > 0. \quad (\text{GR21})$$

The trace retains the full generalized dimensions for every m .

87.0.7 5. Consecutive degrees and the separate first degree

For $N \geq q$, the update is $K_N = K_{N-1} + b_N b_N^* / \omega_N$. If $t = b_N^* G_{N-1} b_N / \omega_N \geq 0$, the determinant lemma gives $\delta_N := V_N / V_{N-1} = (1+t)^{-1} \in (0, 1]$. Multiplying the rank-one inverse formula verifies $b_N^* G_N b_N = \omega_N t / (1+t)$. The next determinant update uses this same G_N . Hence

$$\begin{aligned} b_N^* G_N b_N &= \omega_N (1 - \delta_N), \\ b_{N+1}^* G_N b_{N+1} &= \omega_{N+1} (\delta_{N+1}^{-1} - 1). \end{aligned} \quad (\text{GR22})$$

Substitution in GR17 yields

$$\epsilon_N^2 = \frac{\omega_{N+1}}{\omega_N} (1 - \delta_N) (\delta_{N+1}^{-1} - 1) - \frac{|z_N|^2}{\omega_N^2}. \quad (\text{GR23})$$

Because $0 \leq 1 - \delta_N \leq 1$ and $0 \leq \delta_{N+1}^{-1} - 1 \leq \delta_{N+1}^{-1}$, this gives

$$\epsilon_N^2 \leq \frac{\omega_{N+1}}{\omega_N} \frac{V_N}{V_{N+1}} = \frac{\Lambda_{N+1}}{\Lambda_N}, \quad \Lambda_N = \omega_N / V_N. \quad (\text{GR24})$$

At $N = q-1$, do not invert a preceding rank-deficient Gram. Expand the original monic relation

$$\chi = p_q + \sum_{j=0}^{q-1} \gamma_j p_j, \quad \nu_0 = \|\chi\|_\Gamma^2 = \omega_q + \sum_{j < q} |\gamma_j|^2 \omega_j. \quad (\text{GR25})$$

The degree- $(q-1)$ remainder map is an isomorphism, so its canonical metric satisfies $b_i^* G_{q-1} b_j = \delta_{ij} \omega_j$ for $i, j < q$. Reducing GR25 gives $b_q = -\sum_{j < q} \gamma_j b_j$. Therefore

$$\begin{aligned} b_{q-1}^* G_{q-1} b_{q-1} &= \omega_{q-1}, \\ b_q^* G_{q-1} b_q &= \nu_0 - \omega_q, \\ z_{q-1} &= -\gamma_{q-1} \omega_{q-1}, \\ V_q / V_{q-1} &= \omega_q / \nu_0. \end{aligned} \quad (\text{GR26})$$

The final equality is the forward determinant lemma at K_q . Substitution in GR17 proves the stronger exact endpoint identity

$$\begin{aligned} \epsilon_{q-1}^2 &= \frac{\sum_{j=0}^{q-2} |\gamma_j|^2 \omega_j}{\omega_{q-1}} \\ &= \frac{\nu_0 - \omega_q}{\omega_{q-1}} - |\gamma_{q-1}|^2 \\ &\leq \frac{\nu_0}{\omega_{q-1}} = \frac{\Lambda_q}{\Lambda_{q-1}}. \end{aligned} \quad (\text{GR27})$$

Thus delivered (41) is valid. No G_{q-2} , K_{q-2}^{-1} , or V_{q-2} is used. The endpoint phase term is present before the inequality.

87.0.8 6. Both windows and the literal constant

For either $i = q - 1$ or $i = q$, let $j = i + q$. For each $n = i, \dots, j - 1$, GR20 gives $L_k^2 \leq \epsilon_n^2$, and GR24 or its one initial instance GR27 gives $\epsilon_n^2 \leq \Lambda_{n+1}/\Lambda_n$. Multiplication of these q inequalities telescopes:

$$L_k^{2q} \leq \frac{\Lambda_j}{\Lambda_i} = \frac{\omega_j}{\omega_i} \frac{V_i}{V_j}. \quad (\text{GR28})$$

The indices in ω_j/ω_i are $n = i + 1, \dots, j$, all at most $2q$. Also $k \leq q$ by GR11. Every positive recurrence factor therefore satisfies

$$n(n + k/2 - 1) \leq 2q(2q + q/2 - 1) \leq 5q^2. \quad (\text{GR29})$$

Thus, cancelling the common mass only in the displayed ratio,

$$\frac{\omega_j}{\omega_i} = \prod_{n=i+1}^j n(n + k/2 - 1) \leq (5q^2)^q. \quad (\text{GR30})$$

Combining GR21, GR28, and GR30 yields, at each of the two windows,

$$\frac{V_i}{V_j} \geq \left(\frac{k}{8\sqrt{5}} \right)^{2q}, \quad \log(V_i/V_j) \geq 2q \log \left(\frac{k}{8\sqrt{5}} \right). \quad (\text{GR31})$$

Their final degrees are respectively $2q - 1$ and $2q$. Addition proves

$$\boxed{\mathcal{B}_k^\Gamma = \log \frac{V_{q-1}V_q}{V_{2q-1}V_{2q}} \geq 4q_k \log \left(\frac{k}{8\sqrt{5}} \right)}. \quad (\text{GR32})$$

When the right side is negative the inequality remains valid; the separate monotonicity $V_i/V_j \geq 1$ does not conflict with it. For $k > 1$, division by $q_k \log k$ gives $4 - 4 \log(8\sqrt{5})/\log k$, tending to four. This proves the claimed liminf for every fixed $m \geq 1$.

For centers $1/2 \pm \delta \pm i\gamma$ with fixed $\delta > 0, \gamma \neq 0$, the same occupation calculation is valid because both margins remain distinct. Its trace is $L = 2\delta\ell_k(k+1)\lfloor(k+1)^2/4\rfloor \geq \delta kq/2$. The identical two windows therefore give

$$\mathcal{B}_{h,k}^\Gamma \geq 4q_k \log \left(\frac{\delta k}{2\sqrt{5}} \right). \quad (\text{GR33})$$

This proves delivered (55) for its stipulated quartet geometry. It does not assert that an off-line zeta quartet exists.

The optional Gaussian comparison also checks exactly. Its mass and monic norms are 7^k and $7^k k^n n!$, so the ratio at index $n \leq 2q$ is $kn \leq 2kq$. The same $L \geq kq/8$ gives each window at least $q \log(kq/128)$. At $m = 1$, $q = (k+1)^2$, making this $3q \log k + q(2 \log(1 + 1/k) - \log 128)$. The combined liminf is at least six. The mass remains in each norm and cancels only from the ratio. This calibration does not change either the Gamma source or the original zeta source.

87.0.9 7. The actual arithmetic source and the exact determinant correction

Now fix an actual finite packet h of zeros of $g = 2\xi$ with its complete selected orders. Retain its actual cyclic polynomial $\chi = \chi_{h,k}$, quotient E , and full observation

$$\begin{aligned} \mathcal{V}_{h,k}P &= P(D_1 + \dots + D_k)F_h^{\otimes k}, & \mathcal{M}F_h &= g/h, \\ J^{(k)}\mathcal{V}_{h,k} &= \eta_{h,k}\pi_\chi, & \eta_{h,k}[P] &= v_h^{\otimes k}P(A_h^{(k)})1, & v_h &= j_h(g/h). \end{aligned} \quad (\text{GR34})$$

The actual amplitude and scalar norm observation are

$$\begin{aligned}
A_h(t) &= \frac{(g/h)(1/2 + it)}{\Gamma(1/4 + it/2)}, & B_h(t) &= |A_h(t)|^2, \\
w_h(t) &= B_h(t)r_{1/4}(t), & B_{h;k}(u) &= C_\Sigma(B_h^{\otimes k})(u), \\
m_{h,k}(u) &= r_{1/4,k}(u)B_{h;k}(u).
\end{aligned} \tag{GR35}$$

Here C_Σ is the original conditional integral on $u = t_1 + \cdots + t_k$, with denominator the actual fibre mass $r_{1/4,k}(u)$. Fubini proves the last equality by testing against an arbitrary nonnegative measurable function of that sum. The full complex amplitude multiplies the Gamma tensor amplitude before taking its squared norm; GR35 therefore does not replace that source vector or its phase by a real scalar.

At every degree $N \geq q - 1$, use the same monomial coefficient space $\mathcal{P}_N$, remainder map J_N , and relation injection

$$B_N : \mathcal{P}_{N-q} \longrightarrow \mathcal{P}_N, \quad Q \longmapsto \chi Q. \tag{GR36}$$

At $N = q - 1$, the domain is zero. Let $M_N^\Gamma, M_N^{\text{ar}}$ be the original two source Grams. Each is positive: Gamma has positive density; the nonzero entire function g/h vanishes at a discrete subset of the line, so no nonzero polynomial has zero arithmetic norm. The convolution retains positivity. Every moment is finite in the original source; for a quartet the proved $B_{h;k} \leq C_h^k$ and Gamma moments also prove finiteness.

The coefficient identity $I_N : P \mapsto P$, from $(\mathcal{P}_N, M_N^\Gamma)$ to $(\mathcal{P}_N, M_N^{\text{ar}})$, intertwines both J_N and B_N . Its induced quotient map is the identity on E with the two stated metrics.

Let R_N^Γ be the Gamma minimum section. Every arithmetic representative of a class v is uniquely $R_N^\Gamma v + B_N z$. Orthogonality to the arithmetic relation subspace gives $(B_N^* M_N^{\text{ar}} B_N)z = -B_N^* M_N^{\text{ar}} R_N^\Gamma v$. The relation Gram is positive on its actual domain. Thus

$$R_N^{\text{ar}} = R_N^\Gamma - B_N(B_N^* M_N^{\text{ar}} B_N)^{-1} B_N^* M_N^{\text{ar}} R_N^\Gamma. \tag{GR37}$$

At zero relation dimension, the inverse is the unique automorphism of the zero space; the composite is the zero map $E \rightarrow \mathcal{P}_N$. Applying the actual source map $\mathcal{V}_{h,k}$ to the difference gives an original relation and its theta primitive, while GR34 keeps the full arithmetic jet unchanged. This proves delivered (53) with its exact source, codomain, and original unit.

There is a full determinant formula. Define

$$L_N : E \oplus \mathcal{P}_{N-q} \longrightarrow \mathcal{P}_N, \quad ([P], Q) \longmapsto \text{rem}_\chi(P) + \chi Q. \tag{GR38}$$

In the ordered monomial bases, the first columns are $1, S, \dots, S^{q-1}$; each later χS^j has coefficient one at degree $q + j$ and zero above. The matrix is triangular with determinant one. Its inverse is monic polynomial division into the remainder and quotient. For either source Gram M , $L_N^* M L_N$ has lower-right block $H = B_N^* M B_N$. The triangular change of coefficients determined by GR37 completes the square, with determinant one, and its other diagonal block is the minimum quotient Gram G . Hence

$$\det M = (\det G)(\det H), \quad V_N = \frac{\det M_N}{\det(B_N^* M_N B_N)}. \tag{GR39}$$

At $N = q - 1$, the relation determinant is the empty determinant one. Therefore the positive quotient-volume correction $T_{k,N} = V_{k,N}^{\text{ar}}/V_{k,N}^\Gamma$ is exactly

$$T_{k,N} = \frac{\det M_N^{\text{ar}} \det(B_N^* M_N^\Gamma B_N)}{\det M_N^\Gamma \det(B_N^* M_N^{\text{ar}} B_N)}. \tag{GR40}$$

Taking the four literal endpoint ratios gives

$$\mathcal{B}_{h,k}^{\text{ar}} - \mathcal{B}_{h,k}^\Gamma = \log T_{k,q-1} + \log T_{k,q} - \log T_{k,2q-1} - \log T_{k,2q}. \tag{GR41}$$

This proves delivered (54). The final two minus signs are essential. An individual upper bound on each positive $T_{k,N}$ provides no lower bound for those denominator factors. On the reference itself, $B_{h;k} = 1$ is realized, all $T_{k,N} = 1$, and the correction is zero while GR32 holds. Positivity and the assertion that the multiplier is bounded, without other restrictions, include this reference calibration.

For the stipulated actual off-line quartet displacement $\delta > 0$, an arithmetic upper estimate $(4 - \varepsilon)q \log k$, together with the proved GR33, would force exactly

$$\log \frac{T_{k,q-1}T_{k,q}}{T_{k,2q-1}T_{k,2q}} \leq -\varepsilon q \log k - 4q \log \left(\frac{\delta}{2\sqrt{5}} \right). \quad (\text{GR42})$$

The last term supplies the complete constant represented by the delivered $O_h(q)$. This is the necessary consequence of the displayed estimates, not an assertion that the arithmetic upper estimate has been proved.

87.0.10 8. What this establishes about the broader program

For any monic test polynomial h_0 with centers in the open critical strip, the original theta source proves the exact quotient square

$$\begin{array}{ccc} V/h_0(D)V & \xrightarrow{\Theta} & \mathcal{B}/h_0(D)\mathcal{B} \\ j_{h_0}H \downarrow \wr & & \wr \downarrow j_{h_0}\mathcal{M} \\ E_{h_0} & \xrightarrow{\times j_{h_0}g} & E_{h_0}. \end{array} \quad (\text{GR43})$$

These are the full Taylor-jet maps. The original Euler inverses prove their kernels to be $h_0(D)V$ and $h_0(D)\mathcal{B}$; the seed $H_{P(D)\phi_*} = P$ gives source surjectivity, and the inverse Gram of the independent functions $y^j e^{\rho y}/j!$ against an interval bump gives target surjectivity. The literal identity $\mathcal{M}\Theta\phi = gH_\phi$ proves commutativity.

The associated exact sequence is

$$0 \longrightarrow Q[h_0(D)] \longrightarrow E_{h_0} \xrightarrow{\times j_{h_0}g} E_{h_0} \longrightarrow Q/h_0(D)Q \longrightarrow 0. \quad (\text{GR44})$$

Its first arrow has an explicit inverse on the kernel. If $h_0(D)[F] = 0$, write $h_0(D)F = \Theta\phi$, uniquely by theta injectivity, and send the class to $j_{h_0}H_\phi$. A change by a theta relation changes ϕ by $h_0(D)V$, proving well-definedness. Zero image permits $\phi = h_0(D)\psi$; injectivity of $h_0(D)$ on $\mathcal{B}$ gives $F = \Theta\psi$. Conversely, a polynomial representative P killed by $j_{h_0}g$ gives the class of $S_{h_0}^{\mathcal{B}}\Theta(P(D)\phi_*)$, defined by the original Euler inverse and the range identity. Changing P by h_0T changes this by $\Theta(T(D)\phi_*)$, so its class is independent and maps back to P . Quotienting the square proves the final cokernel statement.

For an actual full packet h , $j_h g = 0$, g/h is entire, and $j_h(g/h)$ is a unit because the exact zero orders were used. These are additional properties of the original source. They have not been established for h_* , and none is assumed in GR8–GR32. Choosing an invertible observation on a calibration model preserves its feasible coefficient sets; it does not identify that observation with the actual Taylor unit.

On each fixed support fibre, all the linear arrows above lift by $(\ell, v) \mapsto (\ell, fv)$, with $\tau \mapsto \tau$. The preimage of the supported zero is exactly $\{(\ell, v) : v \in \ker f\}$. In particular the support lift records the actual kernel of multiplication by $j_{h_0}g$; it does not replace that map by zero.

The Gamma obstruction invalidates the universal sub-threshold estimate using only the generic Gamma source and displayed quotient identities. When the same auxiliary purity is available for these calibration polynomials, adjoining that fact cannot restore this universal implication. The original arithmetic restrictions, full theta primitive, and signed correction GR41 remain present through the proved maps GR34–GR44. No result here states that all F1 geometry or split-base constructions fail, that the desired estimate for the actual arithmetic source is false, or that an off-critical zero of 2ξ exists.

87.0.11 9. Audit findings and verification scope

No correction is required to the Gamma constants, monic recurrence, full multiplicity q_k , reflected rank-two trace, first admitted degree, two consecutive windows, the $8\sqrt{5}$ constant, or the signs of the arithmetic correction. GR27 and GR40 expand portions of the supplied argument into explicit identities.

The delivered verifier's complete canonical-volume calculations are at $m = 1, k = 1$. Its separate repeated-primary check verifies a nonzero nilpotent with square zero. The all- m , all- k statement rests on the written proof GR9–GR33. Its negative-control flag rejects the scalar equality $3/4 = 1/2$; that flag alone does not replay or certify the full auxiliary-purity argument. These scope limits do not affect the proof above.

87.0.12 Appendix: Complete independent Gamma derivation

The following complete proof is appended from the pinned generating-function subreview. It preserves its equation labels G1–G28 and original measures.

87.0.13 Independent Gamma generating-function calculation

Date: 2026-09-13. Scope: the Gamma source, its exact mass and convolution, and the polynomial generating function and recurrence in equations (28), (29), (31), and (35) of the delivered `Tau_Deligne_Bound_Audit/NO TE.tex`. The source SHA-256 is `bfe63094ec360b6059f2936e5e456c6c0fd08db144bbabc29621a527b89c13c6`. The source remains unchanged. The quotient, trace, and determinant estimates are reviewed separately.

Finding. The printed generating function has linear coefficient $+x$, and its exponential generating coefficients are literally monic polynomials in x . The printed substitution produces literally monic polynomials in S , and produces the negative last term of recurrence (35). The constants and convolution mass in (28)–(29) are also correct. No sign or mass correction is required for these formulas.

The proof below retains the original density, coordinate $S = k/2 + ix$, positive integer k , and all factors of 2, i , and π . Euler's Beta integral is recorded in [DLMF 5.12.1](#) and [DLMF 5.12.3](#). The Fourier, convolution, and polynomial calculations here are derived explicitly from that integral.

87.0.14 1. Fourier transform of the unchanged Gamma density

Let $a > 0$, and define

$$r_a(x) = \frac{|\Gamma(a + ix/2)|^2}{2\pi}, \quad c_a = 2^{1-2a}\Gamma(2a), \quad x \in \mathbb{R}. \quad (\text{G1})$$

We use the convention

$$\mathcal{F}_+ f(t) = \int_{\mathbb{R}} f(x) e^{itx} dx. \quad (\text{G2})$$

The Beta identity with arguments $a + iu, a - iu$, followed by $v = e^y$, gives

$$\begin{aligned} \frac{\Gamma(a + iu)\Gamma(a - iu)}{\Gamma(2a)} &= \int_0^\infty \frac{v^{a+iu-1}}{(1+v)^{2a}} dv \\ &= \int_{\mathbb{R}} \frac{e^{ay}}{(1+e^y)^{2a}} e^{iuy} dy \\ &= \int_{\mathbb{R}} f_a(y) e^{iuy} dy, \quad f_a(y) = (2 \cosh(y/2))^{-2a}. \end{aligned} \quad (\text{G3})$$

The function f_a and all its derivatives decay exponentially as $y \rightarrow \pm\infty$. In particular, $f_a, f_a'' \in L^1(\mathbb{R})$; integration by parts twice shows that its Fourier transform is $O((1 + |u|)^{-2})$. Fourier inversion therefore applies as an absolutely convergent integral. Write the left side of (G3) as $F_a(u)$. Then

$$f_a(y) = \frac{1}{2\pi} \int_{\mathbb{R}} F_a(u) e^{-iuy} du. \quad (\text{G4})$$

Since $r_a(x) = \Gamma(2a)F_a(x/2)/(2\pi)$, the change of variables $x = 2u$ in the original density gives

$$\begin{aligned} \mathcal{F}_+ r_a(t) &= \frac{\Gamma(2a)}{\pi} \int_{\mathbb{R}} F_a(u) e^{2itu} du \\ &= 2\Gamma(2a)f_a(-2t) \\ &= 2\Gamma(2a)(2 \cosh t)^{-2a} = c_a(\cosh t)^{-2a}. \end{aligned} \quad (\text{G5})$$

Every integral used in (G5) is absolutely convergent. In particular, its value at $t = 0$ proves the original mass

$$\int_{\mathbb{R}} r_a(x) dx = c_a. \quad (\text{G6})$$

For later coefficient extraction we also prove the exponential moments, rather than assuming them. The expression $f_a(z) = (2 \cosh(z/2))^{-2a}$ has the analytic branch positive on the real axis throughout $|\operatorname{Im} z| < \pi$. For $|\sigma| < \pi$,

$$|\cosh((y + i\sigma)/2)|^2 = \sinh^2(y/2) + \cos^2(\sigma/2) \geq \cos^2(\sigma/2) \cosh^2(y/2). \quad (\text{G7})$$

Consequently $f_a(y + i\sigma)$ is integrable in y , uniformly when σ ranges in a closed smaller strip. The vertical sides of the contour rectangle in (G3) tend to zero because f_a decays exponentially in the real direction. Shifting the contour upward for $u \geq 0$ and downward for $u < 0$ therefore proves, for each $0 < \sigma < \pi$,

$$|F_a(u)| \leq e^{-\sigma|u|} \int_{\mathbb{R}} |f_a(y + i\sigma)| dy. \quad (\text{G8})$$

For $u < 0$ the integral along $-i\sigma$ has the same bound by conjugation. Inserting $u = x/2$ proves that $r_a(x)$ is bounded by a constant times $e^{-\sigma|x|/2}$. Thus every exponential moment of order strictly less than $\pi/2$ is finite. Both sides of (G5) extend holomorphically to $|\operatorname{Im} t| < \pi/2$; the right side uses the branch equal to the positive real value on the real axis. Equality on the real axis and the identity theorem imply

$$\int_{\mathbb{R}} e^{vx} r_a(x) dx = c_a (\cos v)^{-2a}, \quad v \in \mathbb{R}, \quad |v| < \pi/2. \quad (\text{G9})$$

This is the exact moment generating function of the density with mass c_a ; no mass has been divided out.

87.0.15 2. The k -fold convolution and its mass

Fix the original value $a = 1/4$. Since $\Gamma(1/2) = \sqrt{\pi}$, (G1) gives

$$c_{1/4} = 2^{1/2} \Gamma(1/2) = \sqrt{2\pi}. \quad (\text{G10})$$

For every positive integer k , the convolution theorem for the integrable functions in (G1) and formula (G5) give

$$\begin{aligned} \mathcal{F}_+(r_{1/4}^{*k})(t) &= c_{1/4}^k (\cosh t)^{-k/2} \\ &= \mathcal{F}_+ \left(\frac{c_{1/4}^k}{c_{k/4}} r_{k/4} \right) (t). \end{aligned} \quad (\text{G11})$$

Fourier uniqueness proves equality almost everywhere. The densities here are continuous: each r_a is continuous, bounded, and integrable, and convolution of an integrable function with a bounded uniformly continuous function is continuous. The required uniform continuity of r_a follows either from (G4) and the exponential estimate (G8), or directly by dominated differentiation there. Hence the equality holds at every real x :

$$r_{1/4,k}(x) = r_{1/4}^{*k}(x) = \frac{c_{1/4}^k}{c_{k/4}} \frac{|\Gamma(k/4 + ix/2)|^2}{2\pi}. \quad (\text{G12})$$

At $t = 0$, or by Tonelli's theorem in the original k variables,

$$\int_{\mathbb{R}} r_{1/4,k}(x) dx = c_{1/4}^k = (2\pi)^{k/2}. \quad (\text{G13})$$

These are exactly equations (28)–(29) of the delivered note, including the coefficient $c_{1/4}^k / c_{k/4}$.

87.0.16 3. The printed generating function has $+x$, not $-x$

The printed function is, for z near zero,

$$F_a(z, x) = (1 - iz)^{-a+ix/2} (1 + iz)^{-a-ix/2} = \sum_{n=0}^{\infty} b_n^{(a)}(x) \frac{z^n}{n!}. \quad (\text{G14})$$

Use the logarithms vanishing at $z = 0$. Their exact derivatives give

$$\begin{aligned}\partial_z \log F_a(z, x) &= \frac{(-a + ix/2)(-i)}{1 - iz} + \frac{(-a - ix/2)i}{1 + iz} \\ &= \frac{x - 2az}{1 + z^2}.\end{aligned}\tag{G15}$$

In particular $F_a(0, x) = 1$ and $\partial_z F_a(0, x) = x$. For real z near zero the same branches give the exact expression

$$F_a(z, x) = (1 + z^2)^{-a} \exp(x \arctan z).\tag{G16}$$

The sign in the exponential is positive because

$$\log(1 - iz) - \log(1 + iz) = -2i \arctan z, \quad \frac{ix}{2}(-2i \arctan z) = x \arctan z.\tag{G17}$$

Multiply the differential equation (G15) by F_a and compare the coefficient of $z^n/n!$. For $n \geq 1$, the coefficient contributed by $z^2 \partial_z F_a$ is $n(n-1)b_{n-1}^{(a)}$, and that contributed by $2azF_a$ is $2anb_{n-1}^{(a)}$. Therefore

$$b_0^{(a)} = 1, \quad b_1^{(a)} = x, \quad b_{n+1}^{(a)}(x) = xb_n^{(a)}(x) - n(n+2a-1)b_{n-1}^{(a)}(x).\tag{G18}$$

For $n = 0$, the same equation reads $b_1^{(a)} = xb_0^{(a)}$, with the last term omitted. Induction in (G18) proves that $b_n^{(a)} \in \mathbb{R}[x]$ has degree n and leading coefficient exactly 1. For example, the first values are

$$\begin{aligned}b_0^{(a)} &= 1, & b_1^{(a)} &= x, \\ b_2^{(a)} &= x^2 - 2a, & b_3^{(a)} &= x^3 - (6a+2)x.\end{aligned}\tag{G19}$$

Thus no replacement of z , x , or either exponent is needed to obtain monicity.

87.0.17 4. Exact orthogonality and norms

Take real z, w in a neighborhood of zero sufficiently small that $|\arctan z + \arctan w| < \pi/2$. Equations (G9) and (G16) give

$$\begin{aligned}\int_{\mathbb{R}} F_a(z, x) F_a(w, x) r_a(x) dx &= c_a (1 + z^2)^{-a} (1 + w^2)^{-a} (\cos(\arctan z + \arctan w))^{-2a} \\ &= c_a (1 - zw)^{-2a}.\end{aligned}\tag{G20}$$

The last equality uses the exact identity

$$\cos(\arctan z + \arctan w) = \frac{1 - zw}{\sqrt{1 + z^2} \sqrt{1 + w^2}}.\tag{G21}$$

On a sufficiently small closed complex bidisc around $z = w = 0$, the absolute value of the integrand in (G20) is bounded by a constant times $r_a(x)e^{v_0|x|}$ for some $v_0 < \pi/2$. This follows directly from the analytic logarithms in (G14). That dominating function is integrable by (G8). Consequently the integral is holomorphic on the open bidisc. The real identity (G20) extends there by applying the one-variable identity theorem first in z , then in w . Differentiation under the integral at zero is justified by Cauchy's formula and the same domination.

The coefficient of $z^n w^m$ on the left side of (G20) is

$$\frac{1}{n!m!} \int_{\mathbb{R}} b_n^{(a)}(x) b_m^{(a)}(x) r_a(x) dx.$$

The binomial series on the right side is $c_a \sum_{j \geq 0} (2a)_j (zw)^j / j!$. Comparing coefficients yields

$$\int_{\mathbb{R}} b_n^{(a)}(x) b_m^{(a)}(x) r_a(x) dx = \mathbf{1}_{n=m} c_a n! (2a)_n.\tag{G22}$$

The polynomials have real coefficients, so (G22) is also their Hermitian orthogonality relation. In particular it is the norm of the original monic polynomial, with mass c_a retained.

87.0.18 5. Exact transport to $S = k/2 + ix$

Set $a = k/4$ and $c = k/2$. Define the polynomial in the original complex variable S by

$$p_n(S) = i^n b_n^{(k/4)}((S - c)/i). \quad (\text{G23})$$

The coefficient of S^n is $i^n i^{-n} = 1$; hence this is literally monic in S . The lower coefficients are obtained by the displayed affine substitution, with no change to the source norm or its mass. On the source line, $S = c + ix$, equation (G23) gives $p_n(c + ix) = i^n b_n^{(k/4)}(x)$. Therefore (G12) and (G22) imply

$$\begin{aligned} \int_{\mathbb{R}} \overline{p_n(c + ix)} p_m(c + ix) r_{1/4, k}(x) dx &= \frac{c_{1/4}^k}{c_{k/4}} (-i)^n i^m \int_{\mathbb{R}} b_n^{(k/4)}(x) b_m^{(k/4)}(x) r_{k/4}(x) dx \\ &= \mathbf{1}_{n=m} (2\pi)^{k/2} n! (k/2)_n. \end{aligned} \quad (\text{G24})$$

In the surviving term $m = n$, the phase is $(-i)^n i^n = 1$. This proves the exact norm $\omega_{k,n}^\Gamma$ printed in (35).

To transport the recurrence, multiply (G18), in its form $xb_n = b_{n+1} + n(n + 2a - 1)b_{n-1}$, by i^{n+1} . Since $S - c = ix$, the result is

$$\begin{aligned} (S - c)p_n(S) &= p_{n+1}(S) + n(n + k/2 - 1)i^{n+1}b_{n-1}^{(k/4)}((S - c)/i) \\ &= p_{n+1}(S) - n(n + k/2 - 1)p_{n-1}(S). \end{aligned} \quad (\text{G25})$$

The minus sign is exactly $i^{n+1}/i^{n-1} = i^2 = -1$. Restoring $c = k/2$ proves

$$Sp_n = p_{n+1} + \frac{k}{2}p_n - n(n + k/2 - 1)p_{n-1}, \quad \omega_{k,n}^\Gamma = (2\pi)^{k/2} n! (k/2)_n. \quad (\text{G26})$$

The last term is omitted at $n = 0$. The first polynomials in the original coordinate are

$$p_0 = 1, \quad p_1 = S - k/2, \quad p_2 = (S - k/2)^2 + k/2, \quad p_3 = (S - k/2)^3 + (3k/2 + 2)(S - k/2). \quad (\text{G27})$$

Finally, consecutive norm ratios retain the same constants before their displayed cancellation:

$$\frac{\omega_{k,n}^\Gamma}{\omega_{k,n-1}^\Gamma} = \frac{(2\pi)^{k/2} n! (k/2)_n}{(2\pi)^{k/2} (n-1)! (k/2)_{n-1}} = n(n + k/2 - 1), \quad n \geq 1. \quad (\text{G28})$$

This supplies precisely the coefficient needed for the interior cancellation following equation (36). The derivation establishes the Gamma formulas and their original polynomial coordinates; it does not by itself assert the later determinant bound or a comparison with the arithmetic theta source.

88 Complete Deligne comparison and its actual tau-base cohomology

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

88.0.1 Independent audit of the Deligne bound comparison

Date: 13 September 2026. This is a complete written review of the operator, coefficient, period, purity, and critical-kernel parts of the delivered Tau_Deligne_Bound_Audit/NOTE.tex. The complete note was read, including its Gamma argument; independent verification of the quantitative Gamma estimate belongs to the separate Gamma review. This document supplies full proofs for its new comparison statements. It preserves the delivered note unchanged.

88.0.2 Finding and precise scope

The delivered note proves a failure of a particular implication from auxiliary exponential Frobenius purity to the original arithmetic operator estimate. Its rank-one and reflection-stable counterexamples survive the review below. They do not prove failure of the Split-Zero or broader F1 geometry program. Their test polynomials are not known to be factors of the actual function $g = 2\xi$, and the exact arithmetic comparison records that difference by multiplication by $j_h g$.

Two narrow corrections are required in the exposition. The rank and trace statements attached to the Artin-Schreier equation must specify the nontrivial additive-character sheaf, or equivalently its character summand in the cover. The whole affine cover also has a degree-two compact-support contribution. Furthermore, vanishing of $j_{h_0} g$ and entire divisibility by h_0 do not require that every selected zero order be its full actual order; the extra full-order condition makes $j_{h_0}(g/h_0)$ a unit. Neither correction invalidates the exhibited operator counterexamples.

The strongest comparisons proved here include a complete classification of the possible pure-target intertwiners, with nilpotent lengths and exponential collisions retained; a universal observable quotient for each specified target Frobenius; and a tensor construction from the original arithmetic packet whose finite-field realization has the correct tensor weight k . The latter has an explicit injective complex period map retaining the original Taylor unit and sum action. Its existence prevents a failure of the simpler rank- q_k , weight-one auxiliary inference from being mistaken for failure of every geometric comparison.

88.0.3 1. The actual coefficient complex and its recovered operator

Retain the original monic annihilator

$$\chi(S) = S^q + \sum_{a=0}^{q-1} c_a S^a, \quad q > 0, \quad E = \mathbb{C}[S]/(\chi), \quad A = M_S,$$

and the specified potential

$$\Phi_t(S) = \frac{S^{q+1}}{q+1} + \sum_{a=0}^{q-1} \frac{c_a S^{a+1}}{a+1} - tS. \quad (\text{DP.1})$$

Let $B = \mathbb{C}[u, t]$. The two-term complex in degrees zero and one is

$$\mathcal{C} = [B[S] \xrightarrow{D} B[S]dS], \quad D(P) = (u\partial_S P + (\chi - t)P)dS. \quad (\text{DP.2})$$

For a nonzero polynomial P of degree n and leading coefficient b , the term of degree $n+q$ in $D(P)/dS$ is exactly bS^{n+q} . Every other term has smaller degree. Thus D is injective. For a polynomial Q of degree at least q , subtract the image under D/dS of its leading coefficient times $S^{\deg Q - q}$. The degree strictly decreases. The procedure terminates and writes $Q = D(P)/dS + R$ with $\deg R < q$. Uniqueness follows because a nonzero image has degree at least q . Consequently

$$B[S] = \text{im}(D/dS) \oplus \bigoplus_{b=0}^{q-1} BS^b, \quad H^0(\mathcal{C}) = 0, \quad \mathcal{H} = H^1(\mathcal{C}) \cong B^q. \quad (\text{DP.3})$$

This proves freeness over the displayed coefficient ring and its compatibility with every coefficient specialization. The special fibre at $(u, t) = (0, 0)$ is exactly E . No repeated root is removed.

On $u \neq 0$, put $\nabla_t = \partial_t - S/u$ on polynomial coefficients in both terms. Directly,

$$[\partial_t, D/dS] = -1, \quad [-S/u, u\partial_S] = 1, \quad [-S/u, \chi - t] = 0.$$

Their sum is zero, so ∇_t descends to $\mathcal{H}[u^{-1}]$. In the fixed increasing-power frame, reduction of $S \cdot S^{q-1} = S^q$ uses only $D(1) = (\chi - t)dS$; therefore the matrix is

$$\nabla_t = \partial_t - A(t)/u, \quad A(t) = A + t\mathcal{R}, \quad \mathcal{R} = 1_E \otimes \ell, \quad \ell[P] = [S^{q-1}] \text{rem}_\chi P. \quad (\text{DP.4})$$

The operator $-u\nabla_t = -u\partial_t + A(t)$ preserves $(u, t)\mathcal{H}$: its derivative on tv contributes $-uv$, which belongs to that ideal. Hence it induces precisely A on the special fibre. This is a regular operator specialization even though ∇_t itself has a pole. Multiplication by S on arbitrary representatives does not separately define an algebra structure on $\mathcal{H}$; the displayed connection and fixed-frame endomorphism give its exact replacement.

88.0.4 2. Rank-one periods, orientation, and the finite-field trace

For $\chi(S) = S - \lambda$, with $\lambda = 3/4$, the coefficient ring $\mathbb{Z}[1/2]$ contains every coefficient. Let $u > 0$, put $b = \lambda + t$, and first take b real. On the upward contour $S = ix$, $-\infty < x < \infty$,

$$\Pi_{\text{up}}(u, t) = i \int_{\mathbb{R}} e^{-x^2/(2u)} e^{-ibx/u} dx. \quad (\text{DP.5})$$

Write the real integral as $I(b)$. Differentiation is justified by a Gaussian bound. Integration by parts, whose endpoint terms vanish, gives

$$0 = \int_{\mathbb{R}} \partial_x (e^{-x^2/(2u)} e^{-ibx/u}) dx = -u^{-1} \int_{\mathbb{R}} x e^{-x^2/(2u)} e^{-ibx/u} dx - ibu^{-1} I(b).$$

Thus $I'(b) = -bI(b)/u$. The Gaussian value $I(0) = \sqrt{2\pi u}$, obtained by squaring the integral and using polar coordinates, yields

$$\Pi_{\text{up}} = i\sqrt{2\pi u} e^{-b^2/(2u)}, \quad -u \frac{\partial_t \Pi_{\text{up}}}{\Pi_{\text{up}}} = b, \quad |\Pi_{\text{up}}|^2 = 2\pi u e^{-b^2/u}. \quad (\text{DP.6})$$

Both sides of the unsquared period identity are entire in b : compact sets of complex b still admit an integrable Gaussian majorant. Hence the unsquared identity extends to complex t ; the last real norm formula is asserted only for real b .

For the inherited ray order, $d = 2$, $\theta_0 = \pi/2$, $\theta_1 = 3\pi/2$, and $\Gamma_1 = -\ell_0 + \ell_1$. Its path travels from $+i\infty$ to zero and then to $-i\infty$. Thus $\Gamma_{\text{up}} = -\Gamma_1$ as oriented chains and $\Pi_{\text{up}} = -\Pi_1$. The unsquared sign in the delivered note is correct.

Now fix a finite field $\mathbb{F}_Q$ of odd characteristic, a nontrivial complex additive character ψ , $u \in \mathbb{F}_Q^\times$, and $b \in \mathbb{F}_Q$. Translation $x \mapsto x + b$ is a bijection and gives

$$\sum_x \psi((x^2/2 - bx)/u) = \psi(-b^2/(2u)) G_Q(u), \quad G_Q(u) = \sum_x \psi(x^2/(2u)). \quad (\text{DP.7})$$

The character takes values in roots of unity, so its conjugate at y is its value at $-y$. The invertible coordinate change

$$(x, y) \mapsto (r, s) = (x - y, x + y), \quad (r, s) \mapsto ((s + r)/2, (s - r)/2)$$

therefore gives

$$|G_Q(u)|^2 = \sum_{r,s} \psi(rs/(2u)) = Q. \quad (\text{DP.8})$$

Indeed the inner sum is Q at $r = 0$. For $r \neq 0$, choose a with $\psi(ra/(2u)) \neq 1$; shifting s by a multiplies that inner sum by a number unequal to one, so the inner sum vanishes.

The cohomological object for this sum is

$$H_c^1(\mathbb{A}_{\mathbb{F}_Q}^1, \mathcal{L}_\psi((S^2/2 - bS)/u)). \quad (\text{DP.9})$$

With the geometric-Frobenius convention in the source, its trace is the negative of DP.7. The degree-two character-polynomial theorem makes DP.9 one-dimensional and all other compact cohomology of this **character sheaf** zero. Thus the sole Frobenius eigenvalue has modulus $\sqrt{Q}$, including its trace sign.

For precision about the cover, fix $\Psi : \mathbb{F}_p \rightarrow \overline{\mathbb{Q}}_\ell^\times$ and write a nontrivial ψ as $\Psi \circ \text{Tr}_{\mathbb{F}_Q/\mathbb{F}_p}(a \cdot)$, $a \neq 0$. The cover used for this summand is $Y^p - Y = af(S)$; alternatively fix $a = 1$ and the corresponding character. The finite étale pushforward from that cover decomposes by the character idempotents of its translation group $\mathbb{F}_p$. Its trivial summand is the constant sheaf on $\mathbb{A}^1$, whose H_c^2 is $\overline{\mathbb{Q}}_\ell(-1)$. Every nontrivial character summand has the type DP.9. Consequently the whole cover has an additional degree-two contribution, whereas DP.9 has the rank and alternating-trace sign used in the note. This is the required clarification of its equations (14) and (22)–(23).

Finally, on the recovered complex one-dimensional source $A = 3/4$, any positive scalar Gram G gives

$$A^*G + GA - G = \frac{1}{2}G. \quad (\text{DP.10})$$

This identity and DP.8 coexist in the same coefficient family. Hence the indicated coefficient specialization and period identity do not imply a vanishing arithmetic weight-one defect.

88.0.5 3. Primary-source hypotheses and the reflection-stable example

The local original Deligne scan was inspected visually on complete printed pages 215 and 216, including the theorem, its character-sheaf definition, and its family argument. The complete relevant S20 French text and the dated primary correction were also read. The primary bibliographic page was checked online: [Deligne, La conjecture de Weil II](#).

The theorem used is Weil II (3.7.2.3): for a degree- d polynomial in n variables, $p \nmid d$, and smooth leading projective hypersurface, the associated nontrivial additive-character sheaf has compact cohomology concentrated in degree n , of dimension $(d-1)^n$, pure of weight n . The parameter sheaves are lisse by (3.7.3). Its propagation argument uses mixedness as well as lissity in (1.8.12). In (3.7.4) the final reference is Roman **I.8.11**. This audit does not claim a fresh proof of Deligne's theorem or a visual rereading of all Weil II pages.

For DP.1, $n = 1$, $d = q + 1$, and $u \neq 0$, the leading coefficient is exactly $1/(du)$. In $\mathbb{P}^0$, its zero scheme is empty because that coefficient is invertible. The empty scheme is smooth. Taking $p > d$ is stronger than the required $p \nmid d$ and retains all denominators. The lower critical points may collide; they do not alter this leading homogeneous hypothesis. Thus the stated theorem applies after each specified good coefficient reduction.

The proposed quartet polynomial is correct. With $x = S - 1/2$, its four factors have roots $x = \pm 1/4 \pm i$. Pairing conjugates at each real part gives

$$\begin{aligned} h_*(S) &= ((x - 1/4)^2 + 1)((x + 1/4)^2 + 1) \\ &= (x^2 + 17/16)^2 - x^2/4 \\ &= x^4 + (15/8)x^2 + 289/256. \end{aligned} \quad (\text{DP.11})$$

It is monic over $\mathbb{Z}[1/2]$, real, and invariant under $S \mapsto 1 - S$. Its roots have real parts $1/4, 3/4$, including both signs of their nonzero imaginary parts. Its degree-five potential has leading coefficient $1/5$. For all specified good reductions with $p > 5$, the previous theorem applies to its character sheaf and yields weight one. Thus reflection symmetry does not restore the failed operator implication. The statement does not assert that h_* divides 2ξ .

The exact translation proof in the retained source was also read in full. For $\chi_a(S) = \chi(S - a)$, $\Phi_a(S) = \Phi(S - a) - \Phi(-a)$, and $T_a P(X) = P(X + a)$, direct substitution gives the chain isomorphism and

$$T_a A_a T_a^{-1} = A + aI, \quad \Pi_a = f_a \Pi C_a, \quad f_a = e^{(-\Phi(-a) - ta)/u}. \quad (\text{DP.12})$$

The fixed-frame matrix $(C_a)_{rb} = \binom{b}{r} a^{b-r}$ for $r \leq b$ has inverse C_{-a} . The scalar is nonvanishing on $u \neq 0$ and is retained. For a holomorphic determinant-line metric multiplied by $|f_a|^{2p}$, the curvature change is $2p \partial \bar{\partial} \text{Re} \log f_a = 0$ locally; logarithm branches differ by constants and give the same derivative. The corresponding additive trace defect changes by $2p \text{Re} a$. The reflection-preserving DP.11 shows that the broader counterexample does not rely on changing the original reflection centre by DP.12.

88.0.6 4. Classification of all intertwiners to a specified pure target

Fix $Q > 1$, $a = \log Q > 0$, and a finite-dimensional complex vector space V with an invertible operator F . Let the source be the **original** cyclic algebra $E = \mathbb{C}[S]/(\chi)$, $A = M_S$, and $U = e^{aA}$. We classify

$$\mathcal{T} = \{T \in \text{Hom}_{\mathbb{C}}(E, V) : TU = FT\}. \quad (\text{DP.13})$$

Write $\chi = \prod_{\lambda} (S - \lambda)^{r_{\lambda}}$. The Chinese-remainder map, with the full powers, gives

$$E = \bigoplus_{\lambda} E_{\lambda}, \quad E_{\lambda} = \mathbb{C}[\epsilon_{\lambda}]/(\epsilon_{\lambda}^{r_{\lambda}}), \quad A|_{E_{\lambda}} = \lambda I + N_{\lambda}, \quad N_{\lambda} = M_{\epsilon_{\lambda}}. \quad (\text{DP.14})$$

Its inverse exists by Bezout: for each factor, the product of the other factors is a unit modulo that factor; multiply its inverse there and sum the resulting mutually orthogonal idempotent lifts. This retains every nilpotent power.

Let $V_{\mu} = \ker(F - \mu I)^{s_{\mu}}$ be a full primary summand of F , with s_{μ} any exponent at least its longest Jordan length. When $\mu = e^{a\lambda}$, define the nilpotent polynomial

$$L_{\mu} = \frac{1}{a} \sum_{j=1}^{s_{\mu}-1} \frac{(-1)^{j+1}}{j} (\mu^{-1}F - I)^j \quad \text{on } V_{\mu}. \quad (\text{DP.15})$$

The expression is independent of enlarging s_{μ} , because additional powers vanish. The formal identities $\log(\exp z) = z$ and $\exp(\log(1+z)) = 1+z$, valid in the formal power-series ring, become finite polynomial identities after substituting a nilpotent. Therefore

$$e^{aL_{\mu}} = \mu^{-1}F, \quad \frac{1}{a} \log(e^{aN_{\lambda}}) = N_{\lambda}. \quad (\text{DP.16})$$

The source satisfies $(U - e^{a\lambda})^{r_{\lambda}} = 0$ on E_{λ} . Intertwining carries this equation to $(F - e^{a\lambda})^{r_{\lambda}}T = 0$. Projection to any different target primary summand gives zero because $F - e^{a\lambda}$ is invertible there. Hence $T(E_{\lambda}) \subseteq V_{e^{a\lambda}}$, interpreted as zero if that primary summand is absent. Applying the logarithm polynomial to the intertwining equation proves

$$TN_{\lambda} = L_{e^{a\lambda}}T. \quad (\text{DP.17})$$

Conversely DP.17 implies the exponential intertwining by DP.16. Since 1_{λ} generates the source block under N_{λ} , every such map is determined by

$$v_{\lambda} = T(1_{\lambda}) \in \ker L_{e^{a\lambda}}^{r_{\lambda}}, \quad T\left(\sum_{j=0}^{r_{\lambda}-1} c_j \epsilon_{\lambda}^j\right) = \sum_{j=0}^{r_{\lambda}-1} c_j L_{e^{a\lambda}}^j v_{\lambda}. \quad (\text{DP.18})$$

These are inverse constructions. Consequently

$$\mathcal{T} \cong \bigoplus_{\lambda} \ker L_{e^{a\lambda}}^{r_{\lambda}}. \quad (\text{DP.19})$$

No injectivity of $\lambda \mapsto e^{a\lambda}$ is assumed. If two roots differ by $2\pi i n/a$, their source blocks have the same exponential eigenvalue and map independently into the same target primary space. Their images can overlap. Formula DP.18 retains those overlaps and therefore does not incorrectly identify the total kernel with the sum of the individual block kernels for an arbitrary fixed T .

If F is pure of weight k in its specified complex realization, every μ has modulus $Q^{k/2}$. For $\text{Re } \lambda \neq k/2$, $|e^{a\lambda}| = Q^{\text{Re } \lambda}$ differs, so that target primary space is absent. It follows that

$$E_{\text{off}} := \bigoplus_{\text{Re } \lambda \neq k/2} E_{\lambda} \subseteq \ker T \quad (T \in \mathcal{T}). \quad (\text{DP.20})$$

This proves the delivered note's off-critical annihilation including every generalized vector. Purity alone does not assert semisimplicity of F ; DP.15–DP.19 therefore retain all target nilpotents as well.

There is also an exact quotient visible to **all** such maps. Let d_μ be the largest Jordan length of F on V_μ , and set $d_\mu = 0$ when that summand is absent. The nilpotent L_μ has the same Jordan lengths as $F - \mu I$, because it is the latter times an invertible polynomial with nonzero constant coefficient $1/(a\mu)$. Put $b_\lambda = \min(r_\lambda, d_{e^{a\lambda}})$. Then

$$K_F := \bigcap_{T \in \mathcal{T}} \ker T = \bigoplus_{\lambda} \begin{pmatrix} \epsilon_\lambda^{b_\lambda} \\ \epsilon_\lambda^{r_\lambda} \end{pmatrix}. \quad (\text{DP.21})$$

To prove this, DP.18 makes every map kill $\epsilon_\lambda^{b_\lambda}$. Conversely choose a target Jordan chain of length $d = d_{e^{a\lambda}} > 0$. If $d \geq r_\lambda$, choose v of nilpotent length exactly r_λ within that chain; if $d < r_\lambda$, take a top vector of length d . The vectors $v, Lv, \dots, L^{b_\lambda-1}v$ are independent, so the map defined by this v has kernel exactly the displayed ideal in that source block. Set the other source-block maps to zero. This also proves DP.21 in the presence of exponential collisions. If $d = 0$, the displayed ideal is the entire source block.

The quotient has a canonical faithful realization in a pure target without choosing individual maps:

$$\text{ev} : E \longrightarrow \text{Hom}_{\mathbb{C}}(\mathcal{T}, V), \quad \text{ev}(x)(T) = T(x), \quad \ker \text{ev} = K_F. \quad (\text{DP.22})$$

The operator on its target is $F_{\text{out}}\phi = F \circ \phi$. For every T , $\text{ev}(Ux)(T) = T U x = F T x$, hence $\text{ev} U = F_{\text{out}} \text{ev}$. The target is a direct sum of $\dim \mathcal{T}$ copies of (V, F) , so it is pure of the same weight. Thus DP.22 induces an injection of E/K_F onto its actual image. This construction is the maximal quotient detected by all maps of the required type to the specified F . It supplies a complete typed relation rather than replacing a missing faithful map by an assertion of unrelatedness.

In particular, even a critical block can be invisible when its exponential eigenvalue is absent from F . A semisimple target has $d_\mu = 1$, so all higher critical nilpotents are killed by DP.21. A nonsemisimple pure target can preserve them up to its actual Jordan length. No reduction to simple zeros is justified by purity alone.

88.0.7 5. A weight-matched tensor construction from the original arithmetic packet

Let h be the original finite packet polynomial, with its full actual zero orders, and retain

$$E_h = \mathbb{C}[s]/(h), \quad A_h = M_s, \quad v_h = j_h(g/h), \quad g = 2\xi. \quad (\text{DP.23})$$

The original packet uses the product of its monic linear powers, so h is monic in this construction. If an earlier presentation carried a nonzero scalar leading factor, the ideal map is multiplication by that recorded scalar and the factor in g/h must be retained; no such factor is set to one here. Complete zero orders make v_h a unit in the actual finite algebra. Its inverse is $j_h(h/g)$, with the quotient analytically filled at every selected zero.

For the fixed tensor degree k , let

$$\mathcal{E}_k = E_h^{\otimes k}, \quad \mathcal{A}_k = \sum_{j=1}^k I^{\otimes(j-1)} \otimes A_h \otimes I^{\otimes(k-j)}, \quad v_k = 1_h^{\otimes k}. \quad (\text{DP.24})$$

Let $\chi_{h,k}$ be the original minimal annihilator of the cyclic vector v_k under $\mathcal{A}_k$. This is the sum polynomial already used in the source, with all its multiplicities. Polynomial evaluation gives the injective map

$$\iota_k : E_{h,k} = \mathbb{C}[S]/(\chi_{h,k}) \longrightarrow \mathcal{E}_k, \quad [P] \longmapsto P(\mathcal{A}_k)v_k. \quad (\text{DP.25})$$

Indeed its kernel in $\mathbb{C}[S]$ is the ideal generated by that minimal annihilator, proving injectivity on the displayed quotient. Multiplication by S gives $\mathcal{A}_k \iota_k = \iota_k A_k$, where $A_k = M_S$. Let $U_k = M_{v_h}^{\otimes k}$. Each tensor factor of this unit is a polynomial in the corresponding A_h ; hence U_k commutes with $\mathcal{A}_k$. It is invertible with inverse $M_{j_h(h/g)}^{\otimes k}$. Therefore

$$\eta_{h,k} = U_k \iota_k, \quad \mathcal{A}_k \eta_{h,k} = \eta_{h,k} A_k, \quad \eta_{h,k} \text{ is injective.} \quad (\text{DP.26})$$

This is precisely the original arithmetic inclusion. It retains the full Taylor unit rather than replacing it by a basis convention. At the source level the already defined original map satisfies

$$J^{(k)}\mathcal{V}_{h,k} = \eta_{h,k}\pi_{\chi_{h,k}}, \quad \mathcal{V}_{h,k}P = P(D_1 + \cdots + D_k)F_h^{\otimes k}, \quad \mathcal{M}F_h = g/h. \quad (\text{DP.27})$$

In particular the arithmetic source being embedded is the original one.

Apply DP.1–DP.4 to the original degree- d_h polynomial h , with independent parameters $t_1, \dots, t_k$ and the same nonzero parameter u . Tensor the resulting coefficient complexes over $\mathbb{C}[u, t_1, \dots, t_k]$. The total differential has the usual signs: on a homogeneous tensor it differentiates the j -th factor with sign $(-1)^{e_1 + \cdots + e_{j-1}}$, where $e_i \in \{0, 1\}$ are the preceding cochain degrees. The direct decomposition in DP.3 contracts each factor onto its free degree-one remainder module: its other summand is an isomorphism from its degree-zero module onto its own differential image. Tensoring these decompositions leaves exactly the tensor of the degree-one remainders in degree k ; every summand containing one of the isomorphism complexes is contracted using its inverse, with the same total-complex signs. Thus the tensor cohomology is free of rank d_h^k , concentrated in degree k , and its special fibre is $\mathcal{E}_k$.

The parameter connections commute on distinct factors. Their recovered sum is

$$\mathfrak{A} = -u \sum_{j=1}^k \nabla_{t_j} = -u \sum_{j=1}^k \partial_{t_j} + \sum_{j=1}^k A_h(t_j)^{[j]}, \quad \mathfrak{A} \bmod (u, t_1, \dots, t_k) = \mathcal{A}_k. \quad (\text{DP.28})$$

Here the bracket means insertion in that tensor factor. This is the sum, with no division by k .

Let $\Pi_h(u, t_j)$ be the full period matrix in the original ray ordering, including every unsquared phase. Fix $u \neq 0$ in a sector with the stated choice of $\arg u$; the labelled rays have angles $\theta_r = (\arg u + \pi)/(d_h + 1) + 2\pi r/(d_h + 1)$, and $\Gamma_r = -\ell_0 + \ell_r$, $1 \leq r \leq d_h$. Each t_j is an arbitrary complex parameter. Its invertibility follows directly as follows. At the monomial potential the (r, b) period is a nonzero Gamma/ray factor times $\zeta^{r(b+1)} - 1$, with $\zeta^{d_h+1} = 1$. A column dependence would give a polynomial of degree at most d_h vanishing at all $d_h + 1$ roots of unity, hence every coefficient is zero. Along a straight coefficient path the periods satisfy $\Pi' = \Pi B$, because integration of the image of DP.2 is an exact derivative and the endpoints vanish. Uniform domination by a negative leading exponential times a polynomial justifies each derivative. The adjugate determinant identity yields $(\det \Pi)' = (\text{Tr } B) \det \Pi$, so its initially nonzero determinant never vanishes. This argument includes repeated roots.

Consequently the map

$$\mathcal{P}_k(u, \mathbf{t}) = \Pi_h(u, t_1) \otimes \cdots \otimes \Pi_h(u, t_k) : \mathcal{E}_k \longrightarrow \mathbb{C}^{d_h^k} \quad (\text{DP.29})$$

is invertible, with inverse the tensor of the exact inverses. The original arithmetic cyclic source therefore has the explicit injective rectangular period map

$$P_{h,k}(u, \mathbf{t}) = \mathcal{P}_k(u, \mathbf{t})\eta_{h,k} : E_{h,k} \hookrightarrow \mathbb{C}^{d_h^k}. \quad (\text{DP.30})$$

Holding $\eta_{h,k}$ fixed in its original marked coordinates, the individual period equations and DP.26 give the exact first-order identity at $\mathbf{t} = 0$:

$$-u \sum_{j=1}^k \partial_{t_j} P_{h,k}(u, 0) = \mathcal{P}_k(u, 0)\mathcal{A}_k\eta_{h,k} = P_{h,k}(u, 0)\mathcal{A}_k. \quad (\text{DP.31})$$

The nilpotent blocks are retained because DP.30 is injective and DP.31 intertwines the displayed recovered action. No invariance of its image under all deformed $A_h(t_j)$, and no missing higher-order period identity, is assumed.

For any original finite-cutoff positive Gram $G_{k,N}$, put $P = P_{h,k}(u, 0)$ and $L = (P^*P)^{-1}P^*$. Then $LP = I$, and the concrete positive form on $\text{im } P$ is the restriction of $L^*G_{k,N}L$. Its pullback is

$$P^*L^*G_{k,N}LP = G_{k,N}. \quad (\text{DP.32})$$

The action on that image is PA_kL , and its control form pulls back to $A_k^*G_{k,N} + G_{k,N}A_k - kG_{k,N}$. Thus every original mass, source norm, and generalized defect is preserved by an actual metric-and-action map. The ambient form may be degenerate outside the image; no positive extension or orthogonal-complement invariance is asserted.

There is a finite coefficient model retaining this injection. Form the finitely generated subring of $\mathbb{C}$ containing the coefficients of h , $\chi_{h,k}$, v_h , its inverse, and the matrices in DP.25–DP.26, together with all denominators

$1/(d_h + 1)!$. Since $\eta_{h,k}$ has full column rank, choose one of its nonzero square maximal minors Δ and adjoin Δ^{-1} . Call the resulting ring $R_{h,k}$. The selected rows give a left inverse by their adjugate divided by Δ . Thus $\eta_{h,k}$ is a split injection over this very ring, and its action identity holds there because every entry is an element of its subring in $\mathbb{C}$ and the equality holds in $\mathbb{C}$.

For each specified reduction $R_{h,k} \rightarrow \mathbb{F}_Q$ with $p > d_h + 1$, the same matrices remain a split injection and intertwiner of the reduced coefficient algebras. Its reduced cyclic image is therefore isomorphic, through those matrices, to the literal quotient $\mathbb{F}_Q[S]/(\overline{\chi}_{h,k})$. Every nilpotent power of that reduced image is the corresponding power in this quotient, including any root collisions after reduction. The nonzero minor used for this particular finite construction has been inverted. This does not claim that every prime is allowed or that one localization works for unbounded k .

On the finite-field branch, form the **external product** of the k original one-variable nontrivial additive-character sheaves. The Künneth map for compact support identifies its degree- k cohomology, with product-coordinate orientation, with

$$\bigotimes_{j=1}^k H_c^1(\mathbb{A}_{\mathbb{F}_Q}^1, \mathcal{L}_\psi(\Phi_{h,t_j}/u)). \quad (\text{DP.33})$$

Each factor is concentrated in degree one and pure of weight one by the checked theorem. Thus DP.33 is concentrated in degree k , has rank d_h^k , and is pure of weight k : its Frobenius is the tensor product, whose eigenvalues are all products of the factor eigenvalues. To see the last assertion including nonsemisimple factors, triangularize each complex coefficient realization; the tensor basis makes the tensor product triangular, with precisely those products on its diagonal. Each product has modulus $(\sqrt{Q})^k$. The alternating trace sign is $(-1)^k$, agreeing with the product of the k one-variable negative trace signs.

The retained construction therefore has a weight-matched common coefficient span, with DP.28–DP.32 on its complex side and DP.33 on its finite-field side. The reduced finite coefficient injection is not, by its existence, a map into the separate ℓ -adic cohomology. A specified operator-compatible comparison with that target is governed exactly by DP.13–DP.22. This locates the remaining comparison inside an explicit surviving geometric construction, preserving the arithmetic input and tensor degree throughout.

88.0.8 5A. Placement inside the original cohomology program over the privileged tau point

The preceding tensor construction is now placed in the actual base program, using the complete original `Tau_Base_Cohomology_2026-09-12/NOTE.md`, read in full. It does not replace that base by a finite field.

Retain the original pointed blueprint

$$\mathbf{F}_{1,\tau} = \{\tau, 1\}, \quad \mathbf{b}_\tau = \text{Spec } \mathbf{F}_{1,\tau}, \quad j_R : \mathbf{F}_{1,\tau} \rightarrow B_R, \quad \tau \mapsto \tau, \quad 1 \mapsto 1_R^\bullet. \quad (\text{DB.1})$$

Its additive zero relation is that the empty sum represents τ ; no Boolean equation $1 + 1 = 1$ is introduced into this base. For each original nonzero ring R , B_R is the blueprint of $G(R) = \{\tau\} \sqcup R^\bullet$ with its original additive relations. A prime of B_R contains τ and does not contain the multiplicative identity. Its inverse image under j_R is therefore exactly $\{\tau\}$. This proves that the structural spectrum map lands at the single privileged point through the actual prime inverse-image map. The arithmetic map $p_R(\tau) = 0$, $p_R(r^\bullet) = r$, and the Boolean support map $b_R(\tau) = 0$, $b_R(r^\bullet) = 1$, remain attached. Their pair is injective, since support separates τ from every represented element and amplitude distinguishes represented elements. The map here is DB.1; the separate localization that forces $e_R = 1$ is not performed.

For a coefficient map $\varphi : R \rightarrow R'$, its split lift satisfies

$$G(\varphi)j_R = j_{R'}, \quad p_{R'}G(\varphi) = \varphi p_R, \quad b_{R'}G(\varphi) = b_R. \quad (\text{DB.2})$$

Each equality follows on τ and on each $r^\bullet$, the two exhaustive kinds of elements. Apply DB.2 to the maps from $R_{h,k}$ in DP.26–DP.33, to the complex coefficient realization, and to every specified finite-field reduction. All these diagrams remain over the same $\mathbf{b}_\tau$.

There is an exact categorical version for the linear fibres. For an R -module M , set $M^\tau = \{\tau\} \sqcup M^\bullet$, with

$$v^\bullet + w^\bullet = (v + w)^\bullet, \quad r^\bullet v^\bullet = (rv)^\bullet, \quad \tau + z = z, \quad \tau z = \tau, \quad r^\bullet \tau = \tau. \quad (\text{DB.3})$$

For an R -linear map $f : M \rightarrow N$, its lift sends τ to τ and $v^\bullet$ to $f(v)^\bullet$. This is $G(R)$ -linear by the two ordinary linearity identities and the rules for τ . Conversely, a $G(R)$ -linear map between these objects which preserves represented support restricts to a map $f : M \rightarrow N$. Its additive and scalar identities are exactly the original R -linear identities. Moreover its value on $0_M^\bullet = e_R v^\bullet$ is $0_N^\bullet$. Thus this gives a fully faithful equivalence with the category consisting of these split module objects and support-preserving maps.

In that category the zero morphism is the supported-zero map $v^\bullet \mapsto 0_N^\bullet$, with $\tau \mapsto \tau$. The zero object is $\{\tau, 0^\bullet\}$. These assertions follow either by the fully faithful correspondence or directly from DB.3: each zero-object arrow preserving support is forced, and composition through it gives exactly that supported-zero map. Consequently the original equation $d^{i+1}d^i = 0$ is carried to the correct supported-zero composition, preserving the separate absorbing element. This supplies the precise linear-fibre category in which the original support cohomology is reconstructed. With the several masks of the source, apply it at each admitted mask and retain all inclusion transports; do not tensor the masks as if they were unrecorded vector coordinates.

Now retain the actual chart poset

$$+ < \eta < \sigma, \quad - < \eta < \sigma, \quad \mathcal{A} = \text{Fun}(P, \text{Vect}_{\mathbb{C}}), \quad (\text{DB.4})$$

and the actual coefficient sheaf

$$\mathcal{T}_+ = \mathcal{T}_- = V, \quad \mathcal{T}_\eta = \mathcal{B}, \quad \mathcal{T}_\sigma = 0, \quad r_+ = \Theta, \quad r_- = \Theta\mathcal{F} = J\Theta. \quad (\text{DB.5})$$

The J in DB.5 is the original reflection $JF(x) = x^{-1}F(1/x)$; the finite jet map below is written J_Z . Let $P_x(y) = \mathbb{C}$ for $x \leq y$ and zero otherwise. Evaluation gives $\text{Hom}(P_x, F) = F_x$, hence these diagrams are projective. The sequence

$$0 \rightarrow P_\eta \xrightarrow{v \mapsto (v, -v)} P_+ \oplus P_- \xrightarrow{(u, v) \mapsto u+v} \mathbb{C} \rightarrow 0 \quad (\text{DB.6})$$

is exact: at $+$ and $-$ its last map is the identity, and at η and σ its kernel is exactly the displayed anti-diagonal. Each map commutes with the poset arrows because its entries are the same scalar identity at all nonzero stalks. Applying $\text{Hom}(-, F)$ proves

$$\mathbf{A}_\tau(F) = R\Gamma(P, F) \simeq [F_+ \oplus F_- \xrightarrow{r_+ - r_-} F_\eta]. \quad (\text{DB.7})$$

On DB.5 this is the original two-leg theta complex. Its degree-zero kernel consists of $(\hat{\psi}, \psi)$, since Θ is injective, and its degree-one quotient is Q . This identifies the actual arithmetic cohomology over the privileged base point. Restriction to the σ stalk is a separate map: its two degree-zero representatives $r_{+\sigma}x$ and $r_{-\sigma}y$ differ by $r_{\eta\sigma}(r_+x - r_-y)$, so the homotopy is exactly $r_{\eta\sigma}$. This proves its derived comparison to DB.7 without replacing global cohomology by the support stalk.

Define $I_x(W)(y) = W$ for $y \leq x$ and zero otherwise. The identity $\text{Hom}(F, I_x W) = \text{Hom}(F_x, W)$ and exactness of evaluation show that each is injective over $\mathbb{C}$. Dualizing DB.6 gives

$$K_\tau(W) = [I_\eta W \xrightarrow{(+\text{res}, -\text{res})} I_+ W \oplus I_- W] \quad \text{in degrees } -1, 0. \quad (\text{DB.8})$$

Applying $\text{Hom}(F, -)$ gives the explicit differential $\ell \mapsto (\ell r_+, -\ell r_-)$, which is the dual of DB.7. This proves its stated adjunction to $\mathbf{A}_\tau$. The stalk complexes at $+$, $-$ are $[W \xrightarrow{1} W]$ and $[W \xrightarrow{-1} W]$, so they are acyclic; at η the sole term is W in degree -1 , and at σ all terms vanish. Thus $K_\tau(W) \simeq S_\eta W[1]$, with the exact inherited shift.

Tensor DB.6 over $\mathbb{C}$ in the fixed factor order to resolve the constant diagram on P^k . Its differential is the signed sum with sign $(-1)^{\sum_{i < j} e_i}$. In top degree the actual coefficient numerator is $\mathcal{B}^{\otimes k}$, and the boundary subspace is the sum of tensors with ΘV in at least one factor. Quotienting one factor at a time proves, by the defining relations of the tensor quotient,

$$H^k \mathbf{A}_{\tau, k}(\mathcal{T}^{\boxtimes k}) = Q^{\otimes k}, \quad K_{\tau, k}(W) \simeq S_{(\eta, \dots, \eta)} W[k]. \quad (\text{DB.9})$$

The second identity follows by the same dual tensor resolution: any stalk with at least one $+$ or $-$ factor contains its signed two-term identity contraction, any σ factor gives zero, and the all- η stalk has exactly W in degree $-k$. This proves the product right-adjoint calculation with its signs and no deleted cohomological shift.

Use the actual full-jet map $J_Z : \mathcal{B} \rightarrow E_h$. Since $\mathcal{M}\Theta\phi = gH_\phi$, its jets vanish through every full selected zero order; only holomorphy in neighborhoods of those selected zeros in the strip is required here. The map with component J_Z at η and zero at the other stalks is therefore a sheaf map $\mathcal{T} \rightarrow S_\eta E_h$. Its tensor product gives the actual top-cohomology arrow

$$\mathcal{J}_k : H^k \mathbf{A}_{\tau,k}(\mathcal{T}^{\boxtimes k}) = Q^{\otimes k} \longrightarrow \mathcal{E}_k, \quad \mathcal{J}_k = \overline{\mathcal{J}}_Z^{\otimes k}. \quad (\text{DB.10})$$

It is surjective because $\overline{\mathcal{J}}_Z \sigma_Z = I$ in the original full-order packet; tensoring that explicit right inverse gives a right inverse of DB.10. Compose the other way with the original cyclic inclusion to obtain the arithmetic split pair

$$\sigma_Z^{\otimes k} \eta_{h,k} : E_{h,k} \hookrightarrow Q^{\otimes k}, \quad \mathcal{J}_k \sigma_Z^{\otimes k} \eta_{h,k} = \eta_{h,k}. \quad (\text{DB.11})$$

Thus DP.30 is the period realization of the actual cyclic submodule of this tau-base cohomology: the map is $\mathcal{P}_k \mathcal{J}_k$ restricted through DB.11. The units in $\eta_{h,k}$, the full jets, and the original cochain representative boundaries are all present. On top cohomology the scaling action is $U_a^{\otimes k}$; its exact intertwining through DB.10 and DB.11 is $e^{(\log a) \mathcal{A}_k} \eta_{h,k} = \eta_{h,k} e^{(\log a) A_k}$. This follows from DP.26 by the convergent exponential series, or by its finite nilpotent expansions on each block.

The original right-adjoint dual injection also extends to this cyclic module. For the original reflection-stable packet Z , let R_Z be the full residue form from the tau-base note,

$$R_Z(f, v) = \sum_{\rho \in Z} \text{Res}_\rho \frac{f^\dagger(s) v(s)}{g(s)} ds, \quad f^\dagger(s) = \overline{f(1 - \bar{s})}. \quad (\text{DB.12})$$

Its local denominator is the actual $g = z^m u(z)$, $u(0) \neq 0$. Multiplication by u^{-1} is an invertible triangular Taylor map; extracting the coefficient of z^{m-1} pairs powers z^j, z^{m-1-j} with nonzero anti-diagonal. Reflection sends the opposite block's z^j to $(-1)^j \bar{z}^j$ in coefficients. Hence this sesquilinear form is nondegenerate on the full finite direct sum, retaining all nilpotents and the exact reflection signs. Tensor its numerical values in the fixed order to get a nondegenerate sesquilinear pairing $R_Z^{\otimes k}$ on $\mathcal{E}_k$; the tensor Gram is the tensor of invertible Grams and has the tensor of their inverses. No phase is inserted to claim positivity. In particular the skew-Hermitian parity is retained as $(-1)^k$ under conjugate exchange.

Let $\mathcal{L}_k = \mathcal{L}_1^{\otimes k}$ be the original moment line, with scaling action a^k . Define

$$\begin{aligned} \mathcal{D}_{h,k} : \overline{E_{h,k}} &\longrightarrow H^{-k} R \text{Hom}_{\mathcal{A}(P^k)}(\mathcal{T}^{\boxtimes k}, K_{\tau,k}(\mathcal{L}_k)) \\ &\cong \text{Hom}_{\mathbb{C}}(Q^{\otimes k}, \mathcal{L}_k), \\ \mathcal{D}_{h,k}(\bar{x})(q) &= R_Z^{\otimes k}(\eta_{h,k} x, \mathcal{J}_k q). \end{aligned} \quad (\text{DB.13})$$

The displayed cohomological identification follows from the adjunction DB.8–DB.9: over the field, taking the algebraic dual is exact, so degree $-k$ is the dual of top degree k . The formula is linear in $\bar{x}$. It is well-defined on $Q^{\otimes k}$ because DB.10 is, including every theta relation. If it vanishes for all q , surjectivity of DB.10 and nondegeneracy of the tensor residue form imply $\eta_{h,k} x = 0$; injectivity of DP.26 then implies $x = 0$. Thus DB.13 is an actual injection to the computed tau-base dual object.

For real $a > 0$, the original scaling multiplier satisfies $(a^s)^\dagger = a^{1-s}$. Multiplying the two factors in DB.12 therefore gives exactly a , so $R_Z(U_a f, U_a v) = a R_Z(f, v)$, including the full Taylor expansions. Tensoring gives the factor a^k . On the algebraic dual the action is $(U_a \ell)(q) = a^k \ell(U_a^{-\otimes k} q)$. It follows by direct substitution in DB.13 that this injection is equivariant with the conjugate of the original cyclic scaling action. This proves the tensor counterpart of the original tau-base note's (43), with $K_{\tau,k}$ and the correct moment line, rather than leaving the pairing outside the cohomological model.

Finally, each nonempty original support mask retains its copy of the coefficient complex and each transport retains its stated linear map. Reconstructing them by DB.3 gives the supported degree-one object $\{\tau\} \sqcup \coprod_{A \neq \emptyset} \{A\} \times Q$ and the original tensor supported cohomology. All maps DB.10–DB.13 preserve the admitted mask; a zero amplitude maps to that mask's supported zero and external absence maps to τ . The dual mask arrows are precomposition in the opposite mask category, as in the original note. This completes the placement of the weight-matched auxiliary tensor comparison **inside** the actual split cohomology program over $\mathfrak{b}_\tau$.

88.0.9 6. Original critical-line comparison and the retained kernel

The complete local proof of the critical-only comparison and of the arbitrary-polynomial theta sequence is supplied in the companion `deligne_bound_critical_kernel_subreview_20260913.md`. Its sources were read in full independently. The exact sequence from the original theta complex is

$$0 \longrightarrow Q[h_0(D)] \longrightarrow E_{h_0} \xrightarrow{\times j_{h_0} g} E_{h_0} \longrightarrow Q/h_0(D)Q \longrightarrow 0. \quad (\text{DP.34})$$

The first arrow sends a class represented by F , with $h_0(D)F = \Theta\phi$, to $j_{h_0}H_\phi$. It is independent of the representative because changing F by $\Theta\psi$ changes ϕ by $h_0(D)\psi$. The source and target Euler inverse formulas in `arithmetic_input.tex` show that this arrow identifies $Q[h_0(D)]$ with the kernel of the displayed multiplication. The target jet map identifies its cokernel with $Q/h_0(D)Q$. This retains the exact theta source, not an arbitrary test spectral model.

At a selected centre, write $\epsilon = s - \rho$, $h_0 = \epsilon^n a$, $g = \epsilon^m u$, with $a(\rho)u(\rho) \neq 0$, and $r = \min(n, m)$; when $g(\rho) \neq 0$, set $m = r = 0$. In $\mathbb{C}[\epsilon]/\epsilon^n$, multiplication by $j_{h_0}g$ has kernel $(\epsilon^{n-r})/(\epsilon^n)$ and cokernel $\mathbb{C}[\epsilon]/\epsilon^r$. Indeed the factor u is invertible and multiplication by ϵ^m has precisely these kernel and image ideals. These formulas prove that vanishing occurs whenever $n \leq m$, including undercounted orders. Exact full order $n = m$ makes $g/h_0 = u/a$ a unit; it is that unit which appears in DP.23 and the full packet retraction. The precise local map from the kernel to the quotient, through the original cohomology, is proved in the companion, so that no equality between two different jet presentations is presumed here.

For a full actual packet Z , the existing Connes comparison has

$$T_Z = \Gamma\sigma_Z : E_Z \longrightarrow \mathcal{S}(\mathbb{R})/\overline{\zeta(1/2 + it)\mathcal{S}(\mathbb{R})}, \quad \ker T_Z = E_{Z, \text{off}}. \quad (\text{DP.35})$$

The full higher-jet inverse on the selected critical blocks identifies its actual image with $E_{Z, \text{crit}}$. Thus DP.35 yields an exact equivariant sequence

$$0 \longrightarrow E_{Z, \text{off}} \longrightarrow E_Z \xrightarrow{T_Z} \text{im } T_Z \longrightarrow 0, \quad (\text{DP.36})$$

with the canonical primary splitting of its source. Its two-term comparison complex $[E_Z \xrightarrow{T_Z} \text{im } T_Z]$, in degrees zero and one, has degree-zero cohomology $E_{Z, \text{off}}$ and degree-one cohomology zero. The inclusion of the kernel in degree zero is therefore a quasi-isomorphism. If the full target is retained instead, degree-one cohomology is its quotient by $\text{im } T_Z$; it must not be silently set to zero. This is an exact derived record of everything killed by the critical comparison.

For any receiving vector-space fibre labelled by λ , the split lift of a linear map is

$$\tilde{T}(\tau) = \tau, \quad \tilde{T}(\lambda, v) = (\lambda, Tv). \quad (\text{DP.37})$$

The preimages are exactly

$$\tilde{T}^{-1}\{(\lambda, 0)\} = \{(\lambda, v) : v \in \ker T\}, \quad \tilde{T}^{-1}\{\tau\} = \{\tau\}. \quad (\text{DP.38})$$

Consequently DP.35 retains its full off-critical kernel as supported source vectors. The support observation distinguishes those vectors from external absence; it does not turn an annihilating linear map into an injection. At the same time DP.36 gives the precise surviving morphism and the complex that records the lost blocks. That is a structural continuation of the program, not a refutation of it.

88.0.10 7. Acceptance and the next exact arithmetic calculation

Equations (12)–(13), (17)–(24), (26)–(27), and (44)–(50) of the delivered note have the stated mathematical scope after the character-summand clarification. The note's full-order sentence following (57) needs the distinction proved in DP.34. Its quantitative Gamma estimate is covered by the separate independent Gamma review; this document does not convert a full reading of that section into an independent numerical or all- k certificate.

The note's period congruence is exact: with a common invertible Π , $\tilde{G} = \Pi^{-*}G\Pi^{-1}$ and $\tilde{W} = \Pi^{-*}W\Pi^{-1}$ give $\tilde{G}^{-1}\tilde{W} = \Pi(G^{-1}W)\Pi^{-1}$ by direct multiplication. In particular every generalized eigenvalue and every common-index determinant ratio is retained. This is consistent with the faithful tensor map DP.30 and the original theta relation DP.27.

The actual arithmetic multiplier still enters the two source metrics through their identity coefficient map and their different least-norm sections. Its signed endpoint determinant correction in delivered (54) remains an exact quantity in the program. The present audit neither assumes that correction is small nor replaces its calculation by a condition. It establishes the full comparison diagram that remains valid while that source-specific calculation proceeds.

The phrase “the F1 geometry program has failed” does not follow from this package. A defensible conclusion is: the displayed auxiliary purity, by itself and through the existing maps, does not force the desired original theta-source estimate. The exact failures and surviving maps have now been calculated, including a weight- k tensor construction and the complete target-dependent comparison kernel.

88.0.11 Source pins and actual reading record

The companion JSON records SHA-256, byte counts, and reading scope for every selected source, this review, and the independent critical-kernel proof. The new delivered note was read completely. `arithmetic_input.tex`, `Exponential_Translation_Comparison.tex`, and the primary correction were read completely. The SGA trace-period note was read from Sections 6 through 12, including all coefficient, period, tensor-weight, and metric formulas used above. The original Deligne scan was visually inspected on complete printed pages 215–216 only. The retained S20 text is a location aid; the original scan supplies the theorem typography.

No Lean invocation, remote mutation, whole-library audit, or numerical certification is claimed in this review.

89 The original tau-base weight line in the complete exponential reflection flow

89.0.1 The original tau-base weight line in the exponential reflection flow

13 September 2026. This is a calculation on the existing Split-Zero arithmetic construction, not a replacement finite-field model and not a weight estimate. It joins the original moment line in the tau-base right adjoint to an exact reflection and flow on the already constructed polynomial-exponential family. The finite transport identity extends through the special fibre even though the corresponding contour gauge contains an essential exponential in $1/u$.

89.0.2 1. Retained source and conventions

The controlling source is `Tau_Base_Cohomology_2026-09-12/NOTE.md`, SHA256 `d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3`. Its whole body was read. Sections 3–7 supply, respectively,

$$A_\tau(\mathcal{T}) = [V \oplus V \xrightarrow{\Theta(\phi-\hat{\psi})} \mathcal{B}], \quad H^1 = Q = \mathcal{B}/\Theta V, \quad K_\tau(W) \simeq S_\eta W[1]. \quad (\text{RW1})$$

The original action is $U_p F(x) = F(x/p)$. Its two source legs are $(U_p \phi, pU_{1/p} \psi)$, not two copies of U_p . Its Mellin multiplier is p^s . The actual second moment $\int \phi(x) dx$ has multiplier p ; its k -fold tensor is the specified line L_k with multiplier p^k . The dual action is consequently p^k times precomposition by U_p^{-1} . All these maps fix support masks and carry supported zero to supported zero, with external absence tau carried to tau.

Use an actual full quartet packet and its original cyclic tensor module,

$$E = \mathbb{C}[S]/(\chi), \quad q = \deg \chi, \quad A = M_S, \quad S = s_1 + \cdots + s_k. \quad (\text{RW2})$$

Here the retained quartet and its complete multiplicities give

$$\bar{\chi} = \chi, \quad \chi(k - S) = \varepsilon \chi(S), \quad \varepsilon = (-1)^q. \quad (\text{RW3})$$

Indeed complex conjugation and reflection permute the tensor-sum roots with their original multiplicities; the leading coefficient of the reflected monic degree- q polynomial is $(-1)^q$. This statement is about those actual symmetry-stable packets. It does not invent an off-line zero or discard a nilpotent direction. The arithmetic inclusion remains $\eta[P] = v_h^{\otimes k} P(A_h^{(k)})1$. In particular its full Taylor unit is not absorbed into a scalar or removed from the comparison.

The existing exponential family uses the antiderivative with $\Phi(0) = 0$,

$$\Phi' = \chi, \quad \Phi_t(S) = \Phi(S) - tS, \quad D_{u,t} = u\partial_S + \chi(S) - t, \quad \mathcal{H} = \text{coker } D_{u,t}. \quad (\text{RW4})$$

Leading-term division makes H free of rank q over $\mathbb{C}[u, t]$, with basis $1, S, \dots, S^{q-1}$. In that basis the already proved connection is

$$\nabla_t = \partial_t - \frac{A(t)}{u}, \quad A(t) = A + t\mathcal{R}, \quad \mathcal{R} = 1 \otimes \ell_{q-1}. \quad (\text{RW5})$$

The matrix $A(t)$ is multiplication by S in $\mathbb{C}[S]/(\chi - t)$ on these representatives. Multiplication by an arbitrary S -polynomial is not thereby asserted to descend to the full u -deformed differential cokernel. The connection and the chain maps below supply the actual descended operators.

89.0.3 2. Reflection is a cochain map of the actual family

Let $RP(S) = P(k - S)$ and

$$r(u, t) = (-\varepsilon u, \varepsilon t) = (u', t'). \quad (\text{RW6})$$

The matrix R on degree-below- q representatives has the explicit entries

$$R_{ij} = \begin{cases} \binom{j}{i} k^{j-i} (-1)^i & i \leq j, \\ 0 & i > j, \end{cases} \quad R^2 = I. \quad (\text{RW7})$$

For every polynomial P , differentiation and (RW3) give

$$D_{u', t'}(\varepsilon RP) = R(D_{u, t}P). \quad (\text{RW8})$$

In detail, the derivative term on the left is $(-\varepsilon u)\varepsilon(-RP') = uRP'$; its remaining term is $\varepsilon(\chi - \varepsilon t)RP = (\varepsilon\chi - t)RP$, which is exactly the reflected right side. Thus degree-zero map εR and degree-one map R give a cochain isomorphism, with its inverse given by the same reflection. This extends over $(u, t) = (0, 0)$, where it is the original polynomial reflection on E . Adding coefficient conjugation gives the actual dagger operation, with parameter map $(u, t) \mapsto (-\varepsilon \bar{u}, \varepsilon \bar{t})$.

On the companion matrices the same calculation is

$$RA(t)R = kI - A(\varepsilon t). \quad (\text{RW9})$$

This follows either by reducing $(k - S)P(k - S)$ modulo $\chi - \varepsilon t$, or by using the algebra isomorphism defined by (RW3). All entries and all repeated-root blocks remain; no diagonalization is used.

89.0.4 3. The weight twist is the original potential's constant, not a choice

Integrating (RW3) with the original endpoint gives

$$\Phi(k - S) = \Phi(k) - \varepsilon \Phi(S),$$

$$\boxed{\frac{\Phi_t(k - S)}{u} = \frac{\Phi_{\varepsilon t}(S)}{-\varepsilon u} + \frac{\Phi(k) - kt}{u}.} \quad (\text{RW10})$$

Neither $\Phi(k)$ nor k is set to zero. Pull the target connection back along r , keeping u fixed while differentiating t . Since $dt' = \varepsilon dt$,

$$r^*\nabla_t = \partial_t + \frac{A(\varepsilon t)}{u}, \quad (r^*\nabla_t)(Rv) - R\nabla_tv = \frac{k}{u}Rv. \quad (\text{RW11})$$

Consequently the exact horizontal map on $u \neq 0$ is

$$\boxed{\mathcal{F}(u, t) = \exp\left(\frac{\Phi(k) - kt}{u}\right) R.} \quad (\text{RW12})$$

Its logarithmic t -derivative is $-k/u$, so substituting (RW11) proves $(r^*\nabla)(\mathcal{F}v) = \mathcal{F}\nabla v$. This uses the full constant supplied by the original potential. It does not select a new norm on H .

For an oriented rapid-decay contour Γ , its reflected contour is the pushforward $\Gamma' = k - \Gamma$ with that orientation. The substitution $S_{\text{old}} = k - S_{\text{new}}$ has $dS_{\text{old}} = -dS_{\text{new}}$. Therefore the actual integrals satisfy

$$\int_{\Gamma} e^{\Phi_t(S)/u} P(S) dS = -\exp\left(\frac{\Phi(k) - kt}{u}\right) \int_{\Gamma'} e^{\Phi_{t'}(S)/u'} (RP)(S) dS. \quad (\text{RW13})$$

The minus sign is the one-form pullback. The constant exponential is retained. The exponential identity also carries the original decay along Γ to Γ' , so this substitution does not postulate a different contour class.

89.0.5 4. A regular finite flow identity through the special fibre

The scaling calculation computes the regular lift of forward theta dilation from $L = u\partial_t - S$. Its coefficient transport C_a is characterized by

$$\frac{d}{da} C_a(u, t) = -C_a(u, t) A(t + ua), \quad C_0 = I. \quad (\text{RW14})$$

This linear matrix equation, with polynomial coefficients, has a unique entire solution in a , depending holomorphically on u, t . Its local power series recursion is explicit. It obeys

$$C_{a+b}(u, t) = C_a(u, t) C_b(u, t + ua), \quad C_a^{-1}(u, t) = C_{-a}(u, t + ua). \quad (\text{RW15})$$

To prove the product law, differentiate its right side in b and compare its initial value at $b=0$ with C_{a+b} in (RW14). Uniqueness gives equality. In particular this finite transport is invertible even at $u=0$; there $C_a(0, t) = \exp(-aA(t))$.

Its reflection is the new exact formula

$$\boxed{RC_a(u, t)R = e^{-ka} C_{-a}(-\varepsilon u, \varepsilon t).} \quad (\text{RW16})$$

Proof: write the left side as B_a . By (RW9),

$$B'_a = -kB_a + B_a A(\varepsilon t + \varepsilon ua).$$

For $u' = -\varepsilon u$, $t' = \varepsilon t$, the derivative of $C_{-a}(u', t')$ is $C_{-a}(u', t') A(t' - u'a)$. Thus the right side of (RW16) obeys this same equation and has the same initial value I . This proves (RW16) for all parameters, without dividing by u . It is not an attempt to evaluate the singular exponential (RW12) at $u=0$.

Along $t \mapsto t + ua$, the ratio of the two full scalar factors in (RW12) is exactly $\exp(-ka)$. At $a = \log p$, forward theta dilation has moment line p^{-k} ; inverse dilation U_p has moment line p^k . Thus the very same factor appears both in the actual tau-base adjunction and in the exact exponential-family reflection flow. It is not a finite-field cardinality assigned to the absolute base point.

Specializing (RW16) gives the full arithmetic identity

$$Rp^{-A}R = p^{-k}p^A, \quad Rp^A R = p^k p^{-A}. \quad (\text{RW17})$$

Every block is retained:

$$p^{\pm A}|_{\lambda} = p^{\pm \lambda} \sum_{j=0}^{\ell_{\lambda}-1} \frac{(\pm \log p)^j}{j!} N_{\lambda}^j. \quad (\text{RW18})$$

89.0.6 5. The computed adjoint transport and its exact evaluation

On coefficient sections the scaling operator is semilinear: $T_a v(t) = C_a(u, t)v(t + ua)$. The k -fold moment line has $T_a^L z(t) = \exp(-ka)z(t + ua)$. Therefore the actual twisted dual is

$$\boxed{T_a^{\vee} \ell(t) = e^{-ka} C_a(u, t)^{-T} \ell(t + ua).} \quad (\text{RW19})$$

Substitution proves, with no omitted scalar,

$$(T_a^{\vee} \ell)(t)^T (T_a v)(t) = e^{-ka} \ell(t + ua)^T v(t + ua). \quad (\text{RW20})$$

The product rule (RW15) proves the composition law for (RW19). Its infinitesimal generator is

$$u \partial_t + A(t)^T - kI. \quad (\text{RW21})$$

At the actual special fibre and inverse dilation it becomes $p^k(p^A)^{-T}$. This is precisely the action obtained by applying the right adjoint $K_{(\tau, k)}(L_k)$ in the original source, then precomposing finite jet evaluation. In the conjugate packet, the source's dagger and residue pairing give its specified linear map to this twisted dual. No Hermitian positivity has been inferred from this bilinear calculation.

For completeness, the existing constant residue matrix

$$S_{ij} = [S^{-1}] \frac{S^{i+j}}{\chi(S) - t} = [S^{-1}] \frac{S^{i+j}}{\chi(S)} \quad (0 \leq i, j < q) \quad (\text{RW22})$$

has determinant $(-1)^{q(q-1)/2}$ and satisfies $A(t)^T S = SA(t)$. Its t -independence follows because the difference of the two fractions starts at degree at most S^{-2} . With $J = R^T S$, the computed two-parameter pairing identity is

$$\boxed{A(t)^T J + JA(\varepsilon t) = kJ.} \quad (\text{RW23})$$

Indeed transpose $RA(t) = (kI - A(\varepsilon t))R$ and apply the residue self-adjointness of $A(\varepsilon t)$. At $t=0$ this recovers the additive weight relation. For the actual arithmetic residue with denominator g , one must additionally retain the existing full unit $j_h(g/h)$ and the actual arithmetic inclusion eta ; the polynomial χ residue is not silently substituted for that pairing. No extension of that arithmetic unit as a globally invertible operator on every deformed fibre is claimed.

89.0.7 6. Position in Deligne's argument and in the current program

The printed primary text of Weil II, pp. 178, 202, 203 and 206, was read in the supplied S20 source-language records together with the existing primary-scan correction. In (3.3.5), the dual degree and Tate twist give $-n + (2N - i) - 2N = -n - i$. In (3.3.6), opposite bounds then constrain the image of the actual compact-support comparison. Page 203 (3.2.13) tensors the same eigenvalue with itself; its square is not replaced by an unspecified tensor constituent.

Our computation supplies a concrete part of the analogous tau-base diagram: the original moment-weight dual action has been transported through the exact exponential deformation and its reflection, including the full special-fibre blocks. It has not supplied Deligne's geometric upper weight bound for the theta quotient. The canonical arithmetic metrics G_N and their original relation volumes remain unchanged.

The next use of this result is to transport the original residue-dual map and its arithmetic norm comparison along this explicit flow; the factor and parameter shift are now calculated, so they need not be guessed or replaced by a generic purity assertion. The external-product construction and signed determinant calculation are the continuations on those two sides.

89.0.8 Provenance and verification scope

- Full controlling tau-base note as pinned above; no whole-paper Lean claim.
- Existing exponential delivery Tau_Deligne_Exponential_Comparison/RESEARCH_NOTE.md, section 7 (37)–(42), read in full for the constant residue duality; DS66–69 supply the previously constructed family and original theta map.
- The scaling calculation supplies the independent chain-level lift underlying (RW14). Formulas (RW6)–(RW13), (RW16), and their joining to the actual weight line are derived here, with their complete algebra above.
- Exact finite fixtures are supporting checks, not replacements for these general proofs. No new Lean execution, RH proof, or remote publication is claimed by this note.

90 Complete independent tau-base arithmetic determinant transport proof

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

90.0.1 Independent proof review: arithmetic determinant transport

Date: 13 September 2026. Review status: the mathematical statements AT1–AT22, including AT2a, are accepted on the corrected source pinned below. The first-pass proof-order issue in the explanation of AT6 has been repaired. This review retains the original Tau Base cohomology, arithmetic theta source, full Taylor unit, tensor sum coordinate, and both reference and arithmetic masses.

90.0.2 1. Sources and scope

The complete first-pass root source was read at SHA-256 41c7b45a0a94f0e65d422b213a4bcbddedbf983ab5127da6095e449e001fef98. Its corrected proof paragraph was then read completely. The accepted source is work/tau_arithmetic_determinant_transport_20260913.tex, 17706 bytes, SHA-256 24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae. No displayed formula changed between those editions.

The original dependencies checked directly were:

The Gamma norms, all-multiplicity quartet theorem, and exact original arithmetic comparison were independently proved in `work/deligne_bound_gamma_independent_review_20260913.md`, SHA-256 57069ebc4b4eab844d18d3bca9b4b7bd26cda138d9497fe3c126ee65bdfb9186. Its complete 72-equation proof remains a dependency of the application AT22. The section and variation proof for the present transport is given completely in RV6–RV11 below.

The exact finite fixtures described at the end exercise these transport formulas. They are calibration measures for the formulas; they do not assert values of arithmetic zeta moments or the existence of a selected zeta packet. No old suite, Lean process, or remote mutation is part of this review.

90.0.3 2. Original cohomology and the two separately typed injections

On the four-point chart $+, - < \eta < \sigma$, the original coefficient diagram is

$$(\mathcal{T}_+, \mathcal{T}_-, \mathcal{T}_\eta, \mathcal{T}_\sigma) = (V, V, \mathcal{B}, 0), \quad r_+ = \Theta, \quad r_- = J\Theta = \Theta\mathcal{F}. \quad (\text{RV1})$$

Here V is the original even Schwartz space with its value and integral zero, $\mathcal{B}$ is the original strong Schwartz space on the multiplicative line, $JF(x) = x^{-1}F(1/x)$, and $\mathcal{F}$ is the original Fourier transform. The diagram category is the declared linear-fibre realization of the Tau Base chart. At each chart point, the projective resolution

$$0 \rightarrow P_\eta \xrightarrow{v \mapsto (v, -v)} P_+ \oplus P_- \xrightarrow{(u, v) \mapsto u+v} \mathbf{C} \rightarrow 0 \quad (\text{RV2})$$

is exact: at $+$ and $-$, its last map is identity; at η and σ , its kernel is the displayed anti-diagonal. Applying its Hom complex to RV1 gives

$$\mathbf{A}_\tau(\mathcal{T}) = [V \oplus V \xrightarrow{\Theta(\phi - \hat{\psi})} \mathcal{B}]. \quad (\text{RV3})$$

Its degree-one image is exactly ΘV , so its degree-one cohomology is the original $Q = \mathcal{B}/\Theta V$. Tensoring the resolution uses the literal differential sign $(-1)^{\sum_{j < i} |x_j|}$. At top degree the source is $\mathcal{B}^{\otimes k}$, and the relation subspace is the sum of all tensors with ΘV in one factor. Tensoring the quotient maps over the field therefore identifies the top cohomology with $Q^{\otimes k}$. This proves the use of AT1 in the specified category, without replacing the pushforward by evaluation at the zero coefficient stalk σ .

For an actual full packet h , retain $E_h = \mathbb{C}[s]/(h)$, $v_h = j_h(g/h) \in E_h^\times$, $g = 2\xi$, and the actual F_h with Mellin transform g/h . The polynomial tensor algebra is $E_h^{\otimes k}$, its operator is multiplication by $S = s_1 + \cdots + s_k$, and its cyclic annihilator is the original $\chi = \chi_{h,k}$.

The injective algebra map $\alpha : E = \mathbb{C}[S]/(\chi) \rightarrow E_h^{\otimes k}$ sends $[P]$ to $P(A_h^{(k)})1$. Its kernel before quotienting is exactly the defining cyclic annihilator, proving injectivity. Multiplication by the full tensor unit has inverse multiplication by its inverse. Hence the first injection is

$$\eta = M_{v_h^{\otimes k}} \alpha : E \hookrightarrow E_h^{\otimes k}. \quad (\text{RV4})$$

It is a module map; multiplication by a unit is not being assigned the type of a unital algebra map. The original single-packet section $\sigma_h : E_h \hookrightarrow Q$ has a left inverse induced by its full arithmetic jet observation. Tensoring this left inverse proves that $\sigma_h^{\otimes k}$ remains injective. The separate cohomology injection is consequently

$$\sigma_h^{\otimes k} \eta : E \hookrightarrow Q^{\otimes k}. \quad (\text{RV5})$$

The two target spaces in RV4 and RV5 are carried by the explicit arrow $\sigma_h^{\otimes k}$; neither is substituted for the other. Applying the original source map $\mathcal{V}P = P(D_1 + \cdots + D_k)F_h^{\otimes k}$ gives exactly $J^{(k)}\mathcal{V}P = \eta[P]$ and $q^{(k)}\mathcal{V}P = \sigma_h^{\otimes k}\eta[P]$, as in AT2 and AT2a.

Every relation $\chi(S)P(S)$ has its original theta primitive. Indeed, the cyclic annihilator says it belongs to the tensor ideal $(h(s_1), \dots, h(s_k))$. Fixed-order monic division writes it as $\sum_i h(s_i)P_i(\mathbf{s})$. In factor i , replace F_h by ϕ_* , apply $P_i(D_1, \dots, D_k)$, and assign the primitive sign $(-1)^{i-1}$. The tensor differential supplies a second $(-1)^{i-1}$; their product is $+1$, and $h(D)F_h = \Theta\phi_*$ recovers the desired source relation. This checks that every variation below retains an actual top cochain boundary.

90.0.4 3. Finite source, zero relation space, and variations

Let $q = \deg \chi \geq 1$. For $N \geq q - 1$, use the original exact sequence

$$0 \rightarrow \mathcal{P}_{N-q} \xrightarrow{B_N = \times \chi} \mathcal{P}_N \xrightarrow{J_N} E \rightarrow 0 \quad (\text{RV6})$$

in increasing monomial frames, with the fixed remainder section s_N . Its coefficient maps do not depend on the real interpolation parameter t . The densities are precisely $m_0 = r_{1/4,k}$, of mass $(2\pi)^{k/2}$, and $m_1 = w_h^{*k}$, of mass μ_h^k , in $S = k/2 + iu$. Neither mass is changed.

Each source density is positive almost everywhere and has moments of every finite degree. For the arithmetic density, the zeros of the nonzero entire function g/h on a real line are discrete; at $k \geq 2$, its convolution preserves almost-everywhere positivity. A nonzero polynomial has only finitely many zeros on this line, so the two source Grams are positive definite. Their convex interpolation $M_N(t)$ remains positive definite on $0 \leq t \leq 1$. At a fixed finite degree, its eigenvalues have a positive lower bound on this compact interval. The relation $\text{Gram } H_N = B_N^* M_N B_N$ is positive on its actual domain by injectivity of B_N . These facts justify all finite differentiations, including a small open neighborhood of the interval.

The minimum section is $R = s - BH^{-1}B^*Ms$. Orthogonality gives $JR = I$, $B^*MR = 0$, and $G = R^*MR > 0$. To prove the inverse expression without presupposing it, decompose every vector $p \in \mathcal{P}_N$ uniquely as $By + RJp$. Then

$$R^*Mp = GJp, \quad MR = J^*G, \quad (JM^{-1}J^*)G = I. \quad (\text{RV7})$$

The last equality follows from $JR = I$; it proves $G = (JM^{-1}J^*)^{-1}$. This is the noncircular derivation now in the corrected AT6 proof.

The determinant-line sign is also retained. With $r = N - q + 1$, the increasing-degree matrix $[s \ B]$ is triangular with determinant one because χ is monic. Thus $[B \ s]$ has determinant $(-1)^{qr}$. The actual line map wedges the r relation vectors before the q quotient lifts. Replacing a lift by a relation leaves this wedge unchanged. Its Gram block Schur complement is G , so

$$\det H \det G = |(-1)^{qr}|^2 \det M = \det M, \quad V_N = \det G = \det M / \det H. \quad (\text{RV8})$$

At $r = 0$, the domain $\mathcal{P}_{-1}$ is zero, its determinant is one, and its unique endomorphism is invertible as a map from the zero space to itself. Every composite through that space has the zero map of its stated outer domain and codomain. The formula gives $R = s$, $G = s^*Ms$, and $V_N = \det M$; no earlier singular quotient Gram is inverted.

Differentiation of $JR = I$ shows that $\dot{R}$ lies in $\text{im } B$. Differentiation of $B^*MR = 0$ fixes its coefficient. Thus

$$\dot{R} = -BH^{-1}B^*\Delta MR, \quad \dot{G} = R^*\Delta MR, \quad \ddot{G} = -2R^*\Delta MBH^{-1}B^*\Delta MR. \quad (\text{RV9})$$

The two terms involving $\dot{R}$ vanish in the first derivative of R^*MR by orthogonality. In the next derivative they are the two equal displayed negative terms because ΔM is Hermitian. These identities prove AT7 and show that G is concave as an original Hermitian form.

Taking determinant derivatives in RV8, or directly in G , gives

$$\frac{d}{dt} \log V_N = \text{Tr}(M^{-1}\Delta M) - \text{Tr}(H^{-1}B^*\Delta MB) = \text{Tr}(G^{-1}R^*\Delta MR). \quad (\text{RV10})$$

The second derivative is exactly

$$\frac{d^2}{dt^2} \log V_N = -2\|H^{-1/2}B^* \Delta M R G^{-1/2}\|_{\text{HS}}^2 - \|G^{-1/2}\dot{G}G^{-1/2}\|_{\text{HS}}^2. \quad (\text{RV11})$$

Each square is for the indicated exact isometry of the original source forms. No term is removed in this identity. It proves AT8 and AT9, including the empty first square when $r = 0$.

Applying $\mathcal{V}$ to the relation-valued $\dot{R}$ gives the primitive constructed after RV5. The jet $J^{(k)}\mathcal{V}R = \eta$ and cohomology class $\sigma_h^{\otimes k}\eta$ are constant in t . On a fixed nonempty support label A , every such linear map lifts as $(A, v) \mapsto (A, fv)$, with $\tau \mapsto \tau$. Thus a nonzero relation vector can map to the supported zero while its energy in RV9–RV11 is retained. Its preimage is the whole source kernel on that label, not only the zero vector.

90.0.5 4. The exact common-source projection trace

Set $N_* = 2q$, and let $I_N : \mathcal{P}_N \hookrightarrow \mathcal{P}_{N_*}$ be the literal coefficient inclusion. In the common metric $M_* = M_{N_*}(t)$, define

$$\begin{aligned} P_N &= I_N M_N^{-1} I_N^* M_*, \\ Q_N &= I_N B_N H_N^{-1} B_N^* I_N^* M_*, \\ C &= M_*^{-1} \Delta M_*. \end{aligned} \quad (\text{RV12})$$

The first two are orthogonal projections with images $I_N \mathcal{P}_N$ and $I_N \text{im } B_N$. Substitution uses $I_N^* M_* I_N = M_N$ to verify idempotence and M_* -self-adjointness. Since the relation image lies in the polynomial image, $P_N Q_N = Q_N P_N = Q_N$. Thus $P_N - Q_N$ is the orthogonal projection onto $I_N R_N(E)$, with rank and trace q .

The cyclic trace computation has no omitted metric factor:

$$\begin{aligned} \text{Tr}(P_N C) &= \text{Tr}(M_N^{-1} I_N^* \Delta M_* I_N) = \text{Tr}(M_N^{-1} \Delta M_N), \\ \text{Tr}(Q_N C) &= \text{Tr}(H_N^{-1} B_N^* \Delta M_N B_N). \end{aligned} \quad (\text{RV13})$$

Combining these equalities with RV10 proves AT12.

For $i_0 = q - 1, i_1 = q, j_0 = 2q - 1, j_1 = 2q$, set

$$U = (Q_{j_0} - Q_{i_0}) + (Q_{j_1} - Q_{i_1}), \quad W = (P_{j_0} - P_{i_0}) + (P_{j_1} - P_{i_1}). \quad (\text{RV14})$$

For nested subspaces $X \subset Y$ of one Hilbert space, their orthogonal projections satisfy $P_X P_Y = P_Y P_X = P_X$; hence $P_Y - P_X$ is the projection onto $Y \cap X^\perp$. Each difference in RV14 is therefore a positive projection of rank q : the polynomial dimensions differ by q ; the relation dimensions $N - q + 1$, including zero at $q - 1$, also differ by q . Consequently

$$U \succeq 0, \quad W \succeq 0, \quad \text{Tr } U = \text{Tr } W = 2q. \quad (\text{RV15})$$

Their sums need not be idempotent, their two summands need not have orthogonal images, and no such assertion enters RV15. Subtracting the four exact traces in RV13 gives

$$\frac{d}{dt} \log \frac{V_{i_0} V_{i_1}}{V_{j_0} V_{j_1}} = \text{Tr}((U - W)C). \quad (\text{RV16})$$

All inverses are smooth and bounded on the parameter interval. Integrating proves AT15 with the exact arithmetic correction $\Delta \mathcal{B}$. The individual concavity in RV11 gives no sign to this four-term difference; RV16 is its complete signed expression.

90.0.6 5. Pointwise expression and arithmetic density zeros

The two orthogonal source images $\text{im } B_N$ and $\text{im } R_N$ decompose the whole finite polynomial space. Their projection formulas imply

$$M_N^{-1} = B_N H_N^{-1} B_N^* + R_N G_N^{-1} R_N^*. \quad (\text{RV17})$$

For example, multiplication on the right by M_N acts as identity separately on each of those two images, by orthogonality and their own Gram identities; it therefore acts as identity on their direct sum.

For $v_N(u) = (1, S(u), \dots, S(u)^N)$, evaluation of RV17 gives the exact nonnegative function

$$\begin{aligned} d_N(t, u) &= v_N M_N^{-1} v_N^* - |\chi(S(u))|^2 v_{N-q} H_N^{-1} v_{N-q}^* \\ &= v_N R_N G_N^{-1} R_N^* v_N^* \geq 0. \end{aligned} \quad (\text{RV18})$$

At $N = q - 1$ the relation term is absent and defined as zero. The factor $|\chi|^2$ follows from the actual evaluation identity $v_N B_N = \chi(S(u)) v_{N-q}$; it is not a replacement of the relation polynomial or its powers.

Integration against m_t yields $\int d_N m_t = \text{Tr}(G_N^{-1} R_N^* M_N R_N) = q$. Integration against Δm , using the original moment matrices, gives

$$\frac{d}{dt} \log V_N = \int d_N(t, u) \Delta m(u) du. \quad (\text{RV19})$$

Subtracting at the four endpoints and integrating t is exactly AT17. To justify both steps without any quotient of densities, note that $d_N(t, u)$ is a fixed finite-degree polynomial in $S(u)$ and $\overline{S(u)}$, whose coefficients are bounded for $0 \leq t \leq 1$. Its absolute value is bounded by a fixed constant times $1 + |u|^{2N^*}$. The inequality $|\Delta m| \leq m_0 + m_1$ and the two actual moment bounds prove absolute integrability on $[0, 1] \times \mathbb{R}$. Fubini applies. At a zero of m_1 , this expression is still an ordinary polynomial times a finite signed density; no division by m_1 appears. This proves the claimed zero-set and unbounded-ratio domains.

90.0.7 6. Spectral width and the condition number

The operator $D_* = M_*(0)^{-1} M_*(1)$ is positive and self-adjoint for the original $M_*(0)$ metric. Let $b_{\min}, b_{\max} > 0$ be its extreme eigenvalues. Factor the interpolated Gram in its stated matrix order:

$$M_*(t) = M_*(0)((1-t)I + tD_*), \quad C(t) = ((1-t)I + tD_*)^{-1}(D_* - I). \quad (\text{RV20})$$

No commutation of the two original Gram matrices is required for this factorization. The matrix on the right of $C(t)$ is a rational function of the single diagonalizable positive operator D_* . Its eigenvalue on a b -eigenvector is

$$c_b(t) = \frac{b-1}{1-t+tb}. \quad (\text{RV21})$$

The denominator is positive throughout the closed interval. Differentiating with respect to b gives $(1-t+tb)^{-2} > 0$, so the extrema are attained at the same $b_{\min}, b_{\max}$ for every t . Repeated eigenvalues cause no exception. The operator $C(t)$ is self-adjoint in $M_*(t)$ because $M_*(t)C(t) = \Delta M_*$ is Hermitian.

For any positive self-adjoint Z on that same Hilbert space,

$$c_{\min} \text{Tr } Z \leq \text{Tr}(ZC) \leq c_{\max} \text{Tr } Z.$$

Indeed $\text{Tr}(Z(c_{\max}I - C))$ is nonnegative: by cyclicity it is the trace of the positive matrix $Z^{1/2}(c_{\max}I - C)Z^{1/2}$. The lower bound is proved the same way. This does not require Z to commute with C . Applying it to RV15 and subtracting gives

$$|\text{Tr}((U - W)C)| \leq 2q(c_{\max} - c_{\min}). \quad (\text{RV22})$$

For $b > 0$, $c_b(t)$ is the derivative of $\log(1-t+tb)$. For $b = 1$, both are respectively zero and the constant zero logarithm, so the same integral gives $\log b = 0$. Hence

$$\int_0^1 (c_{\max} - c_{\min}) dt = \log b_{\max} - \log b_{\min} = \log \kappa_*, \quad \kappa_* = b_{\max}/b_{\min}. \quad (\text{RV23})$$

The triangle inequality for the real integral of RV16, followed by RV22–RV23, proves

$$|\Delta \mathcal{B}| \leq 2q \log \kappa_*. \quad (\text{RV24})$$

This confirms AT18–AT21 with the factor $2q$. The source data at $N_* = 2q$ are actual finite Gram data. No bound uniform in packet or tensor degree, and no pointwise upper or lower bound for m_1/m_0 , is used.

90.0.8 7. Mass and frame covariance

If $M_*(1) = cM_*(0)$ with its literal positive scalar c , every degree form is $(1-t+tc)M_N(0)$, and every minimum section remains the same. Its quotient form is $(1-t+tc)G_N(0)$, so its determinant is $(1-t+tc)^q V_N(0)$. The two numerator and two denominator factors in $\mathcal{B}(t)$ cancel exactly. Thus $\Delta\mathcal{B} = 0$, also implied by $\kappa_* = 1$. The separate original masses and determinant factors remain those displayed in these formulas.

For a precise source-frame arrow, let F carry new common-source coefficients to old coefficients. Then $M'_* = F^*M_*F$, $\Delta M'_* = F^*\Delta M_*F$, $D'_* = F^{-1}D_*F$, $C' = F^{-1}CF$, and every projection transforms as $P' = F^{-1}PF$ onto the correspondingly transported subspace. Its inclusion matrix is transported as $I'_N = F^{-1}I_N$ if the internal frame of $\mathcal{P}_N$ is unchanged. Products and traces are then identical by conjugacy. This includes nonunitary complex frames and frames mixing the displayed common-source degree coordinates, because the actual degree subspaces are transported with them.

Independently, let a fixed $Y : E_{\text{new}} \rightarrow E_{\text{old}}$ change the common quotient frame. Then $R'_N = R_N Y$, $G'_N = Y^*G_N Y$, and $V'_N = |\det Y|^2 V_N$, with the same factor for every N, t . That factor cancels from the four endpoint ratios. These explicit frame maps prove the covariance paragraph following AT21; they do not change the original source norms.

90.0.9 8. Original quartet application and scope

For the stipulated actual reflection-stable quartet $1/2 \pm \delta \pm i\gamma$, with $\delta > 0$, nonzero imaginary displacement, and complete common order m , the independent Gamma theorem retains

$$q = [1 + k(m-1)](k+1)^2, \quad \mathcal{B}_{h,k}^\Gamma \geq 4q \log \left(\frac{\delta k}{2\sqrt{5}} \right).$$

The exact arithmetic/reference comparison RV24 therefore yields

$$\mathcal{B}_{h,k}^{\text{ar}} \geq 4q \log \left(\frac{\delta k}{2\sqrt{5}} \right) - 2q \log \kappa_*. \quad (\text{RV25})$$

Since $2q > 0$, moving terms and dividing gives

$$\log \kappa_* \geq 2 \log \left(\frac{\delta k}{2\sqrt{5}} \right) - \frac{\mathcal{B}_{h,k}^{\text{ar}}}{2q}. \quad (\text{RV26})$$

Both are exactly AT22. They require no existence claim for such a packet. If the fixed packet restriction is invoked, its g/h , Taylor unit, theta primitive, and finite jet injection remain the original ones in RV4–RV6. In particular this is an analytic comparison on the original finite Tau Base complex with its action-compatible arithmetic observation, and does not replace it by a freely chosen polynomial.

The result computes a finite signed arithmetic term and bounds its magnitude using an actual relative Gram spectrum. It neither proves an arithmetic sub-threshold estimate nor draws a conclusion that the entire Tau Base or F1 geometry program has failed.

90.0.10 9. Exact finite fixtures and final review record

The independent fixture source and its exact JSON receipt are `work/tau_arithmetic_determinant_transport_exact_fixtures_20260913.py` and the same basename with `.json`. The calibration retains the literal original Gamma coordinate $S = 1/2 + iu$ and mass $\sqrt{2\pi}$, takes the test relation $\chi = S^2 - S + 3/16$, and compares that Gamma density with $(u^2 + u/3 + 2)m_0(u)$. This latter multiplier is positive since it is $(u + 1/6)^2 + 71/36$, and it is unbounded. Its mass is $5\sqrt{2\pi}/2$. The test relation is explicitly a calibration polynomial, not a zero-packet assertion.

The fixture tests the first empty relation domain and all four endpoints 1, 2, 3, 4 on cutoff 4. It checks the exact minimum section, relation orthogonality, full inverse splitting, Schur determinants, common-source traces, both positive-sum traces, and the signed four-endpoint identity at $t = 0, 1/3, 1$. It explicitly verifies that each sum U, W is not an idempotent and that neither commutes with C in this calibration, exercising two assumptions deliberately absent from the proof.

It also differentiates the exact inverse-kernel construction at the first nonzero relation space and checks both matrix variations and both nonzero logarithmic curvature losses. Omitting either loss is detected by a

nonzero exact residual. A second fixture rescales the source mass by $7/3$, checks every quotient scales by that literal scalar and the four-volume correction is zero, and verifies that the relative source operator is $(7/3)I$. A complex nonunitary frame change additionally verifies the exact similarity of D_* .

One initial harness comparison encountered an unevaluated symbolic zero written $0\sqrt{2}$. Its exact expression evaluator was repaired; no mathematical identity, hypothesis, or expected value was changed. The actual completed run and source hashes are recorded in the attached receipt. These finite checks supplement the written proof RV1–RV26; they do not prove its analytic moment facts by sampling.

The completed run passed 98 exact checks. Its fixture source SHA-256 is 8f29a721b8409708e3cc6e3b469cf35429743b3e19150fba467636d98085a497, and its JSON output SHA-256 is 367bb7b3c59e092e6b9ea9e444739d83bcf69701e0dd45545dc595f4bbfd67b6. It gives the exact nonzero correction

$$\exp(\Delta\mathcal{B}) = \frac{66206077200175080056805947}{54881827734195887080729255}. \quad (\text{RV27})$$

At $t = 1/3$, the positive relation contribution and the positive metric contribution whose negatives occur in RV11 are, respectively,

$$\frac{77593974624}{617198528867}, \quad \frac{88134062040620154}{21159417165147361}. \quad (\text{RV28})$$

Thus this execution checks the two distinct curvature terms with nonzero exact values. No rounding or interval approximation enters these fixture results.

The AT6 proof-order issue was resolved in the accepted source. No further mathematical correction was found. The complete written calculation in RV1–RV28 and the exact fixture receipt support the mathematical acceptance recorded here.

91 Actual tau-base scaling and its complete exponential cohomology flow

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

Exact revision. 8becda9f286ae37357589af9f85b5520a5981d4689a4d07c0e290e5265ee2304

91.0.1 Actual tau-base scaling and its exponential cohomology flow

Independent local calculation, 2026-09-13. The starting point is the specified $\mathbf{F}_{1,\tau}$ -based arithmetic cohomology, not a replacement finite-field geometry or localization at the generic support point. The construction below applies its actual theta action, full jet maps, right-adjoint pairing, and polynomial-exponential deformation. All source support masks, scalar factors, Taylor units, and multiplicities are retained.

91.0.2 1. Outcome: the existing arithmetic action has a concrete lift

The source already defines $U_p F(x) = F(x/p)$ over the absolute tau-base. It induces p^A on the full finite arithmetic quotient. The forward dilation $L_p F(x) = F(px) = U_{1/p} F(x)$ induces p^{-A} . Their exact finite block formulas, theta-boundary corrections, and tau-base dual maps are given below.

More than a fixed-basis operator is available on the existing exponential deformation. Write

$$D_{u,t} = u\partial_S + \chi(S) - t, \quad L = u\partial_t - S.$$

Then $[D_{u,t}, L] = 0$. The formal cochain automorphism

$$\exp(aL)P(u, t, S) = \exp(-aS)P(u, t + ua, S)$$

preserves the special-fibre ideal (u, t) and induces $\exp(-aA)$ there. On its finite free cohomology it has an entire, explicitly computed matrix $C_a(u, t)$; for $u \neq 0$ the actual oriented period matrices give

$$C_a(u, t) = \Pi(u, t)^{-1} \Pi(u, t + ua).$$

At $u = t = 0$, this is exactly p^{-A} when $a = \log p$. The inverse parameter $a = -\log p$ realizes the source's p^A . Thus the arithmetic scaling acts through the actual cohomological family with its full nilpotent coefficients. Formal polynomial complexes, evaluated finite matrices, and nonpolynomial contour integrands are distinguished below; no nonpolynomial expression is silently treated as a polynomial map.

The same reduced algebraic connection also supplies an explicit characteristic- r power operator, its r -curvature. The finite-field Artin-Schreier Frobenius and its character-twist map are computed in Section 7 as separate operations on the same potential data. This is a positive comparison of actual maps, not a generic failure argument about the tau-base program.

91.0.3 2. Dilation on the original source and both tau-base legs

Fix $p > 0$, $a = \log p$, and use the positive real logarithm. The source spaces are exactly those of arithmetic_inpt.tex, A1, and Tau_Base_Cohomology/NOTE.md, equations (10)–(14):

$$V = \{\text{even Schwartz } \phi : \phi(0) = 0, \int_{\mathbb{R}} \phi = 0\},$$

$$B = \{F : \sup_{x>0} x^b |D^j F(x)| < \infty \text{ for every } b \in \mathbb{Z} \text{ and } j \geq 0\}, \text{ with } D = -x\partial_x,$$

$$\Theta\phi(x) = 2 \sum_{n \geq 1} \phi(nx), MF(s) = \int_0^\infty F(x) x^s dx/x.$$

Let $L_p\phi(x) = \phi(px)$ and $L_p F(x) = F(px)$. Dilation preserves evenness, Schwartz regularity, and the two source moments:

$$(L_p\phi)(0) = \phi(0), \int L_p\phi = p^{-1} \int \phi.$$

For the target seminorms, $\sup x^b |D^j L_p F(x)| = p^{-b} \sup y^b |D^j F(y)|$. Thus these are continuous invertible source maps, with inverse $L_{1/p}$. Termwise theta evaluation and change of Mellin variable give

$$\Theta L_p = L_p \Theta, D L_p = L_p D, M L_p F(s) = p^{-s} M F(s).$$

The theta identity uses the original convergent series, including its factor two. The Mellin identity holds on the entire transform of B ; the source identity $H_{L_p\phi}(s) = p^{-s} H_\phi(s)$ follows on its specified strip from the same change of variables. Hence ΘV is stable and there is an induced invertible action on $Q = B/\Theta V$. The group law is literal: $L_p L_q = L_{pq}$.

The Fourier transform satisfies $\text{Fourier}(L_p\phi) = p^{-1} L_{1/p} \text{Fourier}(\phi)$. The tau-base joint pushforward is the two-leg complex

$$A_\tau(T) = [V_+ \oplus V_- \rightarrow B], d(\phi, \psi) = \Theta(\phi - \text{Fourier}(\psi)).$$

Its correct forward dilation is

$$(\phi, \psi) \rightarrow (L_p\phi, p^{-1} L_{1/p}\psi), F \rightarrow L_p F.$$

Indeed $\text{Fourier}(p^{-1} L_{1/p}\psi) = L_p \text{Fourier}(\psi)$, proving the cochain equality with both signs and the factor p^{-1} . On the original convention $U_p = L_{1/p}$, this becomes

$$(\phi, \psi) \rightarrow (U_p\phi, p U_{1/p}\psi), F \rightarrow U_p F,$$

exactly tau-base equations (32)–(35). The joint degree-zero cycle $(\text{Fourier}(\psi), \psi)$ is sent to the cycle indexed by $p U_{1/p}\psi$. The single-leg degree-zero groups stay zero.

These are actual sheaf automorphisms on the four-point chart model: the displayed maps act at $+$, $-$, η , and the identity acts on every support mask at σ . They commute with restriction, with support inclusions, and with the projective-resolution differential (18). Consequently they induce the stated action on $\text{R}\Gamma(P, T)$ over the actual one-point $\mathbf{F}_{1,\tau}$ base. No localization $G(R)[e^{-1}] = B_{\text{boolean}}$ is performed. The infinite scalar map $G(\mathbb{Z}) \rightarrow \mathbb{Z}$ remains in the original structural square.

91.0.4 3. Full jets, the Taylor unit, and an explicit source boundary

Full finite action For the original full-order packet polynomial h and full jet map $J_Z F = j_h M F$, let $A = M_s$ on $E_h = \mathbb{C}[s]/(h)$. Taylor expansion at a root ρ of its actual order m_ρ gives

$$j_\rho(p^{-s}) = p^{-\rho} \sum_{j=0}^{m_\rho-1} (-\log p)^j z_\rho^j / j!.$$

Therefore

$$J_Z L_p = F_p^- J_Z, F_p^- = p^{-A} = \exp(-(\log p)A).$$

On the block where $A = \rho I + N_\rho$, the entire matrix is

$$F_p^-|_\rho = p^{-\rho} \sum_{j=0}^{m_\rho-1} (-\log p)^j N_\rho^j / j!.$$

The inverse is $F_p^+ = p^A$ with all signs positive in the nilpotent sum. No Jordan level or exponential phase is dropped. Equivalently there is a unique degree-below-deg h Hermite remainder whose full jets are those of p^{-s} , and multiplication by that remainder is the same matrix. This is a linear module automorphism, not a claim that multiplying every class by a unit is a unital ring homomorphism.

The finite source/target square A8 has arrows $\times j_h g$. Multiplication by $j_h(p^{-s})$ commutes with this arrow. Dilation also commutes with $h(D)$ and its unique inverse on its range. Hence every map, kernel, and quotient in A7–10 is equivariant. In particular the original packet summand $Q[h(D)]$ and its complementary $h(D)Q$ remain distinct invariant subspaces with the same original projector.

Write $v = g/h$, $v = j_h v$, $\epsilon = v^{-1} = j_h(h/g)$. These are the full original Taylor units, not just their residue values. The specified representative is

$$R_{\text{ref}}x = S_h^B \Theta(R_Z(x)(D)\phi_*), R_Z(x) = \text{rem}_h(\epsilon x).$$

Since $j_h(p^{-s})$ commutes with both v and ϵ , the same unit remains in this representation after either dilation. In the cyclic tensor source the already specified inclusion

$$\eta[P] = v^{\otimes k} P(A_k)1, A_k = \sum_i A_i,$$

obeys $\exp(-aA_k)\eta = \eta \exp(-aA)$, where A is the original cyclic sum action on $\mathbb{C}[S]/(\chi_{h,k})$. This follows directly by commuting multiplication operators. The existing equivariant cyclic retraction has the same exponential intertwining. This is only the inherited tensor-source action, not a second construction of an external-product exponential family.

The boundary correction is an actual element of V A11 supplies the unchanged finite-rank defect

$$DR_{\text{ref}} - R_{\text{ref}}A = \Theta(\phi_*)\ell, \ell(x) = [s^{\deg h-1}]R_Z(x).$$

Define the finite-interval vector-valued integral

$$K_a x = - \int_0^a L_{\exp(a-r)} \phi_* \cdot \ell(\exp(-rA)x) dr.$$

Every integrand is in the original V ; dependence on r is smooth in its Schwartz topology, so the integral is in V , including for negative a with the usual oriented integral. Differentiate $L_{\exp(a-r)} R_{\text{ref}} \exp(-rA)$ with respect to r . Since the derivative of $L_{\exp(a-r)}$ is $DL_{\exp(a-r)}$, one obtains $L_{\exp(a-r)}(DR_{\text{ref}} - R_{\text{ref}}A) \exp(-rA)$. Integration from zero to a gives the exact sign and boundary formula

$$L_p R_{\text{ref}} - R_{\text{ref}} p^{-A} = \Theta K_{\log p}.$$

Its Mellin expression retains the entire unit and polynomial remainder:

$$H_{K_a x}(s) = [\exp(-as)R_Z(x)(s) - R_Z(\exp(-aA)x)(s)]/h(s).$$

The numerator has all zero jets required by h , because $R_Z = \text{rem}_h(\epsilon \times -)$ and the two finite multipliers commute. The expression is thus holomorphic at every selected root, with its full order. The integral, rather than divisibility alone, establishes that it is the transform of an admitted original V element.

In the exact extension coordinates $B_Z = \Theta V + R_{\text{ref}}E$, dilation is

$$(v, x) \rightarrow (L_p v + K_a x, p^{-A} x).$$

The complete cocycle identity is $K_{a+b} = L_{\exp a} K_b + K_a \exp(-bA)$. It follows by composing the displayed source action, or by splitting its integral. Thus the equivariant roof A13 is equivariant for this actual multiplicative group, not merely for its infinitesimal generator.

For any already specified representative r_N with $D^{(k)}r_N - r_N A = dK_N$, the identical finite-interval argument gives

$$\begin{aligned} L_p^{\otimes k} r_N - r_N p^{-A} \\ = -d \int_0^{\log p} L_{\exp(\log p - r)} K_N \exp(-rA) dr. \end{aligned}$$

Here dilation is the chain action on every term containing K_N ; its commutation with d is the tensor cochain rule. The correction remains an original relation with its specified primitive. The finite representative image need not be invariant as a subspace of the source.

91.0.5 4. Tau-base right adjoint and the existing holonomy observer

The tau-base note computes, with its original signs,

$$K_\tau(W) = [I_\eta(W) \rightarrow I_+(W) \oplus I_-(W)],$$

$$\text{in degrees } -1, 0, \text{ and } \text{RHom}(T, K_\tau(W)) = \text{RHom}(A_\tau(T), W).$$

The source's second-moment line L_1 has U_p action p , since $\int U_p \phi = p \int \phi$. Naturality of that right-adjoint

calculation gives the exact action on a dual functional

$$(U_p \ell)(v) = p \ell(U_p^{-1} v).$$

For forward dilation it is $p^{-1} \ell(L_p^{-1} v)$. This factor comes from the retained moment representation, not the cardinality of the absolute base. On finite coefficient duals the inverse-dilation action is p^{I-A^T} ; the forward action is $p^{-(I-A^T)}$.

The actual injection from the conjugate finite packet into the degree-minus-one right-adjoint cohomology is tau-base equation (43):

$$\bar{f} \mapsto [F] \mapsto \sum_{\rho} \text{Res}_{\rho} f^{\dagger}(s) M F(s) ds/g(s),$$

where $f^{\dagger}(s) = \overline{f(1-\bar{s})}$ retains the Taylor coefficient signs $(-1)^j$. Since $(p^s)^{\dagger} = p^{1-s}$,

$$R_Z(p^A f, p^A h) = p R_Z(f, h).$$

This proves equivariance with the just-computed dual action, at every nilpotent order. For forward dilation the factor is p^{-1} . Changing a source representative by $\Theta \phi$ adds a holomorphic residue, exactly as in the original right-adjoint construction.

The Taylor unit is visible in the residue join to the exponential special fibre. In the monic packet case $\chi = h$, let S_{χ} denote the full bilinear polynomial residue pairing with denominator χ . Then

$$R_Z(f, h) = S_{\chi}(f^{\dagger}, \epsilon h), \epsilon = j_h(h/g).$$

Indeed $1/g = (1/h)(1/v)$ locally, and multiplying by the complete jet ϵ leaves the same residues. Replacing this unit by its constant term would generally change the pairing on higher jets; no such replacement occurs here. The exponential special-fibre coefficient identification therefore receives the same finite packet and this exact unit-bearing pairing.

There is also a direct join to the already written sector holonomy. The original $L^2(dx)$ norm obeys $\|U_p F\|^2 = p \|F\|^2$. Hence $p^{-1/2} U_p$ is the normalized source dilation, and on an actual eigenvector at ρ its finite jet value is $p^{\rho-1/2}$. Including the source's retained unit phase ω gives exactly

$$z_{p,\omega}(\rho) = \omega p^{\rho-1/2}$$

in `split_zero_carriers.tex`, not merely an unrelated scalar analogy. Its full block extension is

$$\omega p^{\rho-1/2} \sum_{j < m_{\rho}} (\log p)^j N_{\rho}^j / j!.$$

For the original k-fold source the literal norm factor is p^k , and the corresponding normalization is $p^{-k/2} U_p^{\otimes k}$. This records an exact source isometry and its algebraic quotient map; it does not set an original finite canonical Gram equal to a new unitarizing metric. The source relation correction in Section 3 stays part of the comparison.

91.0.6 5. Exact cochain scaling flow on the original exponential family

Keep the original $\chi(S)$, all its coefficients, and the potential

$$\Phi_t(S) = S^{q+1}/(q+1) + \sum_{b=0}^{q-1} c_b S^{b+1}/(b+1) - tS.$$

DS66-69 and the original exponential note use the complex

$$C_{u,t} = [\mathbb{C}[u, t, S] \xrightarrow{D_{u,t}} \mathbb{C}[u, t, S] dS], D_{u,t} P = u P_S + (\chi - t) P.$$

Its differential is injective and has the unique degree-below-q remainder, by its monic leading term. Thus its first cohomology is free with the unchanged basis $1, S, \dots, S^{q-1}$, and its special fibre $u = t = 0$ is exactly $E = \mathbb{C}[S]/(\chi)$, with full multiplicities.

Define $L = u \partial_t - M_S$ on the coefficient in each cochain degree. The individual commutators are

$$[D, u \partial_t] = u I, [D, -M_S] = -u I.$$

They cancel, so $DL = LD$. In the formal a -adic completion over characteristic zero this proves that $\exp(aL)$ is a cochain automorphism with inverse $\exp(-aL)$. Since $u \partial_t$ commutes with M_S , each coefficient of its formal series is exactly that of

$$\exp(-aS) P(u, t + ua, S).$$

At every fixed order in a , only finitely many polynomial operations occur. The differential and this formula are therefore well defined on the formal completion; no analytic function has been substituted into the uncompleted polynomial ring. The map is semilinear for the base translation $t \rightarrow t + ua$, while u is fixed. The monic direct-sum reduction commutes coefficientwise with this formal completion, so its cohomology is the corresponding completed free rank-q module; no unproved interchange with an infinite quotient is involved.

The ideal (u, t) is stable: $L(uP)$ is a multiple of u , and $L(tP) = uP + tuP_t - tSP$ lies in (u, t) . Thus formal specialization gives $\exp(-aS)$ on the polynomial quotient, or precisely $\exp(-aA)$ on its finite coefficient module.

Entire finite-cohomology evaluation and the exact periods The descended generator in the retained basis is

$$L_H = u\partial_t - A(t), A(t) = A + tR, R = e_0 e_{q-1}^T.$$

For all complex u, t, a , define $C_a(u, t)$ by the finite matrix ODE

$$\partial_a C_a = -C_a A(t + ua), C_0 = I.$$

Its solution is entire in these parameters. One direct verification is the iterated-integral series: on any compact parameter set the coefficient matrix is bounded along the segment from 0 to a ; the n -th term is bounded by $(|a|M)^n/n!$. The series converges locally uniformly and differentiates to the ODE. Uniqueness follows by the same integral equation. Solving the reverse ODE gives its inverse, so this entire matrix is nonsingular.

The induced action on coefficient sections is

$$v(u, t) \rightarrow C_a(u, t)v(u, t + ua).$$

To check the generator, the ODE and parameter differentiation give $\partial_a C_a = u\partial_t C_a - A(t)C_a$; equivalently this follows from uniqueness of the differential equation for the flow. At $a = 0$ the derivative of the displayed section is exactly $u\partial_t v - A(t)v$. Uniqueness therefore identifies its Taylor series with the formal $\exp(aL_H)$ induced above. Alternatively for $u \neq 0$, the following period formula proves both differential identities directly, and their entire extension proves them at $u = 0$.

XD12 gives $\partial_t \Pi(u, t) = -\Pi(u, t)A(t)/u$. The actual periods are invertible, with their original ray orientations and monomial factors, by XD19–21. Therefore

$$\Pi(u, t)^{-1} \Pi(u, t + ua)$$

satisfies precisely the defining ODE and initial condition. This proves the formula in Section 1 and retains every period coefficient. It also gives the exact cocycle, first for $u \neq 0$ and then by entire continuation,

$$C_a(u, t)C_b(u, t + ua) = C_{a+b}(u, t).$$

At $u = 0$ the ODE is constant, so

$$C_a(0, t) = \exp(-aA(t)), C_{\log p}(0, 0) = p^{-A}.$$

In particular evaluation at $a = \log p$ is legitimate for this entire finite matrix, although the corresponding $\exp(-aS)$ is not a polynomial cochain map after numerical evaluation. This distinction is not removable by writing an exponential symbol alone.

At $u \neq 0$, an equally explicit contour identity is

$$\begin{aligned} & \int_{\Gamma} \exp(\Phi_t(S)/u) \exp(-aS) P(S) dS \\ &= \int_{\Gamma} \exp(\Phi_{t+ua}(S)/u) P(S) dS. \end{aligned}$$

Both integrals converge for every complex a : the original leading negative degree- $q + 1 \geq 2$ ray term dominates the additional linear exponent. Furthermore

$$D_{u,t}(\exp(-aS)P) = \exp(-aS)D_{u,t+ua}P.$$

This identity has the correct source direction: the multiplier takes relations at $t + ua$ to analytic integrands at t , not polynomial relations in an unchanged fibre. On the finite cohomology the actual map from the fibre at $t + ua$ to the fibre at t is $C_a(u, t)$. No quotient by all entire functions is used or asserted.

The distinction from a frozen endomorphism is exactly evaluable:

$$C_a(u, t) = I - aA(t) + a^2(A(t)^2 - uR)/2 + O(a^3).$$

The second derivative follows by differentiating its ODE once. Thus the first correction to $\exp(-aA(t))$ is $-a^2uR/2$. The residue map here is exactly the original coefficient map $R = e_0 e_{q-1}^T$, including $q = 1$; it is not discarded.

Fixed-fibre source-to-period action For any one already specified (u, t) with $u \neq 0$, the original coefficient comparison $E \rightarrow H_{u,t}$ and XD22 also transport the fixed original theta action to the concrete period-coordinate matrix

$$F_{p;u,t}^{\text{per}} = \Pi(u, t)p^{-A}\Pi(u, t)^{-1}.$$

Indeed $\Pi j_E L_p = F_{p;u,t}^{\text{per}} \Pi j_E$ on the admitted original test-function domain, using its full equivariant jet observation. The kernel is exactly $\ker j_E$; on the canonical representative image the inverse comparison is

$r_N \Pi^{-1}$. The difference of source representatives is the theta boundary computed in Section 3. This fixed-fibre conjugate and the base-translating $C_a(u, t)$ are both actual maps, with different domains. Their coincidence at the coefficient special fibre does not identify them elsewhere.

91.0.7 6. The existing logarithmic comparison receives the same action

DS31 defines $F_A = \sum_{j=0}^{q-1} A^j E_0$, with its actual invariant lattice $M_A = F_A O + EO(-D)$. Every polynomial in A , and therefore its finite-matrix exponential, preserves F_A and induces an operator on E/F_A . Hence the same $p^{\pm A}$ acts on the computed complex and its cohomology:

$$H^0(K_A) = F_A, \text{ action } p^{\pm A}|_{F_A};$$

$$H^2(K_A) = (E/F_A) \otimes T, \text{ action } p^{\pm \bar{A}} \otimes I_T.$$

The dual action for ordinary evaluation is the inverse transpose; the tau-base moment-line choice multiplies it by the retained p (or p^k on the inherited tensor moment line). Thus DS34's annihilator lattice and the full boundary quotient also carry these actions. The trace across the two retained groups is the trace of the original finite action, by a basis adapted to F_A .

For the global algebraic power-map discussion in this paragraph only, additionally restrict p to a positive integer; it need not be prime. On the characteristic-zero comparison curve, the separately existing parameter power map $z \rightarrow z^p$ then has the different explicit action $dz/z \rightarrow pdz/z$, and pulls divisor depth one to the integer depth p . It acts on the curve coordinate z , not the Mellin coordinate S or the original positive variable x . No global algebraic power map $z \rightarrow z^p$ is asserted for nonintegral real p . The theta dilations, full-jet actions $p^{\pm A}$, and finite exponential flow at $a = \log p$ retain their stated domains for every real $p > 0$; the integer restriction applies only to this separate curve map and its divisor-depth pullback.

91.0.8 7. Actual finite-field power maps of this same potential

This section applies the already specified coefficient realization in the original exponential note, equations (47)–(49), retaining its privileged characteristic-zero tau-base branch. Use r for residue characteristic to distinguish it from the positive theta-dilation parameter p , and put $Q = r^f$. The source ring is

$$R_0 = \mathbb{Z}[c_0, \dots, c_{q-1}, 1/(q+1)!] \subset \mathbb{C}.$$

Under any of the original specified maps $R_0 \rightarrow \mathbb{F}_Q$ with $r > q + 1$, the same polynomial differential and coefficient basis base-change literally. This is a map from R_0 , not a field map from $\mathbb{C}$. No value of the transcendental parameter $\log p$ is silently assigned a residue-field value.

A computed characteristic- r power operator from the connection Over the reduced coefficient ring, the polynomial derivation obeys $\partial_t^r = 0$: the r -th derivative of every monomial contains a product of r consecutive integers. Since $u\partial_t$ and M_S commute, their characteristic- r binomial expansion gives

$$(u\partial_t - M_S)^r = -M_{S^r}.$$

Moreover $[D_{u,t}, M_{S^r}] = r u M_{S^{r-1}} = 0$. Thus multiplication by S^r , unlike multiplication by S at nonzero u , genuinely descends to the reduced polynomial cohomology. This gives the following completely specified matrix in its original basis:

$$\Psi_r(\partial_t) = -u^{-r}(\text{red}_{u,t}(S^{r+b}))_{0 \leq b < q}.$$

The notation means column b is the indicated remainder vector. It is the r -curvature of $\nabla_t = \partial_t - S/u$, because the restricted r -th power of the base derivation is zero. Multiplying by $-u^r$ gives a regular coefficient endomorphism which at $u = t = 0$ is exactly A^r in the reduced full quotient. Every coefficient is obtained by the same monic reduction algorithm. This is a computed power map supplied by the actual deformation, without attempting to reduce an infinite exponential series with factorial denominators in characteristic r .

The cover Frobenius and the character-twist comparison For the source's specified $u_0 \neq 0, t_0$ in $\mathbb{F}_Q$, write

$$f_t(S) = (\Phi(S) - t_0 S)/u_0.$$

Its actual Artin–Schreier cover is

$$Y^r - Y = f_t(S).$$

The arithmetic Q -power operation on its geometric coordinates is $(S, Y) \rightarrow (S^Q, Y^Q)$. It preserves the cover because coefficients are in $\mathbb{F}_Q$ and $(Y^Q)^r - Y^Q = (Y^r - Y)^Q = f_t(S)^Q = f_t(S^Q)$. It commutes with

every deck transformation $Y \rightarrow Y + c$, $c \in \mathbb{F}_r$. The chosen additive-character eigensheaf is consequently stable. Geometric Frobenius uses the inverse Galois action convention, as fixed in the original DT.12–13 trace statement.

With that convention, its exact trace on the existing compact-support degree-one cohomology is

$$\mathrm{Tr}(\mathrm{Frob}_Q^n | H_c^1) = - \sum_{s \in \mathbb{F}_{Q^n}} \psi(\mathrm{Tr}_{\mathbb{F}_{Q^n}/\mathbb{F}_r} f_t(s)).$$

This follows from the trace formula with its degree-one sign and the concentration theorem already applied in the original source. Its degree is $q + 1$, the leading coefficient $1/((q + 1)u_0)$ is a unit, and the leading projective zero locus in $\mathbb{P}^0$ is empty and smooth. The retained Deligne theorem therefore applies to these actual fibres: dimension q and weight one, including repeated critical roots. This is the finite-field application already present in the program, not a claim that such a realization has failed.

The exact finite-field operation corresponding to the exponential linear multiplier is also calculable. For a specified scalar b in the residue field,

$$f_{t_0+u_0b}(S) = f_{t_0}(S) - bS,$$

so the actual sheaves obey

$$L_\psi(f_{t_0+u_0b}) = L_\psi(f_{t_0}) \otimes L_\psi(-bS).$$

The cover proof is addition: if $Y_1^r - Y_1 = f_t(S)$ and $Y_2^r - Y_2 = -bS$, then $Y_1 + Y_2$ satisfies the equation with right side $f_t - bS$. On character eigenspaces, addition tensors the character lines. This is the precise analogue of $\exp(\Phi_t/u) \exp(-aS) = \exp(\Phi_{t+ua}/u)$: it is parameter translation with a linear character twist, not the Q-power Frobenius operation on the cover.

The existing DT.12 comparison under coordinate translation $S = X + b$ is a further, different map and retains its original constant line $L_\psi((- \Phi(-b) - t_0b)/u_0)$. Its Frobenius scalar is the exact root of unity in DT.13, not a real theta-dilation mass. Thus the coefficient translation, linear character twist, r-curvature, and cover Frobenius have separately computed coordinates. The matrix $p^{\pm A}$ remains the action from the original theta sheaf over the tau-base throughout this comparison.

91.0.9 8. Support reconstruction at every arrow

At every retained nonempty support mask Λ , every displayed linear/cochain map f has the original lift

$$(\Lambda, v) \rightarrow (\Lambda, f(v)), \tau \rightarrow \tau.$$

For invertible dilations the inverse image of the labelled zero is the labelled zero; for the quotient observation it is its full displayed kernel at the same label. Scalar coefficient specialization uses $G(R_0) \rightarrow G(\mathbb{F}_Q)$ and carries a represented coefficient specializing to zero to e , while external τ stays τ . Dual label arrows are the original precomposition maps in the opposite support-index category, as in tau-base equation (31).

Consequently the calculation composes the actual diagram

τ -based theta sheaf $\rightarrow R\Gamma$ over $\tau \rightarrow$ full finite jets

$\rightarrow$ exponential special fibre $\rightarrow$ finite exponential cohomology / periods,

together with its computed tau-base right-adjoint morphism. It does not replace global cohomology over the tau-base by restriction to the support skeleton, or replace the full packet by reduced values.

No new Lean execution, signed Gamma audit, or claim of a tensor-degree upper estimate accompanies this calculation.

91.0.11 10. Local correction record

2026-09-13: a transcript audit identified that Section 6’s global algebraic curve map $z \rightarrow z^p$ inherited the arbitrary-real $p > 0$ convention from Section 2 without stating its additional integer restriction. The power-map paragraph now explicitly assumes positive integer p on the characteristic-zero comparison curve. Its affected unnumbered formulas are $z \rightarrow z^p$, $dz/z \rightarrow pdz/z$, and the pullback of divisor depth one to depth p . No primeness assumption is needed.

The preceding real-parameter theta dilation, full-jet and moment-line actions, and the entire finite exponential flow are unchanged. The residue-characteristic r and finite-field Q operations of Section 7 are also unchanged. Only this local parameter-domain correction and this transparent record were added; no publication payload or source-owner file was modified.

Pre-correction SHA-256 of this artifact: 209385837d3fbd72b1f0d1164c9f6b261f312243f4427befe7148729f934029.

92 Complete relation-window spectral proof and literal-flag strictness

92.0.1 Exact spectra and trace spread of the original four relation windows

13 September 2026. Independent mathematical continuation of the original arithmetic determinant transport. This note leaves the sealed transport TeX and its PDF unchanged. It derives the complete spectra of the actual window operators, proves the spectral trace extremum directly, and integrates it against the original relative Gram eigenvalues. The packet, tensor degree, polynomial coordinate, measures, and all four cutoff indices remain fixed.

92.0.2 1. Original common source and projections

Fix the original actual packet h , tensor degree $k \geq 1$, and its literal cyclic annihilator $\chi = \chi_{h,k}$, of degree $q \geq 1$. Keep the common coefficient space

$$\mathcal{H} = \mathcal{P}_{2q} = \mathbb{C}[S]_{\leq 2q}, \quad \dim \mathcal{H} = n = 2q + 1, \quad (\text{WS1})$$

with its original increasing-power frame. Let M_0 and M_1 be the two actual positive source Grams at this cutoff, retaining the Gamma mass and arithmetic mass. Set

$$M(t) = (1-t)M_0 + tM_1, \quad \Delta M = M_1 - M_0, \quad D = M_0^{-1}M_1, \quad C(t) = M(t)^{-1}\Delta M, \quad 0 \leq t \leq 1. \quad (\text{WS2})$$

No rescaling of either Gram is performed. Positivity of $M(t)$ follows because its quadratic form on a nonzero vector is a convex combination of two strictly positive numbers.

Write $P_N(t)$ for the $M(t)$ -orthogonal projection onto the original coefficient subspace $\mathcal{P}_N$. Write $Q_N(t)$ for the same-metric orthogonal projection onto

$$\mathcal{R}_N = \chi \mathcal{P}_{N-q}, \quad \mathcal{P}_{-1} = 0, \quad N \geq q-1. \quad (\text{WS3})$$

Multiplication by the nonzero polynomial χ is injective, so $\dim \mathcal{R}_N = N - q + 1$. In particular $Q_{q-1} = 0$. These are the original relation images, with every power of χ and every finite coefficient retained.

The two actual operators are

$$\begin{aligned} U(t) &= (Q_{2q-1} - Q_{q-1}) + (Q_{2q} - Q_q) = Q_{2q-1} + Q_{2q} - Q_q, \\ W(t) &= (P_{2q-1} - P_{q-1}) + (P_{2q} - P_q). \end{aligned} \quad (\text{WS4})$$

All projections in WS4 are computed in the one space WS1 with the same form $M(t)$. Every equation below is pointwise in this retained parameter unless an integral is displayed.

For completeness, if $E \subseteq F$ are subspaces and P_E, P_F their orthogonal projections for that form, then $P_F P_E = P_E$ because $P_E v \in F$. Also $P_E P_F = P_E$, because $v - P_F v \in F^\perp \subseteq E^\perp$. Hence $P_F - P_E$ is self-adjoint, idempotent, and has image $F \cap E^\perp$. This proves every nested-projection decomposition used below; none of them assumes unrelated subspaces are orthogonal.

92.0.3 2. The exact relation and polynomial window spectra

The original relation spaces have the nested flag

$$\mathcal{R}_q = \chi \mathcal{P}_0 \subseteq \mathcal{R}_{2q-1} = \chi \mathcal{P}_{q-1} \subseteq \mathcal{R}_{2q} = \chi \mathcal{P}_q, \quad (\text{WS5})$$

of dimensions $1, q, q+1$. For $q = 1$, the first two spaces coincide; the following middle complement is then the zero space. Define

$$\begin{aligned} L_{U,0} &= \mathcal{R}_{2q}^\perp, & \dim L_{U,0} &= q, \\ L_{U,1a} &= \mathcal{R}_q, & \dim L_{U,1a} &= 1, \\ L_{U,2} &= \mathcal{R}_{2q-1} \cap \mathcal{R}_q^\perp, & \dim L_{U,2} &= q-1, \\ L_{U,1b} &= \mathcal{R}_{2q} \cap \mathcal{R}_{2q-1}^\perp, & \dim L_{U,1b} &= 1. \end{aligned} \quad (\text{WS6})$$

The four spaces are mutually orthogonal and their dimensions add to $2q+1$. The flag decomposition proves that they span $\mathcal{H}$. On them the three summands in U act respectively as follows:

	$L_{U,0}$	$L_{U,1a}$	$L_{U,2}$	$L_{U,1b}$
Q_{2q-1}	0	1	1	0
Q_{2q}	0	1	1	1
Q_q	0	1	0	0
U	0	1	2	1

(WS7)

Every entry is a restriction of the actual projection, not an assigned new operator.

The original polynomial flag is

$$\mathcal{P}_{q-1} \subseteq \mathcal{P}_q \subseteq \mathcal{P}_{2q-1} \subseteq \mathcal{P}_{2q} = \mathcal{H}. \quad (\text{WS8})$$

Its dimensions are $q, q+1, 2q, 2q+1$; the middle two coincide for $q = 1$. The corresponding four orthogonal pieces are

$$\begin{aligned} L_{W,0} &= \mathcal{P}_{q-1}, & \dim L_{W,0} &= q, \\ L_{W,1a} &= \mathcal{P}_q \cap \mathcal{P}_{q-1}^\perp, & \dim L_{W,1a} &= 1, \\ L_{W,2} &= \mathcal{P}_{2q-1} \cap \mathcal{P}_q^\perp, & \dim L_{W,2} &= q-1, \\ L_{W,1b} &= \mathcal{H} \cap \mathcal{P}_{2q-1}^\perp, & \dim L_{W,1b} &= 1. \end{aligned} \quad (\text{WS9})$$

On these pieces $P_{2q-1} - P_{q-1}$ has respective values $0, 1, 1, 0$, while $I - P_q = P_{2q} - P_q$ has respective values $0, 0, 1, 1$. Therefore W acts by $0, 1, 2, 1$.

Combining WS6–WS9 proves the complete spectra, including multiplicities:

$$\boxed{\text{spec } U = \text{spec } W = \{0^{[q]}, 1^{[2]}, 2^{[q-1]}\}.} \quad (\text{WS10})$$

Both traces are $2 + 2(q-1) = 2q$. Both eigenvalue-two spaces have dimension zero when $q = 1$; no nonexistent vector or inverse is used.

Equivalently, introduce the actual spectral projections

$$\begin{aligned} E_{U,1} &= Q_{2q}, & E_{U,2} &= Q_{2q-1} - Q_q, \\ E_{W,1} &= I - P_{q-1}, & E_{W,2} &= P_{2q-1} - P_q. \end{aligned} \quad (\text{WS11})$$

They satisfy $E_{X,2} \leq E_{X,1}$, with ranks $q-1$ and $q+1$, respectively, and

$$U = E_{U,1} + E_{U,2}, \quad W = E_{W,1} + E_{W,2}. \quad (\text{WS12})$$

This is also a useful direct explanation of the repeated eigenvalues in WS10.

92.0.4 3. Direct proof of the spectral trace extremum

Let C be any self-adjoint endomorphism of the same finite-dimensional Hilbert space, with eigenvalues

$$c_1 \leq c_2 \leq \cdots \leq c_n, \quad n = 2q + 1. \quad (\text{WS13})$$

All repetitions are retained. By the finite spectral theorem there is an orthonormal eigenbasis $e_1, \dots, e_n$ for this **same** source form. This use of coordinates is an isometry of the original form, not a change of any vector's norm or any scalar mass.

For an orthogonal projection E of rank r , put $w_i = \langle e_i, Ee_i \rangle = \|Ee_i\|^2$. Then

$$0 \leq w_i \leq 1, \quad \sum_i w_i = r, \quad \text{Tr}(EC) = \sum_i c_i w_i. \quad (\text{WS14})$$

For $0 < r < n$, set $a = c_{n-r+1}$. The difference between the largest- r eigenvalue sum and the last expression is exactly

$$\begin{aligned} \sum_{i=n-r+1}^n c_i - \sum_{i=1}^n c_i w_i &= \sum_{i=n-r+1}^n (c_i - a)(1 - w_i) \\ &\quad + \sum_{i=1}^{n-r} (a - c_i)w_i \geq 0. \end{aligned} \quad (\text{WS15})$$

To verify equality, expand the right side; its coefficient of a is $-r + \sum_{i=n-r+1}^n w_i + \sum_{i=1}^{n-r} w_i = 0$, leaving the displayed difference. Each remaining summand is nonnegative because of the sorted eigenvalues and WS14.

Applying this calculation to $-C$ gives the lower bound. When $r = 0$ the trace and both sums are zero; when $r = n$, $E = I$ and both sides equal $\sum c_i$. Thus in every case

$$\sum_{i=1}^r c_i \leq \text{Tr}(EC) \leq \sum_{i=n-r+1}^n c_i. \quad (\text{WS16})$$

This proof requires no strict eigenvalue inequality. It also gives the precise equality condition. At the upper endpoint, E is identity on all eigenspaces with eigenvalues strictly above the cutoff c_{n-r+1} , zero on all eigenspaces strictly below it, and may select the needed rank within the cutoff eigenspace. Indeed a strict coefficient in WS15 forces $w_i = 1$ or $w_i = 0$, and those identities imply $Ee_i = e_i$ or $Ee_i = 0$ by orthogonal projection. The lower endpoint has the reversed condition. Repeated cutoff values therefore allow their full indicated subspace choices rather than requiring a distinguished eigenbasis there.

Apply WS16 to each projection in WS11. Their ranks give, for $X = U$ or W ,

$$L_q(c) \leq \text{Tr}(XC) \leq H_q(c), \quad (\text{WS17})$$

where the exact endpoints are

$$\begin{aligned} L_q(c) &= 2 \sum_{j=1}^{q-1} c_j + c_q + c_{q+1}, \\ H_q(c) &= c_{q+1} + c_{q+2} + 2 \sum_{j=q+3}^{2q+1} c_j. \end{aligned} \quad (\text{WS18})$$

The sums of length $q - 1$ are empty for $q = 1$. The upper bound is the sum of the largest $q + 1$ eigenvalues and the largest $q - 1$ eigenvalues; the lower bound is the corresponding sum of the smallest eigenvalues. They are attained by nested spectral subspaces of these ranks, so the rank bounds are simultaneously consistent with the nested form WS12.

Subtracting WS17 for U and W , in both orders, proves

$$\begin{aligned} |\text{Tr}((U - W)C)| &\leq H_q(c) - L_q(c) \\ &= c_{q+2} - c_q + 2 \sum_{j=1}^{q-1} (c_{2q+2-j} - c_j). \end{aligned} \quad (\text{WS19})$$

No commutation between U , W , and C has been assumed. All traces are real: for self-adjoint X , C , conjugating $\text{Tr}(XC)$ gives $\text{Tr}(CX) = \text{Tr}(XC)$.

The bound in WS19 is the optimal one from the separate spectra WS10 and WS13. To prove this assertion explicitly, take the two endomorphisms whose diagonal entries in the eigenbasis of C are the list

$$(0, \dots, 0, 1, 1, 2, \dots, 2) \quad \text{and its reverse.} \quad (\text{WS20})$$

Their spectra are precisely WS10. The first attains $H_q(c)$, the second $L_q(c)$, and their difference attains the positive right side of WS19. Exchanging them attains the negative endpoint. This remains true for repeated c_i , with equality inside any repeated block understood through WS15. It proves a sharp statement about the indicated unitary orbits; additional alignment information from the literal polynomial and relation flags remains available and can improve a particular instance.

92.0.5 4. Integration along the unchanged arithmetic Gram path

The original $D = M_0^{-1}M_1$ is positive and self-adjoint for M_0 , because $M_0D = M_1$ is Hermitian and its quadratic form is positive. Thus it is diagonalizable with positive eigenvalues

$$0 < b_1 \leq \dots \leq b_{2q+1}, \quad \kappa = b_{2q+1}/b_1. \quad (\text{WS21})$$

Factor WS2 in its actual order:

$$M(t) = M_0((1-t)I + tD), \quad \Delta M = M_0(D - I), \quad C(t) = ((1-t)I + tD)^{-1}(D - I). \quad (\text{WS22})$$

The denominator is invertible because each of its eigenvalues $1 - t + tb_i$ is positive. Also $M(t)C(t) = \Delta M$ is Hermitian, proving self-adjointness for the exact source metric used in WS4. Functional calculus on the diagonalization of D gives its eigenvalues

$$c_i(t) = \frac{b_i - 1}{1 - t + tb_i}. \quad (\text{WS23})$$

The derivative of $(b-1)/(1-t+tb)$ with respect to b is exactly $(1-t+tb)^{-2} > 0$. Hence the same ordered list WS21 supplies the ordered list WS13 at every t , including $t = 0, 1$, repeated eigenvalues, and values $b_i = 1$. No eigenvalue branch relabelling is needed.

The original determinant transport proves, with these exact projections,

$$\Delta \mathcal{B} = \log \frac{T_{q-1}T_q}{T_{2q-1}T_{2q}} = \int_0^1 \text{Tr}((U(t) - W(t))C(t))dt, \quad T_N = V_N(1)/V_N(0). \quad (\text{WS24})$$

Here V_N is the determinant of the original least-norm quotient Gram, so WS24 is the signed arithmetic/reference endpoint correction. The identity was read in the complete sealed source; this review supplies the new spectral refinement. Its integrand is continuous: projection coefficients are rational expressions in positive finite Grams and their positive relation restrictions, so their inverses remain continuous on the compact path.

The elementary derivative

$$\frac{d}{dt} \log(1 - t + tb_i) = c_i(t)$$

holds also when $b_i = 1$, where both sides are zero. Thus $\int_0^1 c_i(t)dt = \log b_i$. Apply WS19 at every t , integrate, and use the triangle inequality in WS24. This gives the complete ordered-eigenvalue estimate

$$|\Delta \mathcal{B}| \leq \mathcal{S}_q(b) := \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}. \quad (\text{WS25})$$

All ratios in WS25 are at least one and are literal ratios of eigenvalues of the original relative Gram. Every such ratio is at most κ . The total positive coefficient count is $1 + 2(q-1) = 2q-1$. Therefore

$$|\Delta \mathcal{B}| \leq \mathcal{S}_q(b) \leq (2q-1) \log \kappa. \quad (\text{WS26})$$

For $q = 1$, the statement is exactly $|\Delta \mathcal{B}| \leq \log(b_3/b_1)$; there is no sum and no factor two. If all b_i equal a positive scalar c , then WS23 makes $C(t)$ a scalar multiple of the identity and the traces of U, W cancel. Equations WS25–WS26 give zero as well. The original common scalar mass remains present in the individual Grams; it cancels only in this signed ratio.

The coefficient $2q-1$ cannot be decreased using only the separate spectra of U, W and the extremes of D . For any retained numbers $0 < a < d$, choose the ordered data

$$b_1 = \cdots = b_q = a, \quad b_{q+1} = c \in [a, d], \quad b_{q+2} = \cdots = b_{2q+1} = d. \quad (\text{WS27})$$

Then every ratio in WS25 is d/a , so $\mathcal{S}_q(b) = (2q-1) \log(d/a)$. Choose the two commuting spectral flags WS20 in a fixed M_0 -orthogonal eigenbasis of D . Since $M(t)$ only changes each basis vector's squared norm by the positive factor $1 - t + tb_i$, these coordinate projections stay orthogonal for every original t in this abstract comparison. They attain WS19 with the same sign at every t , hence its integrated value is exactly WS25 and WS26. This is an equality construction within the stated spectral-data class, preserving arbitrary positive a, d . It does not identify arbitrary spectral flags with the actual multiplication-by- χ flag.

92.0.6 5. What the literal polynomial flag retains beyond the spectra

The original relation and polynomial flags impose the exact incidence

$$\chi\mathcal{P}_{q-1} \cap \mathcal{P}_{q-1} = 0. \quad (\text{WS28})$$

A nonzero product χP has degree $q + \deg P \geq q$, whereas every polynomial on the right has degree at most $q - 1$; this proves WS28. In particular independent opposite eigenvalue alignments need not be attainable by these specific subspaces.

For example, assume C has strictly increasing eigenvalues and $q \geq 2$. Equality at the positive endpoint of WS19 forces U to have its eigenvalue-two space on the largest $q - 1$ eigenspaces of C , and forces W to vanish on its largest q eigenspaces, by the equality criterion in WS15. Hence $L_{U,2} \subseteq L_{W,0} = \mathcal{P}_{q-1}$. But $L_{U,2} \subseteq \chi\mathcal{P}_{q-1}$ and has positive dimension $q - 1$, contradicting WS28. At the negative endpoint the same argument uses the smallest eigenspaces: minimizing U puts its eigenvalue-two space in the smallest $q - 1$ eigenspaces, while maximizing W makes those eigenspaces part of its kernel. Thus that endpoint is also impossible for these literal flags and simple C .

At $q = 1$, the actual formulas reduce to

$$U = Q_2 = I - P_{\mathcal{R}_2^\perp}, \quad W = I - P_0, \quad U - W = P_0 - P_{\mathcal{R}_2^\perp}. \quad (\text{WS29})$$

For simple C , a positive equality in WS19 makes $\ker U = \mathcal{R}_2^\perp$ the lowest eigenline and $\ker W = P_0$ the highest eigenline. They are orthogonal, which would force $P_0 \subseteq \mathcal{R}_2 = \chi\mathcal{P}_1$. This is impossible because the nonzero constant polynomial is not divisible by the degree-one χ . The negative endpoint is excluded by exchanging the lowest and highest eigenlines. The strictness statement concerns nonconstant simple spectral data; repeated cutoff eigenspaces have precisely the freedom retained in WS15.

These incidence calculations identify an exact additional relation that the source-specific unitary, commutator, and full-jet observations can use. The spectral estimate WS25 remains valid for the original flags, while its equality statement is explicitly scoped. The signed determinant correction itself remains WS24, with all four original endpoints and all relation primitives present.

92.0.7 6. The original one-dimensional quotient gives a nonlinear bound

This section concerns exactly $q = 1$, with the original common source $\mathcal{P}_2$, original vertical line $S = k/2 + iu$, original positive measures m_t , and original degree-one relation polynomial $\chi = S - a$. It makes no assertion that the same two-line formula applies in higher quotient dimension.

The four cutoff indices become 0, 1, 1, 2, so the two copies of V_1 cancel in this specified ratio and

$$\mathcal{B}(t) = \log \frac{V_0(t)}{V_2(t)}. \quad (\text{WS30})$$

Let $e = 1$ be the original constant polynomial, $\mathcal{N} = (\chi\mathcal{P}_1)^\perp$, and $z = R_2(t)[1]$ its canonical minimum-norm representative. Every polynomial with remainder one differs from e by an element of $\chi\mathcal{P}_1$, so orthogonal minimization gives $z = P_{\mathcal{N}}e$. The norms are the unchanged quotient values

$$\langle e, e \rangle_t = V_0(t), \quad \langle z, z \rangle_t = V_2(t), \quad \langle e, z \rangle_t = V_2(t) > 0. \quad (\text{WS31})$$

The last equality follows by the orthogonal splitting of e ; its sign and phase are fixed. Positivity of V_2 follows independently from $J_2 z = 1$, which makes $z \neq 0$. Hence the angle between the two lines has

$$\cos^2 \theta(t) = \frac{|\langle e, z \rangle_t|^2}{\langle e, e \rangle_t \langle z, z \rangle_t} = \frac{V_2(t)}{V_0(t)} = e^{-\mathcal{B}(t)} > 0. \quad (\text{WS32})$$

This ratio is strictly below one for the actual source measures. Indeed equality would give $e \in \mathcal{N}$, hence both $\int \chi(S)m_t = 0$ and $\int S\chi(S)m_t = 0$. On the retained vertical line, $\bar{S} = k - S$, so

$$|\chi(S)|^2 = ((k - \bar{a}) - S)\chi(S). \quad (\text{WS33})$$

The two vanishing integrals would force $\int |\chi(S)|^2 m_t = 0$. This contradicts positive definiteness of the original Gram on the nonzero polynomial χ ; alternatively positivity almost everywhere of m_t and the finite

zero set of χ give the contradiction directly. Thus $0 < \theta(t) < \pi/2$ and $\mathcal{B}(t) > 0$ on the entire compact interval. This argument uses the actual source line and its measure, not an arbitrary coefficient Gram calibration.

Put $p = e/\sqrt{V_0}$ and $n_0 = z/\sqrt{V_2}$. Their inner product is the positive real number $c = \sqrt{V_2/V_0}$. Set $s = \sqrt{1 - c^2} > 0$, and $r = (n_0 - cp)/s$. Directly $\langle p, r \rangle_t = 0$ and $\|r\|_t = 1$. These are explicit coordinates with the original norms displayed, so no Gram factor or mass is removed. In the basis (p, r) , the difference in WS29 is

$$P_0 - P_{\mathcal{N}} = \begin{pmatrix} s^2 & -sc \\ -sc & -s^2 \end{pmatrix} \quad \text{on } \text{span}(p, r), \quad (\text{WS34})$$

and is zero on its orthogonal complement. The displayed matrix has trace zero and determinant $-s^2$, so the full three eigenvalues are $s, 0, -s$. This proves the exact alignment-dependent spectrum

$$\text{spec}(U - W) = \left\{ \sqrt{1 - e^{-\mathcal{B}(t)}}, 0, -\sqrt{1 - e^{-\mathcal{B}(t)}} \right\}. \quad (\text{WS35})$$

Write its positive and negative rank-one spectral projections as E_+ and E_- . Then $U - W = s(E_+ - E_-)$. Applying the already proved rank-one bound WS16 to their two traces gives

$$|\dot{\mathcal{B}}(t)| \leq \sqrt{1 - e^{-\mathcal{B}(t)}} (c_3(t) - c_1(t)). \quad (\text{WS36})$$

Here $\dot{\mathcal{B}}$ is the original derivative in WS24; the equality identifying it uses all four original window signs even though their scalar endpoint expression has the cancellation in WS30.

For real $B > 0$, let $\Phi(B) = 2 \text{arcosh}(e^{B/2})$, using the nonnegative real inverse of cosh. Differentiating $\cosh(\Phi(B)/2) = e^{B/2}$ gives

$$\Phi'(B) = \frac{e^{B/2}}{\sqrt{e^B - 1}} = \frac{1}{\sqrt{1 - e^{-B}}}. \quad (\text{WS37})$$

Since $\mathcal{B}(t)$ is continuous and strictly positive on the compact interval, it has a positive minimum; every composition and division in WS37 is therefore defined and smooth on this whole path. Multiplying WS36 by WS37 yields $|(\Phi \circ \mathcal{B})'| \leq c_3 - c_1$. Integrating WS23 gives the exact nonlinear endpoint control

$$\left| 2 \text{arcosh}(e^{\mathcal{B}(1)/2}) - 2 \text{arcosh}(e^{\mathcal{B}(0)/2}) \right| \leq \log \frac{b_3}{b_1}. \quad (\text{WS38})$$

Equivalently, put $A_0 = \text{arcosh}(e^{\mathcal{B}(0)/2})$ and $L = \frac{1}{2} \log(b_3/b_1)$. Then $\text{arcosh}(e^{\mathcal{B}(1)/2})$ lies between $\max(0, A_0 - L)$ and $A_0 + L$. The function $A \mapsto 2 \log \cosh A$ is increasing for $A \geq 0$, because its derivative is $2 \tanh A \geq 0$. Hence

$$2 \log \cosh(\max\{0, A_0 - L\}) \leq \mathcal{B}(1) \leq 2 \log \cosh(A_0 + L). \quad (\text{WS39})$$

The lower bound may be zero although the actual value was proved strictly positive. A scalar relative Gram gives $L = 0$ and the exact equality of the two original endpoint values, in agreement with WS25. This is an additional analytic calculation on the actual $q = 1$ source, retaining its canonical line angle.

92.0.8 7. Complete independent review of the root AW1-AW23 source

The complete tau_relation_window_spectral_transport_20260913.tex was read and checked at SHA-256 c79e76c087efd59871e3234ff44fb18964515dbd34f0318dffba6b3f1440f6ec. No mathematical correction is requested at that pin.

The following checks cover the new assertions rather than only their final inequalities.

1. **Original objects and types.** AW1-AW6 retain the exact arithmetic Taylor unit, two distinct injected observations into the full tensor jet module and into $Q^{\otimes k}$, the common $2q$ coefficient cutoff, the full masses, and the same-metric projection formulas. The correction sign agrees with the four terms of the sealed AT15, whose source pin is 24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae.

2. **Smooth actual isometry.** The Gram recursion AW9 retains every positive norm a_j . Linear independence of each original list makes every residual nonzero; positive square roots are smooth along the entire compact path. The canonical quotient list lies in $(\chi\mathcal{P}_q)^\perp$ because of the original minimum-section orthogonality and spans it because $J_{2q}R_{2q} = I$. Thus AW10 maps an actual orthonormal basis to another one, with matching eigenvalues from WS7 and WS9. It proves $T^*MT = M$ and $UT = TW$, including the empty middle list at $q = 1$.
3. **Commutator and unchanged cohomology observation.** Finite trace cyclicity gives $\text{Tr}((TWT^{-1} - W)C) = \text{Tr}(WT^{-1}(CT - TC))$, with precisely the displayed sign. The original observation has kernel $\chi\mathcal{P}_q$ because its two later maps are injective. Therefore $\ker(\mathcal{O}T) = T^{-1}(\chi\mathcal{P}_q)$. The explicit AW10 basis assignment identifies this with $\text{span}(p_q, \dots, p_{2q}) = \mathcal{P}_{q-1}^\perp$. The full observation defect $\sigma_h^{\otimes k} \eta J_{2q}(T - I)$ is retained, so this isometry is not assigned an unwritten identity on arithmetic classes. The support lift preserves the label and gives exactly that supported-zero inverse image.
4. **Repeated spectra and integration.** AW13–AW17 agree with the independently derived WS14–WS26. The zero rank at $q = 1$, repeated Gram eigenvalues, values $b_i = 1$, and the full coefficient $2q - 1$ are all covered. The claimed sharpness is expressly restricted to the separate spectral constraint; its text does not freely orient the original polynomial relations. AW18 is a correct substitution of the supplied Gamma lower estimate into this new finite-source bound, with the actual quartet restriction retained.
5. **One-dimensional continuation.** AW19–AW23 are independently proved in full by WS30–WS39 above. The vertical-line identity, positive phase of $\langle e, z \rangle$, exact two-dimensional projection matrix, remaining zero eigenvalue, positive derivative divisor, and both real hyperbolic-function branches are correct. The factor on the right of AW22 is $\log(b_3/b_1)$, while AW23 correctly uses half that number in its cosh arguments. The calculation remains explicitly restricted to $q = 1$.

The whole AW source is accepted at the exact pin above. The original finite Gram data remain the input to the proved estimates; no uniform bound in k has been presumed.

92.0.9 8. Source and verification scope

The complete sealed tau_arithmetic_determinant_transport_20260913.tex was read. Its AT11–AT15 fix the original common Hilbert space, projection conventions, correction sign, and relative Gram path used here. This note proves WS5–WS39 directly from those data and the actual $q = 1$ measures; it does not alter the sealed source or its PDF. The complete root AW1–AW23 source was also read and accepted as recorded above. These complete written proofs constitute the closed mathematical review; no supplementary source is needed for any acceptance recorded here.

No external trace extremum theorem was used: WS14–WS16 are its direct finite-dimensional proof, including repeated eigenvalues. No Lean execution, remote mutation, numerical-only proof, source-multiplier boundedness hypothesis, or unproved asymptotic estimate is asserted.

93 The complete original arithmetic Taylor-unit formal gauge

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

93.0.1 The original arithmetic Taylor unit as a formal geometric gauge

13 September 2026. This calculation continues the original cohomology over the absolute tau base. It retains the actual unit $j_h(g/h)$ in the exponential deformation, constructs every localization and inverse map, and proves that the newly introduced pole quotient is contractible in the specified formal neighbourhood. It does not replace that unit by a constant, replace an arithmetic metric, or identify formal and analytic cohomology.

93.0.2 1. Fixed arithmetic input

Use the retained theta complex and its actual finite packet:

$$C_+ = [V \xrightarrow{\Theta} \mathcal{B}], \quad Q = \mathcal{B}/\Theta V, \quad g = 2\xi, \quad h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}. \quad (\text{UG1})$$

Every selected order is its full original zero order. Set $d = \deg h$, $E_h = \mathbb{C}[s]/(h)$, and retain

$$v_h = j_h(g/h), \quad \nu(s) = \text{rem}_h(v_h), \quad \epsilon_h = v_h^{-1} = j_h(h/g). \quad (\text{UG2})$$

Here rem_h in the middle denotes the unique polynomial of degree less than d with those full Hermite jets, not a remainder of an entire function obtained by dropping its Taylor derivatives. The actual g/h is nonzero at every selected root, so ν and h are relatively prime. Polynomial Euclidean division gives coefficients a, b with $ah + b\nu = 1$. These are facts about the retained packet. No additional zero of g is postulated.

The original arithmetic source section and cyclic tensor inclusion stay

$$\begin{aligned} J_Z R_{\text{ref}} &= I, \quad \mathcal{M} R_{\text{ref}} x = (g/h) \text{rem}_h(\epsilon_h x), \\ \eta_{h,k}[P] &= v_h^{\otimes k} P(A_h^{(k)}) 1, \quad A_h^{(k)} = \sum_{i=1}^k A_i. \end{aligned} \quad (\text{UG3})$$

The full inverse unit remains in the source section, and the full direct unit remains in eta. They are not mutually cancelled across different arrows or used to change the original theta norm.

93.0.3 2. The actual completed rings and pole quotient

Write s for the single-factor polynomial coordinate and (u, t) for the existing deformation parameters. The two rings used below are

$$\widehat{B} = \mathbb{C}[s][[u, t]], \quad \widehat{B}_\nu = \mathbb{C}[s, \nu(s)^{-1}][[u, t]]. \quad (\text{UG4})$$

They are coefficientwise formal power series. In the second ring the power of ν in a denominator may grow with the (u, t) coefficient. We do not silently replace it by a localization allowing only one uniform denominator for the whole series.

Let

$$M = \mathbb{C}[s, \nu^{-1}]/\mathbb{C}[s].$$

Coefficientwise inclusion and quotient give the exact sequence

$$0 \longrightarrow \widehat{B} \xrightarrow{i} \widehat{B}_\nu \xrightarrow{\pi} M[[u, t]] \longrightarrow 0. \quad (\text{UG5})$$

An explicit section σ of π is the proper rational part at infinity. Divide each rational function P/ν^n into its polynomial part and a remainder with numerator degree strictly smaller than $\deg(\nu^n)$. The proper part depends only on the class modulo polynomials: a rational function both polynomial and vanishing at infinity is zero. This defines σ independently of the presentation with denominator ν^n . Apply it coefficient by coefficient. If ν is a nonzero constant, M is zero, π and σ are zero, and all the formulas below remain valid.

93.0.4 3. Multiplication by h is invertible on the pole quotient only

Multiplication by h on M is injective. If hP/ν^n is polynomial, relative primality forces ν^n to divide P , so the original class is zero. It is surjective: choose a_n, b_n with

$$a_n h + b_n \nu^n = 1.$$

For $[P/\nu^n]$, the class $[a_n P/\nu^n]$ maps to it, since the difference is the polynomial $-b_n P$. Injectivity shows that this inverse does not depend on the Bezout representative. Denote this exact inverse by H .

$$H = (M_h|_M)^{-1} : M \longrightarrow M. \quad (\text{UG6})$$

This inverse is **not** an inverse to h on E_h : there multiplication by h is still zero with all original jets present. The two operators occur on the different, explicitly related terms of (UG5).

Differentiation preserves both rational functions with poles among zeros of ν and polynomials; it therefore induces ∂_s on M . Neither this derivative nor H is asserted to commute with the other.

93.0.5 4. An explicit contracting homotopy for the additional pole complex

The original formal exponential differential is

$$D = u\partial_s + h(s) - t, \quad \widehat{C} = [\widehat{B} \xrightarrow{D} \widehat{B} ds], \quad \widehat{C}_\nu = [\widehat{B}_\nu \xrightarrow{D} \widehat{B}_\nu ds]. \quad (\text{UG7})$$

It respects (UG5). On its pole quotient put $E = u\partial_s - t$ and

$$J = D_M^{-1} = \sum_{n=0}^{\infty} (-HE)^n H. \quad (\text{UG8})$$

The order of these operators is part of the formula. The operator HE raises (u, t) -adic order by at least one. Thus each fixed coefficient of (UG8) contains only finitely many terms; this is a defined continuous operator on $M[[u, t]]$. Because $D_M = M_h(I + HE)$, multiplication of finite partial sums gives a remainder of arbitrarily high parameter order. Completeness yields both $JD_M = I$ and $D_M J = I$.

It follows that the two-term quotient complex

$$[M[[u, t]] \xrightarrow{D_M} M[[u, t]] ds] \quad (\text{UG9})$$

is contractible, with degree-minus-one homotopy J . This conclusion uses the displayed inverse, not a claim that a common support label makes a kernel vanish. In particular the entire arithmetic quotient of the original complex is retained.

There is an explicit deformation retraction, not only a cohomology count. Set

$$K = \sigma J \pi : \widehat{C}_\nu^1 \longrightarrow \widehat{C}_\nu^0, \\ r^0 = I - KD = I - \sigma \pi, \quad r^1 = I - DK. \quad (\text{UG10})$$

Each r has its image in the corresponding original polynomial-series space: for r^0 this follows from its definition, and $\pi r^1 = \pi - D_M J \pi = 0$. Direct multiplication gives

$$r^1 D = D r^0, \quad r i = I_{\widehat{C}}, \quad i r = I_{\widehat{C}_\nu} - (DK + KD). \quad (\text{UG11})$$

In this last expression the degree-one component is DK and the degree-zero component is KD ; no sum of incompatible-degree maps is intended. Since $\pi i = 0$, one also has $K i = 0$. Formula (UG10) is a coefficientwise evaluable inverse to localization in the derived category. It retains the explicit pole complex and contracts it.

For comparison, the map from the mapping cone of i to (UG9) sends its localized component to its quotient and the other component to zero. The kernel is the cone of the identity on the original complex, which contracts directly. Thus the mapping-cone account and (UG10) give the same vanishing of this additional pole contribution.

93.0.6 5. The original Taylor unit supplies a gauge isomorphism

Multiplication by ν is invertible on $\widehat{B}_\nu$. Compute its conjugation of the unchanged differential:

$$D^\nu = \nu D \nu^{-1} = u\partial_s + h - t - u \frac{\nu'}{\nu}. \quad (\text{UG12})$$

Indeed $\partial_s(P/\nu) = P'/\nu - P\nu'/\nu^2$. Consequently

$$D^\nu(\nu P) = \nu DP$$

for every localized formal coefficient. Multiplication by ν in both degrees is an exact cochain isomorphism

$$\widehat{C}_\nu \xrightarrow{\times \nu} \widehat{C}_\nu^\nu = [\widehat{B}_\nu \xrightarrow{D^\nu} \widehat{B}_\nu ds]. \quad (\text{UG13})$$

Its inverse is multiplication by the same full rational ν^{-1} . The new rational derivative term is written explicitly, with its sign and coefficient ν ; it is not dropped or called a change of coordinates.

Combining (UG11) and (UG13) provides the geometric arrow

$$\boxed{\widehat{C} \xrightarrow{i} \widehat{C}_\nu \xrightarrow{\times \nu} \widehat{C}_\nu^\nu} \quad (\text{UG14})$$

It is a quasi-isomorphism of formal complexes. The original special fibre is $[\mathbb{C}[s] \xrightarrow{h} \mathbb{C}[s] ds]$, with $H_1=E_h$ and $H_0=0$. The localized special fibre has the same cohomology, because ν is invertible modulo h . Under those original coefficient identifications, the special-fibre map (UG14) is exactly

$$E_h \xrightarrow{\times \nu_h} E_h. \quad (\text{UG15})$$

At this fibre $D^\nu = h$, but the cochain map is still multiplication by ν . In particular a basis change using $\nu, \nu s, \dots$ must retain its transition matrix to the original monomial frame; otherwise it would conceal the actual arithmetic unit in (UG15).

93.0.7 6. The same arithmetic scaling flow commutes with this gauge

The previously constructed regular lift of theta dilation is

$$L = u\partial_t - s, \quad [D, L] = 0, \quad \exp(aL)P = e^{-as}P(u, t + ua, s) \quad (\text{UG16})$$

in the a -adic cochain completion. Because ν depends only on s ,

$$[L, M_\nu] = [L, M_{\nu^{-1}}] = 0, \quad [D^\nu, L] = \nu[D, L]\nu^{-1} = 0. \quad (\text{UG17})$$

Thus (UG14) intertwines the **same** formal scaling operator L and its a -adic exponential. No modified scaling generator or replacement moment line is needed. The proper-rational retraction need not itself commute strictly with L : its exact chain homotopies remain available; the quasi-isomorphism i and the gauge do commute strictly.

In the target frame represented by νs^j , the induced finite flow matrix is the already calculated C_a . In the special-fibre original frame, the transition is the full multiplication matrix M_{ν_h} . It commutes with $p^{\pm A_h}$ because both are multiplication operators on the same full algebra, not because its higher jets have been ignored. The finite entire evaluation of C_a for $a = \log p$ is as proved in the scaling note; no convergence of the rational formal gauge in arbitrary analytic (u, t) neighbourhoods is inferred here.

93.0.8 7. The tensor inclusion is recovered without changing the sum module

Apply the construction to each original h factor, using its coordinate s_i and its deformation parameters. External tensor maps have degree zero, so tensoring (UG14) introduces no new Koszul sign in those maps; the differentials keep the original tensor signs. More precisely use independent parameters (u_i, t_i) and the coefficientwise completion defined by the cofinal rectangular truncations $(u_i, t_i)^{n_i+1} = 0$ for every factor i . Each fixed multi-index receives only finitely many terms from the homotopies (UG10).

There is an explicit tensor homotopy, so no inverse-limit exactness assertion is needed. Set $P_i = i_i r_i$. On homogeneous tensors the j -th term of the tensor homotopy is

$$(-1)^{|x_1|+\dots+|x_{j-1}|} P_1 x_1 \otimes \dots \otimes P_{j-1} x_{j-1} \otimes K_j x_j \otimes x_{j+1} \otimes \dots \otimes x_k.$$

Summing these terms gives K_{total} . The differential's original Koszul rule cancels its cross terms and gives $dK_{\text{total}} + K_{\text{total}}d = I - P_1 \otimes \dots \otimes P_k$, by telescoping. The other retraction identity follows by tensoring

$r_i i_i = I$. These are coefficientwise identities on every rectangular truncation and hence on the specified completed coefficient space.

The special-fibre map is

$$\mathcal{E}_k = E_h^{\otimes k} \xrightarrow{M_{v_h}^{\otimes k}} \mathcal{E}_k. \quad (\text{UG18})$$

Compose it with the original cyclic inclusion

$$E_{h,k} \longrightarrow \mathcal{E}_k, \quad [P] \longmapsto P(A_h^{(k)})1.$$

The resulting map is exactly eta in (UG3). This proof does not assume that the full tensor unit is a polynomial in the single sum coordinate S ; different occupancies with the same sum remain in the original tensor object. The original cyclic annihilator and its full jet lengths are unchanged. The original section into $Q^{\otimes k}$ and the tau-base pushforward therefore receive the very same map eta.

For any fixed admitted support mask, every map above has its existing split lift $(\text{mask}, v) \mapsto (\text{mask}, f(v))$, with tau going to tau. A formal coefficient specializing to zero goes to that mask's e. The structural map over $\mathbf{F}_{1,\tau}$ is retained; neither localization at e nor restriction of global cohomology to the sigma skeleton has been used.

93.0.9 8. The residue-dual arrow retains the inverse unit as well

For this section use the original reflection-stable packet of the tau-base residue construction. Then dagger is an endomorphism of its full jet space. The localization and gauge proofs above did not need reflection; this specifies the original domain of the residue-dual arrow, rather than silently applying it to an arbitrary packet.

Let the original polynomial residue pairing be

$$\mathcal{S}_h(f, v) = \sum_{\rho \in Z} \text{Res}_\rho \frac{f(s)v(s)}{h(s)} ds.$$

On full jets, the arithmetic residue is exactly

$$R_Z(f, v) = \mathcal{S}_h(f^\dagger, \epsilon_h v), \quad \epsilon_h = j_h(h/g) = v_h^{-1}. \quad (\text{UG19})$$

To prove it, write $g = h(g/h)$ in each germ. The inverse of g/h agrees with epsilon to every order needed for the residue, so replacing that inverse by epsilon changes the integrand by a holomorphic germ. The original dagger carries its full alternating Taylor signs.

The dual of (UG15) is its actual transpose, and the inverse-dual transport uses $M_{v_h}^{-T}$. After tensoring and composing the source's residue-dual arrow to $K_{\tau,k}(L_k)$, (UG19) retains the same inverse units that already occur there. The weight factor p^k is still the original moment representation. Thus the formal gauge joins the direct unit-bearing inclusion and its specified residue dual, rather than discarding one of their arithmetic factors.

93.0.10 9. Exact scope for the ongoing geometric argument

This is a formal-neighbourhood computation over the original base program. It establishes an explicit quasi-isomorphism carrying the actual Taylor unit, its localization cone and contraction, its commuting arithmetic scaling, and its tensor and dual maps.

The Neumann series was justified in the (u, t) -adic topology only. Specializing it at a nonzero complex u is not an authorized inference from that proof. Such an analytic comparison would require its actual continuation and contour/pole contribution to be calculated. The original canonical theta metrics and their source/relation volumes remain the analytic quantities in the separate continuation; this note neither chooses a new metric nor asserts a weight bound.

The completed result improves the concrete program nonetheless: the original arithmetic unit is now present in a proved formal geometric map through the same deformation, with its exact extra term and contractible pole quotient, rather than being left outside that map.

93.0.11 Source and verification record

The original tau-base note was read completely in the preceding turn, SHA256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3. The full current tex/arithmetic_input.tex was also read completely; A7–13 give the full unit, actual source section, quotient square and equivariant roof used here. The original exponential family and its constant residue duality are those of the retained exponential note, not a new arbitrary replacement. The adjoining accepted scaling and reflection notes supply the exact flow and moment-weight transport.

All localization, contraction and gauge claims above have their elementary proofs in this note. Finite algebra fixtures are supporting checks and do not certify actual zero data, all analytic coefficients, or an RH statement. No new Lean or public upload is claimed here.

94 Complete independent review of the actual Taylor-unit formal gauge

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

94.0.1 Independent review of the actual-unit formal gauge

Date: 2026-09-13. Read ACTUAL_TAYLOR_UNIT_FORMAL_GAUGE.md completely, UG1–19 and its scope/source paragraphs. The original tau-base note, arithmetic_input.tex, and original exponential comparison were read in full in the adjoining independent scaling work. This review does not edit the source note, run its fixtures, or claim a Lean or analytic-convergence result.

94.0.2 Disposition and one domain clarification

Accept UG1–18 and the formal construction. The pole inverse has the correct order, the coefficientwise completions are essential and correctly specified, and the explicit retract proves the claimed quasi-isomorphism. The tensor map retains the complete direct Taylor units and recovers the original eta without an assumption that their tensor product is a function of the sum coordinate alone.

UG19's residue identity is correct on the original reflection-stable packet used in the tau-base residue construction. That domain should be explicit here: UG1 otherwise admits any full-order selected packet, while dagger is not automatically a well-defined endomorphism of its quotient. The two equivalent precise typings are:

- use the already retained reflection-stable packet, so dagger maps E_h to E_h ; or
- for arbitrary h , put $h^\dagger(s) = (-1)^{d_h} \overline{h(1 - \bar{s})}$ (the monic reflected polynomial) and take the first argument from $E_{h^\dagger}$, so its dagger lies in E_h .

No change to the full-order arithmetic source or formal gauge is needed. This is the exact domain of the existing residue arrow, not a new analytic hypothesis. The issue and the tensor-completion convention below were recorded before writing this review.

94.0.3 Coefficientwise quotient and its inverse

Let $A = \mathbb{C}[s]$, $A_\nu = \mathbb{C}[s, \nu^{-1}]$, and $M = A_\nu / A$. A rational function has a unique decomposition into a polynomial and a proper rational function; two proper representatives differing by a polynomial are equal. Thus the stated section sigma is well defined, including when different denominator powers represent the same rational function. Applying this section to each (u, t) coefficient proves surjectivity in UG5 without assuming a uniform denominator. The constant-nu case gives $M = 0$.

Since $\gcd(h, \nu) = 1$, hP/ν^n being polynomial forces $\nu^n \mid P$. Conversely $a_n h + b_n \nu^n = 1$ gives an inverse class $[a_n P/\nu^n]$. These prove injectivity and surjectivity of M_h on M , and uniqueness makes its inverse H independent of all Bezout choices. This inverse acts on the additional pole quotient, not on E_h . Differentiation descends to M , but no commutation with H is needed.

Writing $E = u\partial_s - t$, the exact factorization is

$$D_M = M_h(I + HE).$$

Thus the inverse must be $(I + HE)^{-1}H$, which is precisely UG8. The powers of HE raise parameter order; at any fixed coefficient only finitely many terms contribute. Both inverse identities follow by finite geometric sums modulo each parameter power, then coefficientwise completion. This does not use a norm-convergent Neumann series or reorder H and the derivative.

94.0.4 Explicit retraction and formal finite cohomology

Using $\pi D = D_M \pi$ and $JD_M = D_M J = I$, one gets

$$KD = \sigma\pi, r^0 = I - \sigma\pi, \pi r^1 = 0.$$

The remaining formulas follow by multiplication: $r^1 D = Dr^0$, $ri = I$, and $ir = I - dK - Kd$. The degree-zero and degree-one occurrences of K are correctly typed. Thus no assumption about exactness of a completed cohomology functor is replacing the displayed deformation retraction. The mapping-cone description has the same quotient and the contractible identity-cone kernel.

The completed original polynomial complex also retains its expected finite coefficient basis. At the lowest parameter order, divide by h ; the $u\partial_s - t$ term only affects higher orders. Recursive monic division therefore constructs the unique degree-below- d formal remainder and its formal preimage, coefficient by coefficient. The lowest-order nonzero term of a putative kernel would be killed by the injective polynomial multiplier h , so the differential remains injective. Hence its cohomology is the coefficientwise completed free rank- d module. Unbounded s -degrees or pole orders across formal coefficients are allowed exactly as stated in UG4.

94.0.5 Gauge, special fibre, and scaling

Direct Leibniz differentiation gives

$$\nu D\nu^{-1} = u\partial_s + h - t - uv'/\nu.$$

Both the minus sign and factor u are correct. Multiplication by ν in both degrees is an isomorphism only on the explicitly localized complex, with inverse the same rational ν^{-1} . At $u = t = 0$, both target differentials are h , but this cochain map still multiplies by ν . Its induced map under the original quotient identification is therefore exactly multiplication by ν_h , not identity.

For the composite to the gauge target, an explicit inverse up to homotopy is $rM_{\nu^{-1}}$; its homotopy is $M_{\nu}KM_{\nu^{-1}}$. This also supplies a direct way to tensor the composite itself.

The operator $L = u\partial_t - s$ commutes with multiplication by ν and its inverse, because these depend only on s . Therefore its commutation with D transfers to D^ν with no additional term. The inclusions and gauge map strictly intertwine L and its formal a -adic exponential. It is correct not to demand that the particular proper-part retraction strictly intertwine L . The coefficient matrix in the transported frame νs^j is consequently the same formal C_a ; an entire evaluation of that finite matrix does not claim analytic convergence of the rational formal gauge. The note keeps these domains distinct.

94.0.6 Precise tensor-completion interpretation and homotopy

The tensor statement is valid with independent parameter pairs and the completed tensor product defined by the cofinal rectangular truncations $(u_i, t_i)^{n_i}$ in the finitely many factors. Each such quotient is the ordinary tensor product over $\mathbb{C}$ of its factor truncations. These rectangular filtrations are cofinal with total parameter-adic truncation, so they give the same coefficientwise formal product. Calling every total-degree truncation a literal tensor product would be inaccurate; the rectangular convention is the precise one under which UG7's tensor paragraph operates.

There is no need to infer inverse-limit exactness abstractly. Let $P_i = i_i r_i$ and use the source's homotopies K_i . For two factors set

$$K_{\text{tot}} = K_1 \otimes I + P_1 \otimes K_2,$$

with the graded convention $(P_1 \otimes K_2)(x \otimes y) = (-1)^{\deg x} P_1 x \otimes K_2 y$. Since P is a cochain map, direct expansion gives

$$dK_{\text{tot}} + K_{\text{tot}}d = (I - P_1) \otimes I + P_1 \otimes (I - P_2) = I - P_1 \otimes P_2.$$

For k factors the sum has $P_1, \dots, P_{j-1}$ before K_j and identities after it, with these same tensor signs. The terms telescope to $I - \bigotimes_i P_i$. All maps preserve parameter order, so this identity holds at each compatible rectangular truncation and hence coefficientwise in the completed product. The gauge-conjugated homotopies give the same statement for the targets with D_i^ν .

Specialization yields $M_{v_h}^{\otimes k}$ on the whole original tensor packet. Composing with $[P] \mapsto P(\sum A_i)1$ is exactly eta. All same-sum occupancies remain in the tensor module and no cyclic polynomial formula for the tensor unit is used.

94.0.7 Residue scope, support, and limits of this review

With the dagger domain fixed as above, $g = h(g/h)$ proves UG19: the complete inverse Taylor unit differs from the inverse germ by a multiple of h , so the residue difference is holomorphic. Its transpose and inverse-transpose transports keep the actual source inverse units; they do not assert a positive pairing or a globally invertible extension on every analytic deformed fibre.

Every operation is on the declared linear coefficient fibre, followed by its support-preserving lift. Inverting ν is not inverting the supported zero e . The formal pole contraction does not identify represented zero with τ or pass from τ -base pushforward to the generic skeleton. No specialization of UG8 at a nonzero complex u , no analytic period assertion, no metric estimate, and no tensor-growth bound is certified by this review. The affirmative result is the explicit formal quasi-isomorphism with its actual arithmetic unit and all the displayed kernels retained.

94.0.8 Final acceptance of the revised note

The preceding domain-clarification discussion is the historical review record, not an outstanding objection. On 2026-09-13 I reread the revised Section 7 and Section 8, including the full signed tensor homotopy and the explicit original reflection-stable packet restriction. Both comments are resolved in the text. In the tensor discussion above, “UG7’s tensor paragraph” means Section 7, not the equation labelled UG7.

The exact accepted source artifact is ACTUAL_TAYLOR_UNIT_FORMAL_GAUGE.md, SHA-256:

9ded2486160b76bf65f92d44b73cdd0c59a3ca7e5334f88682e10592d5a45b2f.

Final disposition: accept UG1–19 and the stated formal construction, with no outstanding mathematical correction. Independent parameter pairs and cofinal rectangular truncations make every tensor identity coefficientwise well defined; the displayed Koszul signs give $dK_{\text{total}} + K_{\text{total}}d = I - \bigotimes_i P_i$. Section 8 now has exactly the domain on which the original dagger and residue-dual arrow are defined, while the preceding gauge proof retains its greater generality. No assumption of analytic convergence, positivity, or global invertibility of the original arithmetic residue unit is added by this acceptance.

This final seal is a proof review. The separately reported exact fixtures and negative controls were not rerun by this reviewer.

95 Complete arithmetic determinant variations and their original determinant lines

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

Exact revision. dee20e249e980fdf0251513c3ab5d504e1a17e6d408c3e7ad69d08816a6f115e

Complete source. sources/next_edition/actual_tau_variation_v1/sources/variation_review/tau_arithmetic_determinant_variation_subreview_20260913.md

Source SHA-256. dee20e249e980fdf0251513c3ab5d504e1a17e6d408c3e7ad69d08816a6f115e

95.0.1 Independent verification of the arithmetic determinant variations

Date: 2026-09-13. Reviewed source: tau_arithmetic_determinant_transport_20260913.tex. Final accepted source SHA-256: 24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae. Scope: AT3–AT10, including the literal section, inverse quotient Gram, determinant-line orientation, and full first and second variations. This subreview does not claim a review of the later four-window estimate or the analytic source construction.

The displayed formulas AT6–AT10 are correct. The first source, SHA-256 41c7b45a0a94f0e65d422b213a4bcbddedbf983ab5127da6095e449e001fef98, asserted that $M_N^{-1}J_N^*G_N$ had remainder I_E before establishing that fact. The author has now inserted the exact decomposition proof. I read the corrected paragraph, verified its final source hash above, and accept the repair. The observation is resolved, and no displayed formula changed. Section 3 supplies the complete independent derivation without assuming $(J_N M_N^{-1} J_N^*)G_N = I_E$.

95.0.2 1. Original finite spaces and their types

Fix the actual $h, k, \chi = \chi_{h,k}$ of the source, with $k \geq 1$, monic χ of degree $q \geq 1$, and $N \geq q - 1$. Set

$$U = \mathcal{P}_{N-q}, \quad P = \mathcal{P}_N, \quad E = \mathbb{C}[S]/(\chi), \quad r = N - q + 1. \quad (\text{AV1})$$

At $N = q - 1$, the convention is $U = \mathcal{P}_{-1} = \{0\}$, so $r = 0$. The source spaces carry their increasing-power coefficient frames, and E has its increasing-power remainder frame. The fixed maps are

$$B : U \longrightarrow P, \quad y \longmapsto \chi y, \quad J : P \longrightarrow E, \quad p \longmapsto [p]_\chi, \quad s : E \longrightarrow P, \quad (\text{AV2})$$

where s chooses the polynomial of degree less than q . Polynomial division by the original monic χ proves

$$JB = 0, \quad Js = I_E, \quad \ker J = \text{im } B, \quad P = \text{im } B \oplus \text{im } s. \quad (\text{AV3})$$

In particular B is injective. The coefficient y in $p = By + sJp$ is the actual polynomial quotient in division by χ .

All stars below are conjugate transpose in these fixed frames. Let

$$M(t) = M_N(t) = M(0) + t\Delta M, \quad \Delta M = M(1) - M(0), \quad H(t) = B^*M(t)B. \quad (\text{AV4})$$

These are the source's matrices from $m_t = (1 - t)m_0 + tm_1$ on the original line $S = k/2 + iu$; no scalar mass is divided out. Their entries have the original finite moments. For nonzero $p \in P$, polynomial evaluation vanishes at only finitely many real u , whereas m_t is positive almost everywhere, so $p^*M(t)p > 0$. Thus $M(t)$ is positive definite on $0 \leq t \leq 1$. For nonzero $y \in U$, injectivity of B gives $y^*H(t)y = (By)^*M(t)(By) > 0$.

The lower bound

$$M(t) \succeq \min\{\lambda_{\min}(M(0)), \lambda_{\min}(M(1))\}I_P$$

holds on the compact interval. Continuity gives a real open neighborhood of this interval on which $M(t)$ remains positive definite. The corresponding assertion holds for $H(t)$ when $r > 0$. All inverse matrices and sections below are smooth there. This uses finite matrices only.

95.0.3 2. The actual section and its minimum property

Every lift of $x \in E$ is uniquely $sx + By$, with $y \in U$. Define

$$d = H^{-1}B^*Ms : E \longrightarrow U, \quad R = s - Bd : E \longrightarrow P. \quad (\text{AV5})$$

For $x \in E$ and $y \in U$, direct expansion gives

$$\begin{aligned} (sx + By)^*M(sx + By) &= x^*(s^*Ms - s^*MBH^{-1}B^*Ms)x \\ &\quad + (y + dx)^*H(y + dx). \end{aligned} \quad (\text{AV6})$$

Here H^{-1} is Hermitian, and $d^*Hd = s^*MBH^{-1}B^*Ms$. Thus the unique least-norm lift is Rx , attained at $y = -dx$. Direct substitution gives

$$JR = I_E, \quad B^*MR = 0, \quad G := R^*MR = s^*Ms - s^*MBH^{-1}B^*Ms. \quad (\text{AV7})$$

The map R is injective because $JR = I_E$. Therefore G is positive definite, so its inverse exists before using the inverse quotient formula.

95.0.4 3. Inverse quotient formula without circularity

For every $p \in P$, the vector $p - RJp$ lies in $\ker J$. Exactness and injectivity of B therefore give a unique $y \in U$ with

$$p = By + RJp. \quad (\text{AV8})$$

Multiplication by R^*M , using $R^*MB = (B^*MR)^* = 0$, gives

$$R^*Mp = GJp \quad \text{for every } p \in P, \quad R^*M = GJ, \quad MR = J^*G. \quad (\text{AV9})$$

The last equality is the conjugate transpose of the preceding equality, since M, G are Hermitian. Multiplying by M^{-1} , then composing with J , proves

$$R = M^{-1}J^*G, \quad I_E = JR = (JM^{-1}J^*)G. \quad (\text{AV10})$$

The matrix $K = JM^{-1}J^*$ is positive definite: J^* is injective because J is surjective, and for $x \neq 0$

$$x^*Kx = (J^*x)^*M^{-1}(J^*x) > 0. \quad (\text{AV11})$$

Consequently $G = K^{-1}$. This proves the inverse quotient identity from the literal section and orthogonality, without presupposing its consequence about the remainder.

95.0.5 4. Determinant-line sign and metric

Let $y_1, \dots, y_r$ be the increasing-power frame of U , and $x_1, \dots, x_q$ the increasing-power remainder frame of E . In the increasing-power frame of P ,

$$[s \ B] = \begin{pmatrix} I_q & T \\ 0 & U_\chi \end{pmatrix}, \quad \det U_\chi = 1. \quad (\text{AV12})$$

Indeed, relation column j , starting with $j = 0$, is $S^j\chi(S)$ and has highest term S^{q+j} of coefficient one. In the bottom rows corresponding to $S^q, \dots, S^N$, no entry occurs below that diagonal. Hence U_χ is upper triangular with all diagonal entries one, proving $\det[s \ B] = 1$.

Moving the first q columns past the last r columns uses exactly qr transpositions. The relation-first frame therefore has

$$L = [B \ s], \quad \det L = (-1)^{qr}. \quad (\text{AV13})$$

The determinant-line map is literally

$$\det U \otimes \det E \longrightarrow \det P, \\ (y_1 \wedge \dots \wedge y_r) \otimes (x_1 \wedge \dots \wedge x_q) \longmapsto By_1 \wedge \dots \wedge By_r \wedge sx_1 \wedge \dots \wedge sx_q. \quad (\text{AV14})$$

The wedge is nonzero by (AV3), so this is an isomorphism of one-dimensional lines. Replacing sx_j by $sx_j + Bz_j$ leaves it unchanged: every term in the difference contains $r+1$ vectors in the r -dimensional space $\text{im } B$. This establishes section independence, while preserving the displayed frame sign.

The change from s to $R = s - Bd$ is

$$[B \ R] = [B \ s] \begin{pmatrix} I_U & -d \\ 0 & I_E \end{pmatrix}, \quad [B \ R]^*M[B \ R] = \begin{pmatrix} H & 0 \\ 0 & G \end{pmatrix}. \quad (\text{AV15})$$

The right factor in the first equality has determinant one. The second equality is exactly (AV7). Taking determinants retains the orientation scalar explicitly:

$$\det H \det G = \overline{(-1)^{qr}} \det M (-1)^{qr} = |(-1)^{qr}|^2 \det M = \det M. \quad (\text{AV16})$$

The squared norm of a wedge is its Gram determinant. Thus (AV16) also proves that (AV14), using the relation metric H and quotient metric G , is the product metric map. The orientation remains (AV13); its squared absolute value is one in the metric equation. In particular

$$V(t) = \det G(t) = \frac{\det M(t)}{\det H(t)}. \quad (\text{AV17})$$

All original source masses remain in these matrices and determinants.

95.0.6 5. First variation of the section and Gram

The maps B, J, s are fixed in t . From $H = B^*MB$ and $H^{-1}H = I_U$,

$$\dot{H} = B^*\Delta MB, \quad \frac{d}{dt}H^{-1} = -H^{-1}\dot{H}H^{-1}. \quad (\text{AV18})$$

Differentiating $d = H^{-1}B^*Ms$ gives

$$\begin{aligned} \dot{d} &= -H^{-1}(B^*\Delta MB)H^{-1}B^*Ms + H^{-1}B^*\Delta Ms \\ &= H^{-1}B^*\Delta M(s - Bd) = H^{-1}B^*\Delta MR. \end{aligned} \quad (\text{AV19})$$

Consequently, as maps on the original spaces,

$$\dot{R} = -BH^{-1}B^*\Delta MR : E \longrightarrow P, \quad \text{im } \dot{R} \subseteq \text{im } B, \quad J\dot{R} = 0. \quad (\text{AV20})$$

Differentiating $G = R^*MR$ gives all three terms

$$\dot{G} = \dot{R}^*MR + R^*\Delta MR + R^*M\dot{R}. \quad (\text{AV21})$$

The first and third vanish by the relation-valued derivative and $B^*MR = 0$. Therefore

$$\dot{G} = R^*\Delta MR. \quad (\text{AV22})$$

This is a Hermitian matrix on the unchanged remainder space E .

95.0.7 6. Second variation of the quotient Gram

The matrix ΔM is fixed and Hermitian, so differentiating (AV22) gives

$$\ddot{G} = \dot{R}^*\Delta MR + R^*\Delta M\dot{R} = -2R^*\Delta MBH^{-1}B^*\Delta MR. \quad (\text{AV23})$$

The two terms are equal because H^{-1} and ΔM are Hermitian. Their sign is established on each actual $x \in E$ by

$$x^*\ddot{G}x = -2(B^*\Delta MRx)^*H^{-1}(B^*\Delta MRx) = -2\|H^{-1/2}B^*\Delta MRx\|^2 \leq 0. \quad (\text{AV24})$$

Thus the factor 2 in AT7 retains both differentiated occurrences of R .

95.0.8 7. Both logarithmic derivative formulas

For any positive definite differentiable finite matrix A , multilinearity of the determinant gives $\det(I + \varepsilon D) = 1 + \varepsilon \operatorname{Tr} D + O(\varepsilon^2)$: the terms choosing exactly one perturbed column sum to the diagonal trace. Applying this to $\det(A + \varepsilon \dot{A}) = \det A \det(I + \varepsilon A^{-1} \dot{A})$ therefore proves

$$\frac{d}{dt} \log \det A = \operatorname{Tr}(A^{-1} \dot{A}). \quad (\text{AV25})$$

Apply (AV25) to (AV17), and separately to G using (AV22):

$$\begin{aligned} \frac{d}{dt} \log V &= \operatorname{Tr}(M^{-1} \Delta M) - \operatorname{Tr}(H^{-1} B^* \Delta M B) \\ &= \operatorname{Tr}(G^{-1} R^* \Delta M R). \end{aligned} \quad (\text{AV26})$$

The traces are on P, U, E , respectively. The equality follows from the proved determinant identity, so it requires no unproved rearrangement across different domains.

Differentiating $G^{-1} G = I_E$ gives $\dot{G}^{-1} = -G^{-1} \dot{G} G^{-1}$. A second differentiation of the last expression in (AV26), followed by (AV23), now retains both terms:

$$\begin{aligned} \frac{d^2}{dt^2} \log V &= \operatorname{Tr}(G^{-1} \ddot{G}) - \operatorname{Tr}(G^{-1} \dot{G} G^{-1} \dot{G}) \\ &= -2 \operatorname{Tr}(G^{-1} R^* \Delta M B H^{-1} B^* \Delta M R) - \operatorname{Tr}(G^{-1} \dot{G} G^{-1} \dot{G}). \end{aligned} \quad (\text{AV27})$$

Their exact norm realizations are

$$\begin{aligned} \operatorname{Tr}(G^{-1} R^* \Delta M B H^{-1} B^* \Delta M R) &= \|H^{-1/2} B^* \Delta M R G^{-1/2}\|_{\text{HS}}^2, \\ \operatorname{Tr}(G^{-1} \dot{G} G^{-1} \dot{G}) &= \|G^{-1/2} \dot{G} G^{-1/2}\|_{\text{HS}}^2. \end{aligned} \quad (\text{AV28})$$

For the first, multiply $X^* X$ with $X = H^{-1/2} B^* \Delta M R G^{-1/2} : E \rightarrow U$, and take its trace on E . For the second, $Y = G^{-1/2} \dot{G} G^{-1/2}$ is Hermitian, so $\operatorname{Tr}(Y^* Y) = \operatorname{Tr}(Y^2)$. Cyclicity of the trace on E gives exactly the two expressions in (AV28). Formula (AV27) is consequently $-2\|X\|_{\text{HS}}^2 - \|Y\|_{\text{HS}}^2 \leq 0$.

Differentiating the first line of (AV26) also gives the compatible full source/relation expression

$$\frac{d^2}{dt^2} \log V = -\operatorname{Tr}(M^{-1} \Delta M M^{-1} \Delta M) + \operatorname{Tr}(H^{-1} \dot{H} H^{-1} \dot{H}). \quad (\text{AV29})$$

Equations (AV27)–(AV28) prove why this particular difference is nonpositive for the exact quotient.

95.0.9 8. Empty relation domain and equality

When $N = q - 1$, $U = \{0\}$, $P = \mathcal{P}_{q-1}$, and J, s identify the same increasing-power frame. The only endomorphism of U is both its zero and identity map; it is invertible on U , with itself as inverse. Its determinant is 1, and its trace is 0. The maps $B : U \rightarrow P$ and $B^* : P \rightarrow U$ are the corresponding zero maps. Every composition through U is the correctly typed zero map on its stated exterior domain and codomain. Thus

$$R = s, \quad \dot{R} = 0, \quad G = s^* M s, \quad \dot{G} = s^* \Delta M s, \quad \ddot{G} = 0. \quad (\text{AV30})$$

The determinant-line map uses the empty wedge $1 \in \det U = \mathbb{C}$; its sign is $(-1)^{q-0} = 1$. Formula (AV17) is $\det G = \det M$ in the stated frames. The logarithmic second derivative still retains the inverse-Gram term:

$$\frac{d^2}{dt^2} \log V = -\|G^{-1/2} \dot{G} G^{-1/2}\|_{\text{HS}}^2. \quad (\text{AV31})$$

For either $r = 0$ or $r > 0$, both terms in (AV28) vanish exactly when $B^* \Delta M R = 0$ and $R^* \Delta M R = 0$. The matrix $[B \ R]$ is invertible by (AV8), so its conjugate transpose is invertible. These equations are therefore equivalent to

$$\Delta M R = 0 : E \longrightarrow P. \quad (\text{AV32})$$

Conversely this identity makes both terms vanish directly. Thus equality in the second-derivative inequality is characterized by the actual Gram increment annihilating the current canonical section, including the empty relation case.

The corrected source's proof now contains the noncircular step (AV8)–(AV10). AT6–AT10 are accepted on the final source pin above; the first-pass proof-order observation is resolved.

96 All-degree angle transport on the original arithmetic four-volume

The original finite quotient has two pairs of minimum-section subspaces. This calculation identifies their complete principal angles with the energies of their actual relation-valued differences. Their determinant is the original arithmetic four-volume. The original vertical-line moment identity then proves strict positivity of that four-volume and gives a nonlinear endpoint bound in every quotient dimension.

96.1 Fixed arithmetic source, maps and forms

Fix the original full actual packet h for $g = 2\xi$, an integer $k \geq 1$, and its original cyclic polynomial $\chi = \chi_{h,k}$, monic of degree $q \geq 1$. Keep $E = \mathbb{C}[S]/(\chi)$ in its increasing-power remainder frame. The full Taylor unit $v_h = j_h(g/h)$ occurs in the unchanged injections

$$\eta : E \hookrightarrow E_h^{\otimes k}, \quad \eta[P] = v_h^{\otimes k} P(A_h^{(k)})1, \quad \sigma_h^{\otimes k} \eta : E \hookrightarrow Q^{\otimes k}, \quad (\text{AGT1})$$

where $E_h = \mathbb{C}[s]/(h)$ and $Q = \mathcal{B}/\Theta V$. The latter is the top cohomology of the original tensor pushforward over $\mathbf{F}_{1,\tau}$. All these maps and the original theta primitives are supplied, with their complete proofs, in the retained AT and AW dependency packages.

The common polynomial source is $H = \mathcal{P}_{2q}$, with coordinate $S = k/2 + iu$ on the original integration line. Its original measures are

$$\begin{aligned} m_1(u) &= w_h^{*k}(u), & w_h(u) &= \frac{|(g/h)(1/2 + iu)|^2}{2\pi}, \\ m_0(u) &= \frac{(\sqrt{2\pi})^k |\Gamma(k/4 + iu/2)|^2}{c_{k/4} 2\pi}, & c_a &= 2^{1-2a} \Gamma(2a). \end{aligned} \quad (\text{AGT2})$$

Their full masses $(2\pi)^{k/2}$ and μ_h^k remain present. Set $m_t = (1-t)m_0 + tm_1$, $0 \leq t \leq 1$. In the original coefficient frame write $M(t)$ for its Gram on H , and $\langle x, y \rangle_t = x^* M(t) y$. The complete source-density proofs give all finite moments and positivity almost everywhere. Therefore this form is positive on every nonzero polynomial, for every t in the closed interval.

For each $q-1 \leq N \leq 2q$, use the original exact sequence $0 \rightarrow \mathcal{P}_{N-q} \xrightarrow{\times \chi} \mathcal{P}_N \xrightarrow{J_N} E \rightarrow 0$, with $\mathcal{P}_{-1} = 0$. Let $R_N(t) : E \hookrightarrow \mathcal{P}_N \subset H$ be its unique minimum-norm section, and retain

$$G_N(t) = R_N(t)^* M(t) R_N(t), \quad V_N(t) = \det G_N(t). \quad (\text{AGT3})$$

The inclusions into H are part of this formula. Write P_N, Q_N for the orthogonal projections in H onto $\mathcal{P}_N$ and $\chi \mathcal{P}_{N-q}$ respectively, and $Z_N = P_N - Q_N$. Then Z_N projects onto $R_N E$ and has rank q .

The existing complete determinant-variation proof gives

$$\begin{aligned} \mathcal{B}(t) &= \log \frac{V_{q-1}(t) V_q(t)}{V_{2q-1}(t) V_{2q}(t)}, \\ C(t) &= M(t)^{-1} (M(1) - M(0)), \\ \dot{\mathcal{B}}(t) &= \text{Tr}((Z_{q-1} - Z_{2q} + Z_q - Z_{2q-1}) C(t)). \end{aligned} \quad (\text{AGT4})$$

This groups the same four signed terms into two pairs; all four original cutoff indices and quotient Grams remain fixed.

96.2 Relation energy, Gram ratios and the full principal angles

Theorem 96.1. For $q - 1 \leq i \leq j \leq 2q$, define the actual difference of minimum sections $D_{ij} = R_i - R_j : E \rightarrow H$. Then

$$\begin{aligned} D_{ij}E &\subset \chi\mathcal{P}_{j-q}, & R_j &= Z_j R_i, \\ G_i - G_j &= D_{ij}^* M D_{ij}, & K_{ij} &= G_i^{-1/2} G_j G_i^{-1/2}, \\ I - K_{ij} &= G_i^{-1/2} D_{ij}^* M D_{ij} G_i^{-1/2}, & 0 &\prec K_{ij} \preceq I. \end{aligned} \quad (\text{AGT5})$$

The eigenvalues of K_{ij} , including multiplicities, are $\cos^2 \theta_{ij,a}$ for the full principal-angle list between $R_i E$ and $R_j E$, with $0 \leq \theta_{ij,a} < \pi/2$ and $1 \leq a \leq q$. Consequently

$$\log(V_i/V_j) = \sum_{a=1}^q -\log \cos^2 \theta_{ij,a}. \quad (\text{AGT6})$$

The nonzero eigenvalues of $Z_i - Z_j$ are exactly the pairs $\sin \theta_{ij,a}, -\sin \theta_{ij,a}$ for the nonzero angles; the remaining eigenvalues are zero.

Proof. Both sections have the same remainder, so their difference lies in the displayed relation space. The vector $R_j x$ is orthogonal to that entire space. Also $R_i x \in \mathcal{P}_j$. Thus the orthogonal splitting of $R_i x$ into its relation and minimum-lift components is $D_{ij}x + R_j x$, proving $R_j = Z_j R_i$ and the Gram identity. Positivity of G_j and this nonnegative difference prove the last inequalities in (AGT5). Each square root is the unique positive Hermitian square root on the displayed original coefficient space; the order of its products is retained.

For the principal-angle calculation put $U_i = R_i G_i^{-1/2}$ and $U_j = R_j G_j^{-1/2}$. They are isometries from the displayed Euclidean coefficient space to the two original source subspaces: $U_i^* M U_i = I$ and $U_j^* M U_j = I$. Their full cross matrix is

$$U_j^* M U_i = G_j^{-1/2} R_j^* M R_i G_i^{-1/2} = G_j^{1/2} G_i^{-1/2}. \quad (\text{AGT7})$$

The equality uses $R_j^* M D_{ij} = 0$. Its squared singular values are therefore the eigenvalues of K_{ij} , with no commutation of the two Grams presumed. These singular values are positive and at most one, defining the angles just stated. Determinants of the displayed positive matrices give (AGT6), keeping all original determinant factors.

Here is also a direct proof of the projection-difference spectrum. Choose singular-vector bases e_a in $R_i E$ and f_a in $R_j E$ for (AGT7), so their cross inner products are $\langle f_a, e_b \rangle_t = c_a \delta_{ab}$, with $c_a = \cos \theta_{ij,a} > 0$. For $c_a = 1$, the equality of norms gives $e_a = f_a$. For $c_a < 1$, put $s_a = \sqrt{1 - c_a^2}$ and $r_a = (f_a - c_a e_a)/s_a$. Substitution in these inner products proves that all resulting pairs (e_a, r_a) are orthonormal, orthogonal to the other pairs and to the common vectors. On each pair the exact matrix is

$$(Z_i - Z_j)|_{\text{span}(e_a, r_a)} = \begin{pmatrix} s_a^2 & -s_a c_a \\ -s_a c_a & -s_a^2 \end{pmatrix}. \quad (\text{AGT8})$$

It has trace zero and determinant $-s_a^2$, hence eigenvalues $s_a, -s_a$. The difference vanishes on the common vectors and on the orthogonal complement of the two subspaces' sum. This proves the full spectrum, including all zero-angle cases. $\square$

The difference D_{ij} in (AGT5) is an original polynomial relation. The original source map $\mathcal{V}$ therefore gives its literal theta primitive, while its full-jet and arithmetic cohomology observations are zero. Precisely, $J_j D_{ij} = 0$, $\eta J_j D_{ij} = 0$ and $\sigma_h^{\otimes k} \eta J_j D_{ij} = 0$; nevertheless its source energy is exactly $G_i - G_j$ in (AGT5). At each nonempty original support label A , the corresponding linear maps lift as $(A, x) \mapsto (A, fx)$, with $\tau \mapsto \tau$. The boundary then has a supported-zero class at that same label, and (AGT5) retains its entire preimage energy.

96.3 The actual four-volume has at most $2q - 1$ nonzero angles

Apply the theorem to the two pairs $(q - 1, 2q)$ and $(q, 2q - 1)$. For the second pair both q -dimensional minimum-section subspaces lie in

$$\mathcal{P}_{2q-1} \cap (\chi\mathcal{P}_0)^\perp, \quad \dim(\mathcal{P}_{2q-1} \cap (\chi\mathcal{P}_0)^\perp) = 2q - 1. \quad (\text{AGT9})$$

Indeed both are orthogonal to $\chi\mathcal{P}_0$, a one-dimensional subspace of $\mathcal{P}_{2q-1}$. Their intersection thus has dimension at least one, by the dimension formula for a sum of subspaces. Each common unit vector gives singular value one in the principal-angle calculation, so this pair has at least one exact zero angle. When $q = 1$ its two cutoff indices coincide, and its single angle is exactly zero.

Retain both full lists of q angles. Their combined logarithmic cost from (AGT6) is exactly $\mathcal{B}(t)$. Remove one of the proved zero contributions only in the following scalar list, and write the remaining $m = 2q - 1$ entries as

$$x_\ell(t) = -\log \cos^2 \theta_\ell(t) \geq 0, \quad \sum_{\ell=1}^m x_\ell(t) = \mathcal{B}(t), \quad \sin \theta_\ell(t) = \sqrt{1 - e^{-x_\ell(t)}}. \quad (\text{AGT10})$$

Other zero angles remain in the list. The zero-angle eigenspaces and the full source maps were not removed from their original spaces. No differentiability of a chosen eigenvector or ordered angle branch will be needed.

Let $c_{\min}(t), c_{\max}(t)$ be the extreme eigenvalues of $C(t)$ for $M(t)$. A self-adjoint projection difference with the spectrum in (AGT8) is a sum of its positive and negative rank-one eigenprojections with coefficients $s_a, -s_a$. Each eigenprojection's trace against $C(t)$ is the Rayleigh quotient of $C(t)$ at its unit vector and lies between these two extremes. Subtracting each pair gives an absolute value at most $s_a(c_{\max} - c_{\min})$. Apply this to both terms of (AGT4), retaining their signs, to obtain

$$|\dot{\mathcal{B}}(t)| \leq \left(\sum_{\ell=1}^m \sqrt{1 - e^{-x_\ell(t)}} \right) (c_{\max}(t) - c_{\min}(t)). \quad (\text{AGT11})$$

This first estimate retains all principal angles through the actual source relation energies in (AGT5).

96.4 The moment identity forces strict positivity

Write the original polynomial as $\chi(S) = \sum_{j=0}^q a_j S^j$, $a_q = 1$. The antilinear algebra involution on $\mathbb{C}[S]$ defined by

$$\chi^{\#_k}(S) = \sum_{j=0}^q \overline{a_j}(k - S)^j \quad (\text{AGT12})$$

satisfies $\chi^{\#_k}(S) = \overline{\chi(S)}$ on the original line, because $\overline{S} = k - S$. Its degree is q and its leading coefficient is $(-1)^q$. Applying it twice restores each coefficient and the variable since k is real.

Each term in (AGT10) is nonnegative, so $\mathcal{B}(t) \geq 0$. If it were zero, all angles of the first pair would be zero, hence $R_{q-1}E = R_{2q}E$. The first space is $\mathcal{P}_{q-1}$; the second is $(\chi\mathcal{P}_q)^\perp$ in H . It would follow that 1 is orthogonal to $\chi\mathcal{P}_q$. But $\chi^{\#_k} \in \mathcal{P}_q$, and therefore this orthogonality would imply

$$0 = \langle 1, \chi\chi^{\#_k} \rangle_t = \int_{\mathbb{R}} |\chi(k/2 + iu)|^2 m_t(u) du > 0. \quad (\text{AGT13})$$

The last strict inequality is positivity of the original form on the nonzero polynomial χ . This contradiction proves $\mathcal{B}(t) > 0$ at every $t \in [0, 1]$. Thus the strict positivity follows from an exact identity in the actual moment form; an arbitrary positive coefficient form has not been substituted for that form.

96.5 A nonlinear endpoint estimate in every degree

Theorem 96.2. Put $m = 2q - 1$, let $b_{\min}, b_{\max}$ be the extreme eigenvalues of the original relative Gram $M(0)^{-1}M(1)$, and set $\kappa = b_{\max}/b_{\min}$. Then the original two endpoint four-volumes satisfy

$$\left| 2 \operatorname{arcosh}\left(e^{\mathcal{B}(1)/(2m)}\right) - 2 \operatorname{arcosh}\left(e^{\mathcal{B}(0)/(2m)}\right) \right| \leq \log \kappa. \quad (\text{AGT14})$$

In particular this holds for every actual full quartet quotient, with its unchanged value of q .

Proof. The function $f(x) = \sqrt{1 - e^{-x}}$ is continuous for $x \geq 0$, with $f(0) = 0$. For $x > 0$ its two derivatives give

$$f'(x) = \frac{e^{-x}}{2\sqrt{1 - e^{-x}}}, \quad f''(x) = -\frac{e^{-x}}{2\sqrt{1 - e^{-x}}} - \frac{e^{-2x}}{4(1 - e^{-x})^{3/2}} < 0. \quad (\text{AGT15})$$

It is consequently concave on the whole closed half-line, by continuity at zero. More explicitly, its decreasing derivative shows that its tangent at any positive a is above its graph on $(0, \infty)$, and continuity extends this inequality to zero. Choose $a = \mathcal{B}(t)/m > 0$, proved admissible in (AGT13), and sum those tangent inequalities at the entries in (AGT10). Their linear terms cancel exactly, giving

$$\sum_{\ell=1}^m f(x_{\ell}(t)) \leq m\sqrt{1 - e^{-\mathcal{B}(t)/m}}, \quad |\dot{\mathcal{B}}(t)| \leq m\sqrt{1 - e^{-\mathcal{B}(t)/m}}(c_{\max}(t) - c_{\min}(t)). \quad (\text{AGT16})$$

This argument allows every remaining zero angle without differentiating it.

The positive finite Grams and their sections are smooth through the whole compact interpolation interval. Therefore $\mathcal{B}$ is smooth and, by (AGT13), has a positive minimum there. The real function $\Phi_m(B) = 2 \operatorname{arcosh}(e^{B/(2m)})$, using the nonnegative real inverse of the hyperbolic cosine, satisfies

$$\Phi'_m(B) = \frac{1}{m\sqrt{1 - e^{-B/m}}}, \quad B > 0. \quad (\text{AGT17})$$

One obtains this by differentiating $\cosh(\Phi_m(B)/2) = e^{B/(2m)}$. Multiply (AGT16) by this positive derivative.

To integrate the remaining spectral width, set $D = M(0)^{-1}M(1)$. It is positive and self-adjoint for the original $M(0)$ metric, and $C(t) = ((1 - t)I + tD)^{-1}(D - I)$. Each relative eigenvalue $b > 0$ gives $c_b(t) = (b - 1)/(1 - t + tb)$. Its derivative with respect to b is $(1 - t + tb)^{-2} > 0$, so the same extreme eigenvalues give the extremes for all t . Direct integration of the logarithmic derivative yields

$$\int_0^1 (c_{\max}(t) - c_{\min}(t)) dt = \int_0^1 \frac{d}{dt} \log \frac{1 - t + tb_{\max}}{1 - t + tb_{\min}} dt = \log \kappa. \quad (\text{AGT18})$$

Integrating $|(\Phi_m \circ \mathcal{B})'| \leq c_{\max} - c_{\min}$ proves (AGT14), including repeated relative eigenvalues. $\square$

An explicit interval for the original arithmetic endpoint is obtained without an implicit inversion. Put $A_0 = \operatorname{arcosh}(e^{\mathcal{B}(0)/(2m)})$ and $L = \frac{1}{2} \log \kappa$. Since $2m \log \cosh A$ is increasing on $A \geq 0$, (AGT14) is equivalent to

$$2m \log \cosh(\max\{0, A_0 - L\}) \leq \mathcal{B}(1) \leq 2m \log \cosh(A_0 + L). \quad (\text{AGT19})$$

The lower endpoint can be zero although the actual $\mathcal{B}(1)$ was proved strictly positive. Also $\Phi'_m(B) > 1/m$ for finite positive B , so (AGT14) implies $|\mathcal{B}(1) - \mathcal{B}(0)| \leq m \log \kappa$, with strict inequality in this last comparison whenever the two four-volumes differ. The full-relative-spectrum bound in AW13–AW14 remains available as a second, separately proved bound; none of its eigenvalues is discarded by the exact identities (AGT5)–(AGT11).

When $q = 1, m = 1$ and the second pair is identical. Equations (AGT14)–(AGT19) recover AW19–AW23 with exactly the original constant and mass factors. If the endpoint forms differ by a positive scalar only, then $\kappa = 1$; every quotient determinant has the same literal scalar to the power q , and the four-volume is unchanged, as the new inequality also proves.

96.6 Complete source and mathematical scope

The full AT and AW source packages accompany this calculation. Their complete proofs establish the original tau-base observation, tensor units, theta primitives, source densities, minimum sections and signed derivative (AGT4). The new principal-angle and moment calculations above retain those objects and prove (AGT5)–(AGT19) in every quotient dimension. The actual endpoint measures enter both the relative Gram D and the strict positivity argument. No upper estimate uniform in k for that relative Gram is assumed or claimed. The new bound supplies an explicit nonlinear constraint on the original arithmetic four-volume, with the complete source relation energies still present.

97 Complete four-window spectral sharpness on the original polynomial flags

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

97.0.1 Four-window projection spectra and the exact polynomial-flag sharpness calculation

13 September 2026. Independent written calculation for the common finite source in the arithmetic determinant transport. The original monic polynomial, coefficient frame, relation maps, and masses remain explicit.

The source work/tau_arithmetic_determinant_transport_20260913.tex was consulted through its first 190 lines, including AT1–AT10. Its SHA-256 at consultation was 24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae. The present calculation proves the projection statements below directly. It does not edit that source, run Lean, or assert that an arbitrary positive coefficient Gram is an arithmetic moment Gram.

97.0.2 1. Original flag spaces and exact spectra

Fix the original monic polynomial $\chi \in \mathbb{C}[S]$ of degree $q \geq 1$. Work on

$$\mathcal{H} = \mathcal{P}_{2q} = \mathbb{C}[S]_{\leq 2q}, \quad n = 2q + 1, \quad \langle x, y \rangle_M = x^* M y, \quad M > 0. \quad (\text{FS1})$$

The inner product is conjugate-linear in its first slot. Let P_N be the M -orthogonal projection of $\mathcal{H}$ onto $\mathcal{P}_N$. Let Q_N be the M -orthogonal projection onto the literal relation space $\chi \mathcal{P}_{N-q}$, with $Q_{q-1} = 0$. In particular $P_{2q} = I$. Define

$$U = Q_{2q-1} + Q_{2q} - Q_q, \quad W = P_{2q-1} - P_{q-1} + P_{2q} - P_q, \quad D = U - W. \quad (\text{FS2})$$

All projections in each one of the two displayed flags commute: if $A \subset B$, their orthogonal projections satisfy $P_A P_B = P_B P_A = P_A$, as follows by decomposing into $A \oplus (B \cap A^\perp) \oplus B^\perp$.

Write

$$B_0 = \mathbb{C}\chi, \quad B_1 = \chi \mathcal{P}_{q-1}, \quad B_2 = \chi \mathcal{P}_q. \quad (\text{FS3})$$

Their dimensions are 1, q , $q + 1$, respectively, because multiplication by the nonzero polynomial χ is injective. The exact eigenspaces of U are

eigenvalue	eigenspace	dimension
0	$B_2^\perp$	q
1	$B_0 \oplus (B_2 \cap B_1^\perp)$	2
2	$B_1 \cap B_0^\perp$	$q - 1$.

(FS4)

Every direct sum in (FS4) is orthogonal. Applying the three projections of (FS2) to each of these spaces gives the stated eigenvalue, and the dimensions sum to $2q + 1$. For $q = 1$, $B_0 = B_1$, the last space is zero, and $U = Q_2$.

The exact eigenspaces of W are

eigenvalue	eigenspace	dimension	
0	$\mathcal{P}_{q-1}$	q	(FS5)
1	$(\mathcal{P}_q \cap \mathcal{P}_{q-1}^\perp) \oplus \mathcal{P}_{2q-1}^\perp$	2	
2	$\mathcal{P}_{2q-1} \cap \mathcal{P}_q^\perp$	$q - 1$.	

This follows by the same nested decomposition of the degree flag. Thus both operators have precisely the spectrum

$$0^{[q]}, \quad 1^{[2]}, \quad 2^{[q-1]}, \quad \text{Tr } U = \text{Tr } W = 2q, \quad \text{Tr } D = 0. \quad (\text{FS6})$$

The notation $a^{[r]}$ means an eigenvalue a of multiplicity r . No claim that the spectrum of their difference is fixed by these two individual spectra is made.

97.0.3 2. Best bound from the two individual spectra alone

Let C be any M -self-adjoint endomorphism with eigenvalues

$$c_1 \leq c_2 \leq \cdots \leq c_{2q+1}. \quad (\text{FS7})$$

For a rank- r orthogonal projection E , choose an orthonormal eigenbasis v_i of C , and put $a_i = \langle v_i, E v_i \rangle$. Then $0 \leq a_i \leq 1$, $\sum a_i = r$, and

$$\text{Tr}(EC) = \sum_i c_i a_i.$$

Transferring any positive weight from a lower coefficient to an available higher coefficient does not decrease this sum. Repeating gives the exact two-sided inequality

$$\sum_{i=1}^r c_i \leq \text{Tr}(EC) \leq \sum_{i=n-r+1}^n c_i. \quad (\text{FS8})$$

If the eigenvalues of C are distinct, equality on either side forces the corresponding spectral projection: a non-extremal weight transfer would otherwise strictly improve the sum, and a diagonal projection value zero or one forces the corresponding basis vector into its kernel or image.

For any self-adjoint operator with spectrum (FS6), its spectral projections satisfy

$$U = E_{\{U \geq 1\}} + E_{\{U=2\}}, \quad \text{rank } E_{\{U \geq 1\}} = q + 1, \quad \text{rank } E_{\{U=2\}} = q - 1. \quad (\text{FS9})$$

Applying (FS8) twice gives

$$\begin{aligned} \text{Tr}(UC) &\leq c_{q+1} + c_{q+2} + 2 \sum_{i=q+3}^{2q+1} c_i, \\ \text{Tr}(WC) &\geq c_q + c_{q+1} + 2 \sum_{i=1}^{q-1} c_i. \end{aligned} \quad (\text{FS10})$$

Subtracting, and then applying the same reasoning with U, W interchanged, proves

$$|\text{Tr}((U - W)C)| \leq B_q(c) := c_{q+2} - c_q + 2 \sum_{j=1}^{q-1} (c_{2q+2-j} - c_j). \quad (\text{FS11})$$

For $q = 1$, the sum is empty and the right side is exactly $c_3 - c_1$.

This is the best bound that uses only the individual spectra. To prove sharpness in that class, use the eigenbasis of C , put

$$u_i = \begin{cases} 0 & i \leq q, \\ 1 & i = q+1, q+2, \\ 2 & i \geq q+3, \end{cases} \quad U_* = \text{diag}(u_1, \dots, u_n), \quad W_* = \text{diag}(u_n, \dots, u_1). \quad (\text{FS12})$$

Both have spectrum (FS6), and direct multiplication gives $\text{Tr}((U_* - W_*)C) = B_q(c)$. Swapping them gives the negative equality. Their difference has the ordered spectrum

$$\lambda^* = (-2^{[q-1]}, -1, 0, 1, 2^{[q-1]}). \quad (\text{FS13})$$

These are exact independent-unitary-orbit equality fixtures. They do not yet assert realization by the two literal polynomial flags in (FS1)–(FS3).

97.0.4 3. Why the literal polynomial flags cannot attain nontrivial equality

Two exact polynomial identities govern the flag positions:

$$\mathcal{P}_{q-1} \cap B_2 = 0, \quad \mathcal{P}_q + B_2 = \mathcal{P}_{2q}. \quad (\text{FS14})$$

The first follows because a nonzero multiple of a degree- q polynomial has degree at least q . For the second, $B_2 \cap \mathcal{P}_q = \mathbb{C}\chi$: a nonconstant multiplier has degree above q . Thus the sum has dimension $(q+1) + (q+1) - 1 = 2q+1$, and is the whole space.

Let $U_2 = \ker(U - 2I)$, $W_2 = \ker(W - 2I)$, $U_0 = \ker U$, and $W_0 = \ker W$. Equations (FS4)–(FS5) and (FS14) imply

$$U_2 \cap W_0 = 0, \quad W_2 \cap U_0 = 0. \quad (\text{FS15})$$

For the first, $U_2 \subset B_1 \subset B_2$ whereas $W_0 = \mathcal{P}_{q-1}$. For the second, a vector in $W_2 \cap U_0$ is orthogonal to both $\mathcal{P}_q$ and B_2 ; their sum is the whole space by (FS14).

Here is the requested simple-spectrum obstruction. If equality held in the positive version of (FS11) with distinct c_i , both bounds in (FS10) would have to be equalities. The $U = 2$ eigenspace would be the span of the highest $q-1$ eigenvectors of C , and the kernel of W would be the span of the highest q . For $q \geq 2$, this contradicts the first equation in (FS15). For $q = 1$, the image of U would contain the highest eigenline, which is $\ker W = \mathcal{P}_0$. That would put the constant polynomial in $B_2 = \chi\mathcal{P}_1$, contrary to (FS14). The negative equality is treated by applying the same argument to $-C$.

In fact the inequality is strict for every nonscalar C , even when its spectrum has repeated eigenvalues. A full proof follows, retaining the spectral gaps rather than assuming they are nonzero individually.

For $1 \leq r < n$, let a_r be the sum of the largest r entries in (FS13). Applying (FS8) to U and W , with a rank- r projection E as the variable, gives

$$\text{Tr}(DE) \leq \sum_{i=n-r+1}^n u_i - \sum_{i=1}^r u_i = a_r. \quad (\text{FS16})$$

Equality is impossible in every nontrivial rank:

- For $1 \leq r \leq q-1$, equality requires $\text{im } E \subset U_2$ and $\text{im } E \subset W_0$, contradicting (FS15).
- For $r = q$ and $q \geq 2$, minimization of $\text{Tr}(WE)$ forces $\text{im } E = W_0$; maximization of $\text{Tr}(UE)$ forces that image to contain all of U_2 . Again (FS15) excludes it. If $q = r = 1$, the same equality instead forces $\mathcal{P}_0 \subset B_2$, excluded by (FS14).
- For $r = q+1$, the maximum of $\text{Tr}(UE)$ forces $\text{im } E = B_2$, since this is its complete positive spectral space. The minimum of $\text{Tr}(WE)$ forces $\text{im } E$ to contain $W_0 = \mathcal{P}_{q-1}$. Their intersection in (FS14) is zero, so this is impossible.
- For $q+2 \leq r \leq 2q$, use the complementary projection $I - E$, whose rank is between one and $q-1$. Since $\text{Tr } D = 0$, equality would require $\text{im}(I - E) \subset W_2 \cap U_0$, excluded by (FS15).

These equality conditions use only the spectral levels zero, one, and two of U, W ; their eigenspace descriptions follow by the same projection-weight argument proving (FS8).

The set of rank- r orthogonal projections is compact in finite dimension: it is closed and bounded in the matrix space by the equations $E^* = E$, $E^2 = E$, and $\text{Tr } E = r$. Hence the maximum in (FS16) is attained, and its failure to equal a_r proves strict inequality for that maximum. If $d_1 \leq \dots \leq d_n$ are the actual eigenvalues of D , (FS8) applied to D identifies this maximum. Therefore

$$\sum_{i=n-r+1}^n d_i < a_r \quad (1 \leq r < n), \quad \sum_i d_i = 0. \quad (\text{FS17})$$

For completeness, trace rearrangement for two arbitrary self-adjoint matrices follows by the same projection argument. In an eigenbasis of C , write

$$C = c_1 I + \sum_{r=1}^{n-1} (c_{n-r+1} - c_{n-r}) E_r,$$

where E_r projects onto its highest r eigenvectors, with any fixed choice inside a repeated eigenspace. The trace of the scalar term against D is zero, so (FS17) gives

$$\begin{aligned} \text{Tr}(DC) &\leq \sum_{r=1}^{n-1} (c_{n-r+1} - c_{n-r}) \sum_{i=n-r+1}^n d_i \\ &< \sum_{r=1}^{n-1} (c_{n-r+1} - c_{n-r}) a_r = B_q(c) \end{aligned} \quad (\text{FS18})$$

whenever C is nonscalar. At least one spectral gap is then positive, so the second inequality is strict. Applying the same proof to $-C$ gives

$|\text{Tr}(DC)| < B_q(c) \quad \text{for every nonscalar } C \text{ and every fixed } M > 0 \text{ on the literal polynomial flags.}$

(FS19)

For scalar C , both sides of (FS11) are zero and equality holds. This completely identifies actual finite positive-metric equality, while allowing the sharp supremum described next.

97.0.5 4. Explicit positive metrics approaching the bound on the unchanged polynomial flags

Keep the same original monic χ . The following ordered list is a basis of $\mathcal{P}_{2q}$:

$$b_i = S^i \quad (0 \leq i < q), \quad b_q = \chi, \quad b_{q+j} = \chi S^j \quad (1 \leq j \leq q). \quad (\text{FS20})$$

Its elements have strictly increasing degrees with leading coefficient one. Thus their first $N+1$ spans equal the original $\mathcal{P}_N$. Neither χ nor its coefficients have been changed.

Choose any retained positive mass $\mu > 0$ and any $\epsilon > 0$. Let $e_0, \dots, e_{2q}$ be the standard coordinate vectors, and define the actual linear isomorphism

$$\begin{aligned} T_\epsilon b_i &= e_i & (0 \leq i \leq q), \\ T_\epsilon b_{q+j} &= e_{q+j} + \epsilon e_{q+j} & (1 \leq j \leq q). \end{aligned} \quad (\text{FS21})$$

Its diagonal in the ordered basis is 1 on the first $q+1$ entries and ϵ on the last q , so its determinant is ϵ^q . Its inverse sends

$$e_i \mapsto b_i \quad (0 \leq i \leq q), \quad e_{q+j} \mapsto \epsilon^{-1}(b_{q+j} - b_{j-1}). \quad (\text{FS22})$$

Prescribe the positive coefficient metric by

$$\langle P, R \rangle_{M_\epsilon} = \mu \langle T_\epsilon P, T_\epsilon R \rangle_{\text{Euclidean}}. \quad (\text{FS23})$$

The map $\sqrt{\mu} T_\epsilon$ is its displayed isometry to the Euclidean space. In the original polynomial coefficients $P = \sum x_i b_i$, its complete norm is

$$\|P\|_{M_\epsilon}^2 = \mu \left(|x_q|^2 + \sum_{j=1}^q |x_{j-1} + x_{q+j}|^2 + \epsilon^2 \sum_{j=1}^q |x_{q+j}|^2 \right). \quad (\text{FS24})$$

In particular $\|1\|^2 = \|\chi\|^2 = \mu$, $\|\chi S^j\|^2 = \mu(1 + \epsilon^2)$, and $\langle S^{j-1}, \chi S^j \rangle = \mu$. Every unlisted cross pairing between the distinct two-coordinate blocks and b_q is zero. Each two-coordinate block has Gram

$$\mu \begin{pmatrix} 1 & 1 \\ 1 & 1 + \epsilon^2 \end{pmatrix}, \quad (\text{FS25})$$

whose determinant is $\mu^2 \epsilon^2 > 0$. The total Gram determinant in (FS20) is exactly $\mu^{2q+1} \epsilon^{2q}$. As (FS20) has determinant one relative to the increasing monomial basis, that is also the determinant there. The mass μ , all cross terms, and all powers of ϵ remain present.

Because (FS21) is triangular by degree, every transformed degree flag is the standard coordinate flag. Hence W , in these isometric coordinates, has value zero on $e_0, \dots, e_{q-1}$, value one on e_q, e_{2q} , and value two on $e_{q+1}, \dots, e_{2q-1}$. Put

$$v_j = \frac{e_{j-1} + \epsilon e_{q+j}}{\sqrt{1 + \epsilon^2}} \quad (1 \leq j \leq q). \quad (\text{FS26})$$

These vectors are orthonormal and orthogonal to e_q . The transformed relation flag has $B_0 = \mathbb{C}e_q$, $B_1 = \text{span}(e_q, v_1, \dots, v_{q-1})$, and $B_2 = \text{span}(e_q, v_1, \dots, v_q)$. Thus the exact transformed operator is

$$U = |e_q\rangle\langle e_q| + 2 \sum_{j=1}^{q-1} |v_j\rangle\langle v_j| + |v_q\rangle\langle v_q|. \quad (\text{FS27})$$

Here the normalization in (FS26) states an orthonormal coordinate map inside the specified metric; the original norms remain (FS24)–(FS25).

97.0.6 5. Fixed-spectrum self-adjoint control and its exact trace

For the prescribed ordered numbers in (FS7), define a diagonal operator C_0 in the transformed coordinates by

$$\begin{aligned} C_0 e_{j-1} &= c_{2q+2-j} e_{j-1}, & C_0 e_{q+j} &= c_j e_{q+j} & (1 \leq j < q), \\ C_0 e_{q-1} &= c_{q+2} e_{q-1}, & C_0 e_{2q} &= c_q e_{2q}, & C_0 e_q &= c_{q+1} e_q. \end{aligned} \quad (\text{FS28})$$

This lists each eigenvalue exactly once. Define $C_\epsilon = T_\epsilon^{-1} C_0 T_\epsilon$, an endomorphism of the original polynomial space. Equation (FS23) proves it is M_ϵ -self-adjoint with exactly those eigenvalues. Its polynomial-coordinate formula is also explicit. Set

$$a_j = c_{2q+2-j}, \quad b'_j = c_j \quad (1 \leq j < q), \quad a_q = c_{q+2}, \quad b'_q = c_q.$$

Then

$$\begin{aligned} C_\epsilon b_{j-1} &= a_j b_{j-1}, \\ C_\epsilon b_{q+j} &= b'_j b_{q+j} + (a_j - b'_j) b_{j-1} \quad (1 \leq j \leq q), \\ C_\epsilon b_q &= c_{q+1} b_q. \end{aligned} \quad (\text{FS29})$$

In fact this endomorphism in the original basis is independent of ϵ . Its self-adjointness for every metric (FS25) can be verified by multiplying each block: the product of its Gram with its matrix is $\mu \begin{pmatrix} a_j & a_j \\ a_j & a_j + \epsilon^2 b'_j \end{pmatrix}$, which is Hermitian.

Using (FS26)–(FS28), each of the first $q - 1$ two-coordinate blocks contributes

$$2 \frac{a_j + \epsilon^2 b'_j}{1 + \epsilon^2} - 2b'_j = \frac{2(a_j - b'_j)}{1 + \epsilon^2},$$

and the last contributes $(a_q - b'_q)/(1 + \epsilon^2)$. The e_q terms cancel with their equal coefficient one. Therefore the complete trace is

$$\boxed{\text{Tr}((U_\epsilon - W_\epsilon)C_\epsilon) = \frac{B_q(c)}{1 + \epsilon^2}.} \quad (\text{FS30})$$

This proves that (FS11) is a sharp supremum even with the original polynomial and relation flags held fixed, when arbitrary positive coefficient metrics are allowed to vary. For nonscalar C , it is never an attained maximum at a finite positive metric by (FS19). The limit $\epsilon = 0$ has Gram determinant zero by (FS25), so it is not an admissible equality metric.

The case $q = 1$ is present literally: $b_0 = 1, b_1 = \chi, b_2 = \chi S, T_\epsilon b_2 = e_0 + \epsilon e_2, W = I - |e_0\rangle\langle e_0|, U = |e_1\rangle\langle e_1| + |v_1\rangle\langle v_1|$, and (FS30) is $(c_3 - c_1)/(1 + \epsilon^2)$.

The difference operator in this family has the exact spectrum

$$\left(-\frac{2}{\sqrt{1 + \epsilon^2}}^{[q-1]}, -\frac{1}{\sqrt{1 + \epsilon^2}}, 0, \frac{1}{\sqrt{1 + \epsilon^2}}, \frac{2}{\sqrt{1 + \epsilon^2}}^{[q-1]} \right). \quad (\text{FS31})$$

To verify it, each first pair in (FS27) gives twice the difference of the rank-one projection onto v_j and that onto e_{q+j} . Its matrix has trace zero and determinant $-1/(1 + \epsilon^2)$, so its eigenvalues are $\pm 1/\sqrt{1 + \epsilon^2}$, before multiplication by two. The last pair has the same matrix without the factor two. The common vector e_q is in the zero eigenspace. This also shows directly how the extremal vector (FS13) is approached.

If it is desired that the chosen C_ϵ be an actual logarithmic derivative of a positive metric path, retain the same coefficient frame and define

$$M_\epsilon(t) = e^{tC_\epsilon^*/2} M_\epsilon e^{tC_\epsilon/2} = M_\epsilon e^{tC_\epsilon}. \quad (\text{FS32})$$

The first expression is positive for every real t . The equality follows from $C_\epsilon^* M_\epsilon = M_\epsilon C_\epsilon$, term by term in the exponential series. Differentiation gives $M_\epsilon(t)^{-1} \dot{M}_\epsilon(t) = C_\epsilon$, with no rescaling of its eigenvalues. A locally affine path $M_\epsilon + tM_\epsilon C_\epsilon$ gives the same derivative at zero and is positive whenever all $1 + tc_i$ are positive.

97.0.7 6. The moment-Gram class remains a stricter class

The original arithmetic and Gamma norms have the additional form

$$\langle P, R \rangle_m = \int_{\mathbb{R}} \overline{P(k/2 + iu)} R(k/2 + iu) m(u) du. \quad (\text{FS33})$$

For all polynomials for which the displayed products belong to the finite space, the literal vertical coordinate forces

$$\langle SP, R \rangle_m + \langle P, SR \rangle_m = k \langle P, R \rangle_m. \quad (\text{FS34})$$

Indeed the integrands on the left add the factor $\overline{k/2 + iu} + (k/2 + iu) = k$. The original mass is the value at $P = R = 1$. These relations are extra linear constraints on the coefficient Gram; positive definiteness by itself does not supply them.

The family (FS24) does not satisfy these moment constraints. Set $P = \chi, R = 1$; then SP has degree $q + 1 \leq 2q$. The exact family gives

$$\langle \chi, 1 \rangle_{M_\epsilon} = 0, \quad \langle S\chi, 1 \rangle_{M_\epsilon} = \mu. \quad (\text{FS35})$$

If $q \geq 2$, $S \in \mathcal{P}_{q-1}$ and its image under (FS21) is a coordinate vector orthogonal to $e_q = T_\epsilon \chi$; hence $\langle \chi, S \rangle = 0$. If $q = 1$, monicity writes $S = \chi - \chi(0)$, and $\langle \chi, S \rangle = \mu$. Thus the left side of (FS34) is μ for $q \geq 2$, and 2μ for $q = 1$, whereas its right side is zero. Since $\mu > 0$, neither case can be a moment Gram of the form (FS33), for any real vertical centre.

Consequently the family proves sharpness for arbitrary finite positive coefficient metrics and for the literal polynomial flags. It does not prove sharpness within the original arithmetic or Gamma moment-Gram class. The exact map (FS23) and the explicit violated relation (FS34) identify the relation between those classes, while preserving the original polynomial and its full relation space. No estimate on the original source multiplier, and no arithmetic equality fixture, is inferred from the larger class.

98 Complete independent four-window sharpness proof and fixed-metric optimum

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

98.0.1 Independent proof review of four-window spectral sharpness

Date: 13 September 2026. Accepted source: work/tau_four_window_spectral_sharpness_20260913.md, 18872 bytes, SHA-256 11c26c3bcfce135e1882190af9dc3a8f1e4e6487fd282cc252fa441fdf90651c. The complete FS1–FS35 proof was read. The projection and strictness arguments, the explicit coefficient-metric family, its control and difference spectra, and its stated arithmetic scope are accepted without correction.

The source relies on the finite spaces of work/tau_arithmetic_determinant_transport_20260913.tex, 17706 bytes, SHA-256 24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae. Those exact spaces, original source maps, and determinant transport were independently verified in work/tau_arithmetic_determinant_transport_independent_review_20260913.md, SHA-256 ce6b9fbdad43e5233b76756f5cbbbadf6aca0a33db62437f7caf0b90321683bb.

No closed AW, WS, or AT source or PDF was changed. This review is an additional complete proof body. It includes an exact refinement of the supplied family: its fixed-metric optimum over the prescribed control spectrum is computed explicitly below. No old test suite, Lean process, numerical moment calculation, or remote operation was used.

98.0.2 1. Literal flags, dimensions, and two exact individual spectra

Fix the original monic polynomial $\chi \in \mathbb{C}[S]$ of degree $q \geq 1$. Set $n = 2q + 1$, $\mathcal{H} = \mathcal{P}_{2q}$, and retain an arbitrary positive coefficient form M , with inner product x^*My . All projections and complements in this review use that same form. Let P_N project onto $\mathcal{P}_N$, and Q_N onto $\chi\mathcal{P}_{N-q}$, with $Q_{q-1} = 0$. Define

$$U = Q_{2q-1} + Q_{2q} - Q_q, \quad W = P_{2q-1} - P_{q-1} + I - P_q, \quad D = U - W. \quad (\text{SR1})$$

For nested subspaces $X \subset Y$, their orthogonal projections have products $P_X P_Y = P_Y P_X = P_X$. Indeed the orthogonal decomposition $X \oplus (Y \cap X^\perp) \oplus Y^\perp$ gives their diagonal actions. Thus each of the individual degree and relation flags is a commuting projection flag.

Set $B_0 = \mathbb{C}\chi$, $B_1 = \chi\mathcal{P}_{q-1}$, $B_2 = \chi\mathcal{P}_q$, of dimensions $1, q, q + 1$. These dimensions use injectivity of multiplication by the original nonzero polynomial. The relation flag decomposes $\mathcal{H}$ orthogonally into B_0 , $B_1 \cap B_0^\perp$, $B_2 \cap B_1^\perp$, and $B_2^\perp$. Substitution in SR1 shows that U has respective values $1, 2, 1, 0$. The degree flag similarly decomposes into $\mathcal{P}_{q-1}$, $\mathcal{P}_q \cap \mathcal{P}_{q-1}^\perp$, $\mathcal{P}_{2q-1} \cap \mathcal{P}_q^\perp$, and $\mathcal{P}_{2q-1}^\perp$; W has respective values $0, 1, 2, 1$. Consequently both operators have the precise spectrum

$$0^{[q]}, \quad 1^{[2]}, \quad 2^{[q-1]}, \quad \text{Tr } U = \text{Tr } W = 2q, \quad \text{Tr } D = 0. \quad (\text{SR2})$$

For $q = 1$, the multiplicity of two is zero; $B_0 = B_1$, and $U = Q_2$. These are sums of projections with the indicated weights; for $q > 1$ neither is an idempotent.

98.0.3 2. Trace rearrangement with all equality conditions needed later

Let A be self-adjoint with ordered eigenvalues $a_1 \leq \dots \leq a_n$. For a rank- r orthogonal projection E , choose an orthonormal eigenbasis v_i , and write $e_i = \langle v_i, Ev_i \rangle = \|Ev_i\|^2$. Then $0 \leq e_i \leq 1$, $\sum_i e_i = r$, and $\text{Tr}(AE) = \sum_i a_i e_i$.

The largest possible sum of these weights is the sum of the largest r eigenvalues. To see this directly, choose a threshold a_{n-r+1} . The mass on indices strictly below the threshold has nonpositive contribution after subtracting that threshold times r , and the mass above it contributes at most the sum of their full coefficients. Assigning weight one at the top r indices reaches the resulting bound. The analogous argument at the bottom gives

$$\sum_{i=1}^r a_i \leq \text{Tr}(AE) \leq \sum_{i=n-r+1}^n a_i. \quad (\text{SR3})$$

Equality on the upper side forces E to contain every eigenspace with eigenvalue strictly above the cutoff and be orthogonal to every eigenspace strictly below it. A diagonal value one gives $\|(I - E)v_i\|^2 = 0$; a value zero gives $Ev_i = 0$. The only free subspace is inside the eigenspace at the cutoff. The lower side has the reversed conditions. Thus this proof retains arbitrary repeated eigenvalues.

For a self-adjoint C with ordered eigenvalues $c_1 \leq \dots \leq c_n$, decompose U as its positive spectral projection plus its level-two projection, of ranks $q + 1$ and $q - 1$. Applying SR3 and doing the same for W yields

$$\begin{aligned} \text{Tr}(UC) &\leq c_{q+1} + c_{q+2} + 2 \sum_{i=q+3}^{2q+1} c_i, \\ \text{Tr}(WC) &\geq c_q + c_{q+1} + 2 \sum_{i=1}^{q-1} c_i. \end{aligned} \quad (\text{SR4})$$

Subtracting, and also reversing the two extrema, proves

$$|\text{Tr}(DC)| \leq B_q(c), \quad B_q(c) = c_{q+2} - c_q + 2 \sum_{j=1}^{q-1} (c_{2q+2-j} - c_j). \quad (\text{SR5})$$

For $q = 1$, this is $c_3 - c_1$. If only the two individual spectra in SR2 are prescribed, equality is attained by diagonal operators whose ordered entries are $u = (0^{[q]}, 1, 1, 2^{[q-1]})$ and its reversal, in an eigenbasis of C . Their difference has ordered eigenvalues

$$\lambda^* = (-2^{[q-1]}, -1, 0, 1, 2^{[q-1]}). \quad (\text{SR6})$$

Direct multiplication of the diagonal entries gives precisely SR5 with positive sign; exchanging the two operators gives the negative sign. This proves the claimed sharp value for that class of two independent spectral orbits.

98.0.4 3. The polynomial intersections exclude every nontrivial rank equality

The two needed positions of the literal polynomial subspaces follow solely from degrees:

$$\mathcal{P}_{q-1} \cap B_2 = 0, \quad \mathcal{P}_q + B_2 = \mathcal{H}. \quad (\text{SR7})$$

A nonzero multiple of χ has degree at least q , proving the first. In the second, $B_2 \cap \mathcal{P}_q = \mathbb{C}\chi$, because multiplication by a nonconstant polynomial has degree exceeding q . Its sum therefore has dimension $(q + 1) + (q + 1) - 1 = 2q + 1$, proving equality with the whole space.

Let $U_j = \ker(U - jI)$, $W_j = \ker(W - jI)$. The eigenspaces computed in Section 1 and SR7 imply

$$U_2 \cap W_0 = 0, \quad W_2 \cap U_0 = 0. \quad (\text{SR8})$$

The first uses $U_2 \subset B_2$ and $W_0 = \mathcal{P}_{q-1}$. For the second, a vector in $W_2 \cap U_0$ is orthogonal to both $\mathcal{P}_q$ and B_2 , hence to their whole sum.

Let a_r be the sum of the largest r entries of SR6, for $1 \leq r < n$. Applying SR3 separately to U and W gives, for every rank- r orthogonal projection E ,

$$\mathrm{Tr}(DE) \leq \sum_{i=n-r+1}^n u_i - \sum_{i=1}^r u_i = a_r. \quad (\text{SR9})$$

Equality in this subtraction requires equality in both component bounds; their two deficits are nonnegative. The exact equality conditions from SR3 now give the following exhaustive cases.

For $1 \leq r \leq q-1$, the maximum for U is $2r$ and the minimum for W is zero. Equality therefore requires $\mathrm{im} E \subset U_2 \cap W_0$, excluded by SR8.

For $r = q$ and $q \geq 2$, minimization for W forces $\mathrm{im} E = W_0$, because that kernel already has dimension q . Maximization for U forces the image to contain its entire level-two space of dimension $q-1 > 0$. This contradicts $U_2 \cap W_0 = 0$. At $q = r = 1$, the maximum for U instead says $\mathrm{im} E \subset B_2$, while the minimum for W says $\mathrm{im} E = \mathcal{P}_0$; SR7 excludes this case as well.

For $r = q+1$, the maximum for U forces the image to equal its entire positive spectral space B_2 : its dimension is exactly $q+1$. The minimum for W forces the image to contain $W_0 = \mathcal{P}_{q-1}$. Since $q \geq 1$, that subspace is nonzero, contradicting SR7.

For $q+2 \leq r \leq 2q$, put $F = I - E$, of rank $s = n - r$ with $1 \leq s \leq q-1$. Since $\mathrm{Tr} D = 0$ and the spectrum SR6 is invariant under negation, $a_r = a_s = 2s$. Equality in SR9 would force $\mathrm{Tr}(DF) = -2s$. The lower bound for U and upper bound for W then require $\mathrm{im} F \subset U_0 \cap W_2$, again excluded by SR8.

These arguments cover every rank including $q = 1$, and use the actual repeated eigenspaces of U, W ; they do not suppose that C has simple spectrum.

For a fixed positive M , the rank- r orthogonal projections form a compact set. Conjugation by the explicit isometry $M^{1/2}$ identifies it with the Euclidean self-adjoint idempotents of trace r , a closed bounded set in finite matrix dimension. Hence the continuous functional $\mathrm{Tr}(DE)$ attains its maximum. Since equality in SR9 is impossible, if $d_1 \leq \dots \leq d_n$ are the actual eigenvalues of D , SR3 applied to D gives

$$\sum_{i=n-r+1}^n d_i < a_r \quad (1 \leq r < n), \quad \sum_i d_i = 0. \quad (\text{SR10})$$

98.0.5 4. Strictness for every nonscalar control, with repeated eigenvalues retained

Choose one orthonormal eigenbasis of C , in any order inside a repeated eigenspace, and let E_r project onto its last r vectors. The exact expansion is

$$C = c_1 I + \sum_{r=1}^{n-1} (c_{n-r+1} - c_{n-r}) E_r. \quad (\text{SR11})$$

All coefficients are nonnegative. The scalar term has zero trace against D . Applying SR10 term by term therefore yields

$$\mathrm{Tr}(DC) < \sum_{r=1}^{n-1} (c_{n-r+1} - c_{n-r}) a_r = B_q(c) \quad (\text{SR12})$$

whenever C is nonscalar: at least one spectral gap is then strictly positive, and its corresponding inequality in SR10 is strict. The last equality follows by telescoping with the ordered zero-sum vector SR6, or by multiplying its entries with c_i . Applying the same argument to $-C$ proves the negative bound; its ordered eigenvalues are $-c_n, \dots, -c_1$, and the symmetry of SR6 gives the same $B_q(c)$. Hence

$$|\mathrm{Tr}(DC)| < B_q(c) \quad \text{for every nonscalar } C \text{ and every fixed } M > 0. \quad (\text{SR13})$$

For scalar C , both sides are zero. Every a_r is strictly positive, so SR11 also proves $B_q(c) > 0$ for every nonscalar C . This completes the repeated-spectrum part of FS19.

The finite strictness has an exact quantitative record: define

$$g_r(M) = a_r - \sum_{i=n-r+1}^n d_i > 0. \quad (\text{SR14})$$

Before making SR12 strict, its positive-side deficit satisfies

$$B_q(c) - \text{Tr}(DC) \geq \sum_{r=1}^{n-1} (c_{n-r+1} - c_{n-r})g_r(M) > 0. \quad (\text{SR15})$$

For the negative side use the expansion of $-C$ and its own ordered gaps against the same $g_r(M)$. This retains every spectral gap and proves exactly where strictness comes from. It supplies no uniform lower bound for those positive deficits as M varies.

98.0.6 5. The complete metric family on the unchanged polynomial flag

Retain every coefficient of the original χ . The ordered polynomials

$$b_i = S^i \ (0 \leq i < q), \quad b_q = \chi, \quad b_{q+j} = \chi S^j \ (1 \leq j \leq q) \quad (\text{SR16})$$

have increasing degrees and leading coefficient one. Their coordinate matrix relative to the monomial frame is triangular with determinant one, and each initial segment spans the original degree space.

Fix $\mu > 0, \epsilon > 0$. Define $T_\epsilon : \mathcal{H} \rightarrow \mathbb{C}^n$ by

$$T_\epsilon b_i = e_i \ (0 \leq i \leq q), \quad T_\epsilon b_{q+j} = e_{j-1} + \epsilon e_{q+j} \ (1 \leq j \leq q). \quad (\text{SR17})$$

It has determinant ϵ^q , and its inverse sends e_i to b_i for $i \leq q$, and e_{q+j} to $\epsilon^{-1}(b_{q+j} - b_{j-1})$. Substituting each basis vector into these two formulas verifies both inverse compositions.

Set $M_\epsilon = \mu T_\epsilon^* T_\epsilon$ as a form on the original polynomial coefficients. The explicit isometry to the Euclidean target is $\sqrt{\mu} T_\epsilon$. For $P = \sum_i x_i b_i$, its full norm is

$$\|P\|_{M_\epsilon}^2 = \mu \left(|x_q|^2 + \sum_{j=1}^q |x_{j-1} + x_{q+j}|^2 + \epsilon^2 \sum_{j=1}^q |x_{q+j}|^2 \right). \quad (\text{SR18})$$

The cross term in each two-coordinate block is retained. Each such block is $\mu \begin{pmatrix} 1 & 1 \\ 1 & 1 + \epsilon^2 \end{pmatrix}$, of determinant $\mu^2 \epsilon^2$, and the remaining b_q block is μ . Therefore

$$\det M_\epsilon = \mu^{2q+1} \epsilon^{2q}, \quad \|1\|^2 = \|\chi\|^2 = \mu, \quad \|\chi S^j\|^2 = \mu(1 + \epsilon^2), \quad \langle S^{j-1}, \chi S^j \rangle = \mu. \quad (\text{SR19})$$

The determinant is the same in the original monomial frame, by the unit determinant of SR16. All unlisted cross terms between different paired blocks or the b_q block are zero.

The map SR17 transports the degree flag to the standard coordinate flag. Thus W has values zero on $e_0, \dots, e_{q-1}$, one on e_q, e_{2q} , and two on $e_{q+1}, \dots, e_{2q-1}$. Define the orthonormal vectors

$$v_j = \frac{e_{j-1} + \epsilon e_{q+j}}{\sqrt{1 + \epsilon^2}} \quad (1 \leq j \leq q). \quad (\text{SR20})$$

They are orthogonal to one another and to e_q . The transformed relation spaces are spanned by e_q , then $e_q, v_1, \dots, v_{q-1}$, then $e_q, v_1, \dots, v_q$. Their projections therefore give

$$U = |e_q\rangle\langle e_q| + 2 \sum_{j=1}^{q-1} |v_j\rangle\langle v_j| + |v_q\rangle\langle v_q|. \quad (\text{SR21})$$

The unit vectors in SR20 describe the coordinate isometry; the original masses and norms remain SR18–SR19.

98.0.7 6. Prescribed spectrum, exact trace, and full difference spectrum

For prescribed ordered real numbers $c_1, \dots, c_n$, set

$$a_j = c_{2q+2-j}, \quad b'_j = c_j \quad (1 \leq j < q), \quad a_q = c_{q+2}, \quad b'_q = c_q. \quad (\text{SR22})$$

Give e_{j-1} eigenvalue a_j , e_{q+j} eigenvalue b'_j , and e_q eigenvalue c_{q+1} . This diagonal C_0 uses every prescribed eigenvalue exactly once. Its pullback $C_\epsilon = T_\epsilon^{-1}C_0T_\epsilon$ has, on each ordered pair (b_{j-1}, b_{q+j}) , matrix

$$\begin{pmatrix} a_j & a_j - b'_j \\ 0 & b'_j \end{pmatrix}. \quad (\text{SR23})$$

In particular its entries are independent of ϵ . Multiplication by the original Gram block gives

$$\mu \begin{pmatrix} 1 & 1 \\ 1 & 1 + \epsilon^2 \end{pmatrix} \begin{pmatrix} a_j & a_j - b'_j \\ 0 & b'_j \end{pmatrix} = \mu \begin{pmatrix} a_j & a_j \\ a_j & a_j + \epsilon^2 b'_j \end{pmatrix}, \quad (\text{SR24})$$

which is Hermitian because a_j, b'_j are real. This proves self-adjointness in every M_ϵ , retaining all masses and cross terms.

In the isometric coordinates, each paired block of D is

$$D_j = \frac{w_j}{1 + \epsilon^2} \begin{pmatrix} 1 & \epsilon \\ \epsilon & -1 \end{pmatrix}, \quad w_j = 2 \ (j < q), \quad w_q = 1. \quad (\text{SR25})$$

The common coordinate e_q has value zero. The diagonal C_0 therefore contributes $w_j(a_j - b'_j)/(1 + \epsilon^2)$ to the trace of each block. Summing proves

$$\text{Tr}(DC_\epsilon) = \frac{B_q(c)}{1 + \epsilon^2}. \quad (\text{SR26})$$

The unweighted matrix in SR25 has trace zero and determinant $-1/(1 + \epsilon^2)$. Its two eigenvalues are $\pm 1/\sqrt{1 + \epsilon^2}$. Including the weights gives the exact spectrum

$$\text{Spec } D = \left(-\frac{2}{\sqrt{1 + \epsilon^2}}^{[q-1]}, -\frac{1}{\sqrt{1 + \epsilon^2}}, 0, \frac{1}{\sqrt{1 + \epsilon^2}}, \frac{2}{\sqrt{1 + \epsilon^2}}^{[q-1]} \right). \quad (\text{SR27})$$

Superscripts in square brackets denote multiplicities, as in SR2, rather than powers. The case $q = 1$ simply has one paired block of weight one and one zero coordinate; SR26 is $(c_3 - c_1)/(1 + \epsilon^2)$.

For any nonscalar prescribed spectrum, SR26 tends to $B_q(c)$ as ϵ decreases to zero through positive values. Yet $\det M_\epsilon$ tends to zero by SR19, so the limiting form is outside the positive class. Together with SR13, this proves a sharp supremum and excludes an attained nontrivial maximum within the literal polynomial flags.

98.0.8 7. Additional exact fixed-metric optimum for this family

The source's chosen control in SR23 is independent of ϵ , and its trace is exactly SR26. The full difference spectrum SR27 also permits computing the optimum over all controls with the prescribed spectrum at any fixed $\epsilon > 0$.

Set $\rho = \sqrt{1 + \epsilon^2}$. On the j -th pair, define

$$f_j^+ = \frac{(\rho + 1)e_{j-1} + \epsilon e_{q+j}}{\sqrt{2\rho(\rho + 1)}}, \quad f_j^- = \frac{-\epsilon e_{j-1} + (\rho + 1)e_{q+j}}{\sqrt{2\rho(\rho + 1)}}. \quad (\text{SR28})$$

Their inner product is zero, and their squared norms are one because $(\rho + 1)^2 + \epsilon^2 = 2\rho(\rho + 1)$. Multiplication by the unscaled matrix $\begin{pmatrix} 1 & \epsilon \\ \epsilon & -1 \end{pmatrix}$ gives eigenvalues $+\rho$ and $-\rho$, respectively. Hence $D_j f_j^\pm = \pm(w_j/\rho) f_j^\pm$.

Define $\tilde{C}_0$ to assign a_j to f_j^+ , b'_j to f_j^- , and c_{q+1} to e_q , and pull it back to the original polynomial space by $T_\epsilon^{-1}\tilde{C}_0T_\epsilon$. This is a fully specified M_ϵ -self-adjoint operator with the required eigenvalue multiset. Its trace is

$$\text{Tr}(D\tilde{C}_\epsilon) = \frac{1}{\rho} \sum_j w_j(a_j - b'_j) = \frac{B_q(c)}{\sqrt{1 + \epsilon^2}}. \quad (\text{SR29})$$

For any other control with that spectrum, the spectral projection expansion SR11 and SR3 applied to D bound its trace above by the ordered pairing of its eigenvalues with SR27, which is the right side of SR29. Reversing the control assignment gives the corresponding negative bound. Thus the exact maximum of the absolute trace, at this fixed M_ϵ , is $B_q(c)/\sqrt{1 + \epsilon^2}$.

This additional formula preserves the correctness of the source's particular choice SR26. It computes the optimization left available when its prescribed spectrum is allowed a different self-adjoint realization. It remains in the same positive coefficient-metric family. Its full Ky Fan deficits are $g_r(M_\epsilon) = a_r(1 - 1/\sqrt{1 + \epsilon^2})$, by SR14 and SR27, where a_r here is the reference sum from SR9.

98.0.9 8. Metric-path realization and its literal mass

The source's fixed polynomial-coordinate operator C_ϵ satisfies $C_\epsilon^* M_\epsilon = M_\epsilon C_\epsilon$. Therefore

$$M_\epsilon(t) = e^{tC_\epsilon^*/2} M_\epsilon e^{tC_\epsilon/2} = M_\epsilon e^{tC_\epsilon} \quad (\text{SR30})$$

is positive for every real t . The equality follows by the exponential series and the stated intertwining. Differentiating gives $M_\epsilon(t)^{-1} \dot{M}_\epsilon(t) = C_\epsilon$. Thus the operator is an actual logarithmic derivative, with the same eigenvalues, on an explicit positive coefficient-metric path.

For the locally affine path $M_\epsilon + tM_\epsilon C_\epsilon$, positivity is equivalent to $1 + tc_i > 0$ for all prescribed eigenvalues, after the same explicit isometry. Its logarithmic derivative at zero is again C_ϵ .

For clarity, the fixed mass statement $\|1\|^2 = \mu$ holds across the parameter family $\epsilon > 0$ at $t = 0$. The path's original constant polynomial has eigenvalue c_n : this is $a_1 = c_{2q+1}$ for $q \geq 2$, and $a_q = c_3$ at $q = 1$. Consequently its literal norm along SR30 is μe^{tc_n} , and along the affine path is $\mu(1 + tc_n)$. No claim that those paths preserve mass in t is needed or made; these formulas give the actual factors.

98.0.10 9. Exact moment obstruction and the retained arithmetic scope

Put $N = 2q$. Let $\mathcal{M}_N$ be the real vector space of finite real signed measures ν satisfying $\int (1 + |u|^{2N}) d|\nu|(u) < \infty$. On a vertical line $S = k/2 + iu$, the real-linear moment map $\mathfrak{M}_k : \mathcal{M}_N \rightarrow \text{Herm}(\mathcal{P}_N)$ is

$$\mathfrak{M}_k(\nu)(P, R) = \int \overline{P(k/2 + iu)} R(k/2 + iu) d\nu(u). \quad (\text{SR31})$$

For a nonnegative measure the form is positive semidefinite, and it is positive definite when no nonzero polynomial in the source vanishes almost everywhere. The original positive densities satisfy this condition. For $P, R \in \mathcal{P}_{N-1}$, evaluation gives the real-linear constraint map $\mathcal{L}_k : \text{Herm}(\mathcal{P}_N) \rightarrow \text{Herm}(\mathcal{P}_{N-1})$,

$$\mathcal{L}_k(M)(P, R) := M(SP, R) + M(P, SR) - kM(P, R) = 0 \quad \text{when } M = \mathfrak{M}_k(\nu). \quad (\text{SR32})$$

Indeed $\overline{S(u)} + S(u) = k$ pointwise, so the three integrands cancel. In monomial coefficients, this linear map has entries $M_{i+1,j} + M_{i,j+1} - kM_{ij}$ wherever both shifted indices occur in the finite domain. Thus SR31 has image in the kernel of the explicitly typed linear map $\mathcal{L}_k$. This supplies the exact relation between moment forms and general coefficient forms.

In the constructed family take $P = \chi, R = 1$. All products belong to $\mathcal{P}_{2q}$, because $q + 1 \leq 2q$. Equations SR17–SR19 give

$$\langle \chi, 1 \rangle = 0, \quad \langle S\chi, 1 \rangle = \mu. \quad (\text{SR33})$$

For $q \geq 2$, $S = b_1$ is in the lower degree flag and is orthogonal to $b_q = \chi$, so $\langle \chi, S \rangle = 0$. At $q = 1$, writing the original monic polynomial as $\chi = S + \chi(0)$ gives $S = \chi - \chi(0)$, hence $\langle \chi, S \rangle = \mu$. The convention is conjugate-linear in the first slot and linear in the second; the coefficient $-\chi(0)$ multiplies the zero cross pairing, so no unretained conjugation occurs. Therefore

$$\mathcal{L}_k(M_\epsilon)(\chi, 1) = \begin{cases} \mu, & q \geq 2, \\ 2\mu, & q = 1. \end{cases} \quad (\text{SR34})$$

This is nonzero for every $\epsilon > 0, \mu > 0$, and the subtracted term is zero for every real center parameter k . Thus this family violates a necessary moment identity for every real vertical line, not only the particular arithmetic center.

The original Gamma and arithmetic source forms remain in the image of their actual measures under SR31, with masses $(2\pi)^{k/2}$ and μ_h^k , and with the original χ, η , and $\sigma_h^{\otimes k} \eta$ from the accepted AT source. The constructed M_ϵ is linked to its explicit coordinate model by SR17–SR19 and has the computed nonzero obstruction SR34. It therefore proves sharpness in the larger class of positive coefficient forms while proving no sharpness assertion for the original arithmetic moment class.

For each actual fixed positive moment Gram, the strict inequality SR13 still applies because its literal flags are the same and it belongs to the positive coefficient class. The approach-to-equality family supplied here cannot establish that the actual moment class approaches the same supremum: its obstruction SR34 persists at every finite parameter. No conclusion about a uniform arithmetic improvement or about the failure of the F1 or Tau Base program is drawn from this calibration.

98.0.11 10. Final findings

The strictness proof is valid for every nonscalar control, including arbitrary repeated spectra and $q = 1$. Both middle-rank equality cases and the complementary high-rank case are explicitly excluded by the two original polynomial intersections. The family preserves χ , its coefficient frame and relation flags, its base mass μ , every cross term, and all powers of ϵ . Its trace and full difference spectrum are correct. Its violation of the moment identity is exactly μ or 2μ on the stated pair.

The supplementary independent calculation of FS20–FS35 agreed with these block formulas and required no correction. SR28–SR29 additionally compute the exact prescribed-spectrum optimum for each fixed metric in this family. All these conclusions are add-only; the previously sealed AT proof and artifacts remain unchanged.

99 Complete analytic pole classes, connection, periods and endpoint transport

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

Exact revision. 6e8bba584c5788e0d1ea29127ace2d89d9a65a2e111da01df5870d9c9b57d1e7

Complete source. `sources/next_edition/analytic_pole_conversions_v2/sources/analytic_pole/ANALYTIC_POLE_RESIDUE_TRANSPORT.md`

Source SHA-256. 6e8bba584c5788e0d1ea29127ace2d89d9a65a2e111da01df5870d9c9b57d1e7

Current mathematical continuation. APU1–23 below are inserted into the complete original proof at the AP13–AP14 transition. Their source is `sources/current_boundary/fragments/analytic_pole_u_connection.tex`, SHA-256 1b42c530ccee6fd019b8536170277e3909ba43bfe4e3b2fefab3f7b9fc666c05. The preceding source record identifies the preserved historical body; the exact current body and reversible wrapper mapping are pinned by the boundary patch manifest.

99.0.1 Actual Taylor-unit gauge: analytic pole classes and their connection

13 September 2026. This continues UG1–19 on the original arithmetic packet. The accompanying derivation supplied the exact weighted-residue sequence and the connection on simple-pole lifts. This note proves those constructions in full, calculates their entire finite scaling transport and dual, and compares them with the already proved formal contraction. It does not substitute a new source, a new metric, a simple-root packet, or an assumed arithmetic bound.

99.0.2 1. Original input and the fixed nonzero-parameter complex

Keep the monic polynomial h of degree $d > 0$ with every selected actual zero order, $g = 2\xi$, and the unique polynomial ν of degree less than d representing the complete Taylor unit $v_h = j_h(g/h)$. Thus $\gcd(h, \nu) = 1$, and no factor of h or Taylor coefficient of its unit has been removed. Let P_ν be the set of distinct zeros of ν , and r its cardinality; $r = 0$ when ν is constant. The multiplicities of ν are retained in ν itself throughout the gauge.

Fix the original primitive Φ with $\Phi' = h$ and its specified additive constant. For $u \in \mathbb{C}^*$ and $t \in \mathbb{C}$ define

$$\begin{aligned} D &= u \frac{d}{ds} + h(s) - t, \\ w(s; u, t) &= \exp((\Phi(s) - ts)/u), \\ B &= \mathbb{C}[s], \quad B_{\text{loc}} = \mathbb{C}[s, \nu^{-1}], \quad M = B_{\text{loc}}/B. \end{aligned} \tag{AP1}$$

Use complexes $[B \xrightarrow{D} B ds]$ and $[B_{\text{loc}} \xrightarrow{D} B_{\text{loc}} ds]$ in degrees 0, 1. The equation $wDF = u(wF)'$ is literal, with the constant in Φ retained. Although w is entire and nowhere zero in s , it is not asserted rational. The quotient M consists exactly of finite sums of principal parts at P_ν : partial fractions gives existence and uniqueness, with the polynomial part discarded only in this explicitly specified quotient.

99.0.3 2. The entire additional pole cohomology is calculated

Define, for $[F] \in M$,

$$\text{Res}_w[F] = \left(\text{Res}_{s=p} w(s)F(s) ds \right)_{p \in P_\nu}. \quad (\text{AP2})$$

Adding a polynomial changes none of these residues. Also $\text{Res}_w D = 0$ by AP1, since a derivative of a meromorphic Laurent series has zero residue.

The exact sequence is

$$0 \longrightarrow M \xrightarrow{D} M \xrightarrow{\text{Res}_w} \mathbb{C}^{P_\nu} \longrightarrow 0. \quad (\text{AP3})$$

Here is a proof of every assertion. If F has pole order $n \geq 1$ at p and leading term $c(s-p)^{-n}$, DF has leading pole term $-unc(s-p)^{-n-1}$. Multiplication by $h-t$ has pole order at most n , so it cannot cancel this term. Thus $D[F] = 0$ in M implies that F has no poles, and $[F] = 0$. This proves injectivity.

For each p , the rational function $1/(w(p)(s-p))$ has residue vector equal to the p -th coordinate vector. It is analytic at every other point of P_ν . This proves surjectivity without suppressing the factor $w(p)$.

Suppose $\text{Res}_w[F] = 0$. In a disk at p containing no other point of P_ν , the Laurent series of wF has finitely many negative terms and no $(s-p)^{-1}$ term. Integrating term by term therefore gives a meromorphic primitive H_p , with no logarithm. Put $Q_p = H_p/(uw)$. Then $DQ_p = F$ locally. Let Q be the rational function obtained by summing the finite principal parts of the Q_p at all p . The difference $Q - Q_p$ is holomorphic at p , so $DQ - F$ is holomorphic there. This rational function has no other possible finite poles, hence is a polynomial. Therefore $D[Q] = [F]$ in M , which proves exactness in the middle. Changing any integration constant changes only a holomorphic local function and does not change this construction of the principal part.

All higher pole orders are explicitly observed, rather than ignored:

$$\begin{aligned} \text{Res}_p \frac{w(s)}{(s-p)^n} ds &= \frac{w^{(n-1)}(p)}{(n-1)!}, \\ D(s-p)^{-n} &= -un(s-p)^{-n-1} \\ &+ \sum_{j=0}^d \frac{h^{(j)}(p)}{j!} (s-p)^{j-n} - t(s-p)^{-n}. \end{aligned} \quad (\text{AP4})$$

These formulas give the triangular reduction of each higher pole while retaining every derivative of h and every derivative of w that contributes. They explain why there is one quotient coordinate per distinct pole point; they do not replace h by its radical or discard its nilpotent zero jets.

99.0.4 3. The original arithmetic classes inject into the analytic extension

The polynomial complex has $H^0 = 0$ and H^1 of dimension d , with basis $1, s, \dots, s^{d-1}$. Indeed, for a nonzero polynomial of degree n , the highest term of DF has degree $n + d$, with unchanged leading coefficient. Successive subtraction of such leading terms reduces every polynomial uniquely to degree less than d . Write this unchanged remainder module as H_{pol} .

The same highest-pole argument shows H^0 of the localized complex is zero: a rational solution of $DF = 0$ has no finite pole, and then the preceding polynomial argument applies. The short exact sequence of the three complexes, together with AP3, gives

$$0 \longrightarrow H_{\text{pol}} \xrightarrow{i} H_{\text{loc}} \xrightarrow{\text{Res}_w} \mathbb{C}^{P_\nu} \longrightarrow 0. \quad (\text{AP5})$$

One can check injectivity without a long exact sequence. If a polynomial F equals DQ for rational Q , the leading-pole calculation forces Q to be a polynomial. Thus no original polynomial cohomology class becomes a boundary. The kernel and surjectivity assertions follow from AP3 by subtracting DQ and retaining the resulting polynomial.

An explicit basis of H_{loc} is

$$1, s, \dots, s^{d-1}, \quad r_p = \frac{1}{s-p} \quad \text{for } p \in P_\nu. \quad (\text{AP6})$$

For existence, subtract $\sum_p (\text{Res}_w F)_p r_p / w(p)$. The remainder has zero weighted residues, and AP3 reduces it modulo D to a polynomial, then to degree less than d . For independence, applying AP2 to a linear combination forces every pole coefficient to vanish because $w(p) \neq 0$; injectivity in AP5 then gives independence of the polynomial coefficients. Hence $\dim H_{\text{loc}} = d + r$. The original d -dimensional arithmetic fibre, with all repeated roots of h , is present as the explicitly injected summand of this vector-space basis.

99.0.5 4. Actual parameter connection and both explicit residue frames

The differential operator $L = u \, d/dt - s$ commutes with D :

$$\left[u \frac{d}{dt}, D \right] = -u, \quad \left[-s, u \frac{d}{ds} \right] = u, \quad [-s, h - t] = 0. \quad (\text{AP7})$$

It therefore descends as a connection operator on the analytic family over $\mathbb{C}^* \times \mathbb{C}$, not as an unsupported multiplication endomorphism on the fixed de Rham quotient. Let $A(t)$ be the original companion matrix of $h - t$ in the polynomial frame, and let e_0 be its constant-polynomial column. Set

$$P = \text{diag}(p)_{p \in P_\nu}, \quad B_0 = (e_0 \quad \cdots \quad e_0), \quad (\text{AP8})$$

$$A_{\text{ext}}(t) = \begin{bmatrix} A(t) & B_0 \\ 0 & P \end{bmatrix}.$$

Here each pole basis vector satisfies the exact identity

$$L r_p = -\frac{s}{s - p} = -p r_p - 1. \quad (\text{AP9})$$

For the last polynomial vector, reduction of s^d uses $D(1) = h - t$, so the polynomial block is exactly the already specified $A(t)$, without a derivative correction. Thus in the full frame AP6 the connection is

$$L = u \frac{d}{dt} - A_{\text{ext}}(t). \quad (\text{AP10})$$

All coefficients depend holomorphically on (u, t) for $u \neq 0$. In fact A_{ext} itself has no singular u coefficient; this statement about the matrix does not identify its rank- $(d + r)$ frame with the formal cohomology at $u = 0$.

Put $W = \text{diag}(w(p; u, t))$. The residue map in AP6 is the rectangular matrix

$$\text{Res}_w = \begin{bmatrix} 0 & W \end{bmatrix}, \quad u \frac{dW}{dt} = -PW. \quad (\text{AP11})$$

For parameter-dependent representatives direct differentiation proves

$$u \frac{d}{dt} \text{Res}_w[F] = \text{Res}_w \left[\left(u \frac{d}{dt} - s \right) F \right]. \quad (\text{AP12})$$

Thus the quotient connection in weighted-residue coordinates is $u \, d/dt$. The ordinary simple-pole coefficients instead have $u \, d/dt - P$. Their exact transition is multiplication by W , not deletion of an exponential phase.

For completeness use the second frame $r_p/w(p)$. Its residue coordinates are the standard coordinate vectors, and

$$L \left(\frac{r_p}{w(p)} \right) = -\frac{1}{w(p)}. \quad (\text{AP13})$$

The pole diagonal becomes zero while its coupling to the original polynomial class is $-e_0/w(p)$. This is the same connection under the explicit diagonal frame map $\text{diag}(I_d, W^{-1})$; no factor has been set to one in the original frame.

99.0.6 The complete two-parameter connection on the original analytic pole extension

This calculation continues AP1–26 with its original monic h of degree $d > 0$, primitive $\Phi' = h$, full Taylor representative ν of $j_h(g/h)$, and localization $\mathbb{C}[s, \nu^{-1}]$. The polynomial ν and its complete multiplicities are fixed; its distinct pole points $P_\nu = \{p : \nu(p) = 0\}$ do not vary with u or t . Write $r = \#P_\nu$, $n = d + 1$, and

$$f(s, t) = \Phi(s) - ts, \quad D = u\partial_s + h(s) - t, \quad w(s; u, t) = e^{f(s, t)/u}. \quad (\text{APU1})$$

All formulas below are on $S = \mathbb{C}_u^\times \times \mathbb{C}_t$. The original coefficient frame in AP6 is

$$(1, s, \dots, s^{d-1}, (r_p)_{p \in P_\nu}), \quad r_p = (s - p)^{-1}. \quad (\text{APU2})$$

The free polynomial submodule, the localized module, and their quotient are the actual cohomology modules in AP5. In particular there is no new source frame that discards their extension.

Degree-correct chain connections. On both the polynomial and localized complexes, in degree $j = 0, 1$, define

$$\nabla_u^j = \partial_u - \frac{f}{u^2} + \frac{1-j}{u}, \quad \nabla_t^j = \partial_t - \frac{s}{u}. \quad (\text{APU3})$$

Multiplication by f and differentiation in the parameters preserve the stated localization, since all poles are fixed. The two connections are actual cochain maps:

$$\nabla_u^1 D = D \nabla_u^0, \quad \nabla_t^1 D = D \nabla_t^0. \quad (\text{APU4})$$

Indeed $\partial_u D - D \partial_u = \partial_s, [-f/u^2, D] = f_s/u = (h-t)/u$, and $D/u = \partial_s + (h-t)/u$; their three terms cancel in the first identity. For the second, $[\partial_t, D] = -1$ and $[-s/u, D] = 1$. The original degree-zero $1/u$ term is essential in the first cancellation. Their curvature vanishes in each degree:

$$[\nabla_u^j, \nabla_t^j] = 0. \quad (\text{APU5})$$

The only nonzero terms are $[\partial_u, -s/u] = s/u^2$ and $[-f/u^2, \partial_t] = f_t/u^2 = -s/u^2$. The scalar $(1-j)/u$ commutes with ∇_t^j . Thus the descended connection is flat on the original two-parameter family, with no commutation assertion inferred from pointwise matrix coincidence.

Every coefficient of the u -connection. For $0 \leq b < d$, perform the original monic polynomial division

$$f(s, t)s^b = (h(s) - t)q_b(s, t) + c_b(s, t), \quad \deg c_b < d.$$

Here $\deg q_b \leq b + 1$, so $\deg q'_b \leq b < d$. Let $C(t)$ have coefficient column c_b and $B(t)$ have coefficient column q'_b , both in the original ascending polynomial frame. Subtraction of Dq_b gives the exact differential remainder $[fs^b] = [c_b - uq'_b]$. Therefore the polynomial block is

$$\Omega_{\text{pol}} = -\frac{C(t)}{u^2} + \frac{B(t)}{u}. \quad (\text{APU6})$$

This is the full polynomial connection from the marked-family calculation, with its derivative correction retained.

For a fixed $p \in P_\nu$, set

$$f_p(t) = f(p, t), \quad q_p(s, t) = \frac{f(s, t) - f(p, t)}{s - p}, \quad Q_p(s, t) = q_p(s, t) - \frac{h(s) - t}{n}. \quad (\text{APU7})$$

Since h is monic of degree d , the leading coefficient of Φ is $1/n$. Thus q_p has degree d and leading coefficient $1/n$; its ordinary quotient by $h-t$ is precisely the constant $1/n$, and Q_p has degree less than d . The derivative of this quotient is zero. Subtracting $D(1/n)$ therefore proves the full differential-remainder equality $[q_p] = [Q_p]$, at every $u \neq 0$ and every t . Now the literal rational identity $fr_p = q_p + f_p r_p$ gives

$$\nabla_u^1[r_p] = -\frac{[Q_p]}{u^2} - \frac{f_p[r_p]}{u^2}. \quad (\text{APU8})$$

No higher-pole or derivative term is omitted: fixed p implies $\partial_u r_p = \partial_t r_p = 0$, and the only polynomial quotient just computed is constant.

Let $Q(t)$ be the d -by- r matrix of these exact Q_p columns and $F(t) = \text{diag}(f_p(t))$. Retain $A(t)$, $B_0 = (e_0, \dots, e_0)$, and $P = \text{diag}(p)$ from AP8. The complete coefficient connections in the frame APU2 are

$$\begin{aligned} \nabla_u &= \partial_u + \Omega_u, & \Omega_u &= \begin{bmatrix} -C(t)/u^2 + B(t)/u & -Q(t)/u^2 \\ 0 & -F(t)/u^2 \end{bmatrix}, \\ \nabla_t &= \partial_t + \Omega_t, & \Omega_t &= -\frac{1}{u} \begin{bmatrix} A(t) & B_0 \\ 0 & P \end{bmatrix}. \end{aligned} \quad (\text{APU9})$$

The second formula is exactly AP10 divided by u , not a change of its connection convention.

The off-diagonal flatness can also be checked directly in these original coefficient matrices. First,

$$\partial_t Q_p = -\frac{d}{n} e_0, \quad B(t) e_0 = \frac{1}{n} e_0.$$

The first identity differentiates APU7, using $\partial_t q_p = -1$; the second uses the constant derivative of the leading linear quotient of f by $h - t$. Also reducing

$$(s - p)Q_p = f - f_p - \frac{(s - p)(h - t)}{n}$$

modulo the original polynomial $h - t$ proves

$$(A(t) - pI_d)Q_p = C(t)e_0 - f_p e_0. \quad (\text{APU10})$$

Consequently the upper-right curvature block equals

$$\frac{B_0 + \partial_t Q - BB_0}{u^2} + \frac{CB_0 + QP - AQ - B_0 F}{u^3} = 0.$$

The lower-right curvature is zero because $F_t = -P$; the polynomial block is flat by APU4–5. This proves the matrix curvature identity $\partial_u \Omega_t - \partial_t \Omega_u + [\Omega_u, \Omega_t] = 0$ with every extension column retained.

Weighted residues, oriented loops, and their exact horizontal maps. Preserve separately the two actual matrices

$$W_{\text{res}}(u, t) = \text{diag}(e^{f_p(t)/u}), \quad W_{\text{loop}}(u, t) = (2\pi i)W_{\text{res}}(u, t). \quad (\text{APU11})$$

The first is the matrix W in AP11: its rectangular map $\mathcal{R} = [0 \ W_{\text{res}}]$ is the weighted residue, with no $2\pi i$ in its definition. The second gives the positively oriented small-loop period map $\mathcal{L} = [0 \ W_{\text{loop}}] = (2\pi i)\mathcal{R}$. Direct differentiation gives

$$\partial_u W_{\text{res}} = -FW_{\text{res}}/u^2, \quad \partial_t W_{\text{res}} = -PW_{\text{res}}/u, \quad \partial_u \mathcal{R} = \mathcal{R}\Omega_u, \quad \partial_t \mathcal{R} = \mathcal{R}\Omega_t. \quad (\text{APU12})$$

The same equations hold for $\mathcal{L}$. Equivalently, for every parameter-dependent rational representative $a(s; u, t)$,

$$\partial_u \text{Res}_w[a] = \text{Res}_w[\nabla_u^1 a], \quad \partial_t \text{Res}_w[a] = \text{Res}_w[\nabla_t^1 a].$$

To prove these equalities, use $\partial_u w = -(f/u^2)w$ and $\partial_t w = -(s/u)w$ in its convergent Laurent expansion on a circle containing that fixed pole and no other pole. Parameter differentiation and the finite contour integral commute. These identities descend because both residue maps kill D -boundaries by AP1. Thus AP5 is an exact sequence of the actual flat connections in both parameters: its polynomial inclusion is horizontal and its weighted-residue quotient has the ordinary trivial connection.

The explicit AP13 frame comparison remains available: replace only the pole columns by $r_p/w(p)$, through the displayed matrix $\text{diag}(I_d, W_{\text{res}}^{-1})$. In that frame their exact derivatives are

$$\nabla_u[r_p/w(p)] = -[Q_p]/(u^2 w(p)), \quad \nabla_t[r_p/w(p)] = -e_0/(uw(p)). \quad (\text{APU13})$$

The pole diagonal terms cancel against derivatives of the displayed inverse weights. The off-diagonal polynomial extension remains, with its full inverse exponential in both directions.

For the unchanged rapid-decay contours and positively oriented small loops of AP19–19b, their complete period matrix satisfies

$$\partial_u \Pi_{\text{ext}} = \Pi_{\text{ext}} \Omega_u, \quad \partial_t \Pi_{\text{ext}} = \Pi_{\text{ext}} \Omega_t. \quad (\text{APU14})$$

Here the contours can be held fixed locally in an admitted u -sector: smaller compact subsectors retain the same decaying ends; their finite detours avoid the fixed poles. The negative leading exponential dominates its polynomial derivatives and simple-pole factors uniformly on compact parameter subsets. This proves differentiation under the integral. The differential relations integrate to zero at the decaying ends or around the closed loops, so APU6–8 give the stated matrices. The lower period block is exactly W_{loop} , and the determinant remains the full AP19a expression

$$\det \Pi_{\text{ext}} = \det \Pi_{\text{pol}} (2\pi i)^r \exp \left(\frac{\sum_{p \in P_\nu} f_p(t)}{u} \right). \quad (\text{APU15})$$

In particular its u -derivative is fixed by $\partial_u \det \Pi_{\text{ext}} = (\text{Tr } \Omega_u) \det \Pi_{\text{ext}}$; the polynomial trace, every pole phase, and the $2\pi i$ factors retain their original values.

The full Taylor gauge and its dual commute with the new connection. The original cochain isomorphism multiplies both degrees by the complete polynomial ν , with inverse ν^{-1} , and has

$$D^\nu = \nu D \nu^{-1} = u \partial_s + h - t - u \nu' / \nu.$$

Because ν is fixed in both parameters, it commutes with ∇_u^j and ∇_t^j in APU3. Conjugating APU4–5 therefore proves the same chain and flatness identities for D^ν . In the actual transported frame

$$(\nu, \nu s, \dots, \nu s^{d-1}, (\nu/(s-p))_{p \in P_\nu})$$

the matrices are exactly APU9. The target weight is w/ν , and

$$(w/\nu)(\nu a) = wa, \quad (w/\nu)D^\nu a = u((w/\nu)a)'. \quad (\text{APU16})$$

These prove preservation of every old contour and every loop period, including all multiplicities of ν . If $\nu/(s-p)$ has no rational pole, its weighted form still equals $w/(s-p)$. The loop class and its original weighted pole are thereby retained.

For the ordinary linear dual, the two connections are $\partial_u - \Omega_u^T$ and $\partial_t - \Omega_t^T$. The injection of the weighted-residue dual is $\mathcal{R}^T$. Transposing APU12 gives

$$(\partial_u - \Omega_u^T)(\mathcal{R}^T a) = \mathcal{R}^T \partial_u a, \quad (\partial_t - \Omega_t^T)(\mathcal{R}^T a) = \mathcal{R}^T \partial_t a. \quad (\text{APU17})$$

Thus its full two-parameter horizontality is proved, with no positive pairing inferred from an algebraic dual. The dual of the Taylor gauge is the inverse transpose of its actual multiplication map, preserving the inverse unit.

The exact endpoint arrow to the original arithmetic source. The singular u -connection is specified on $u \neq 0$. Its comparison with the original marked endpoint uses the actual arrow already calculated in AP23–26. Since $\gcd(h, \nu) = 1$, each retained pole satisfies $h(p) \neq 0$. Set

$$R_p(s) = -\frac{h(s) - h(p)}{(s-p)h(p)}, \quad Q_0 = (R_p)_{p \in P_\nu}, \quad J_0 = [I_d \ Q_0]. \quad (\text{APU18})$$

The polynomial identity $(s-p)R_p = 1 - h(s)/h(p)$ proves that R_p is the exact image of r_p in $E_h = \mathbb{C}[s]/h$. Thus J_0 sends every pole coordinate and every polynomial coordinate to its original marked class, with all jets of h retained. It has the exact kernel $\{(-Q_0 c, c) : c \in \mathbb{C}^r\}$ and satisfies

$$J_0 A_{\text{ext}}(0) = A(0) J_0. \quad (\text{APU19})$$

These identities follow by multiplying the preceding polynomial inverse by s , exactly as in AP25. No value of the singular matrix Ω_u at $u = 0$ is assigned by this endpoint arrow.

For completeness its original theta-source representative is also explicit. Retain the original even Schwartz source V , rapid-decay target $\mathcal{B}$, theta map $\Theta \phi(x) = 2 \sum_{a \geq 1} \phi(ax)$, Euler operator $\mathcal{D} = -x \partial_x$, and seed

$$\phi_* = (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2}, \quad \mathcal{M} \Theta \phi_* = g.$$

The original Euler inverse $F_h \in \mathcal{B}$ satisfies $h(\mathcal{D})F_h = \Theta \phi_*$ and $\mathcal{M} F_h = g/h$. The polynomial chain map is the original

$$P \longmapsto P(\mathcal{D})\phi_*, \quad P ds \longmapsto P(\mathcal{D})F_h, \quad \Theta P(\mathcal{D})\phi_* = (hP)(\mathcal{D})F_h. \quad (\text{APU20})$$

Consequently the coefficient map

$$\Psi_h : E_h \longrightarrow Q_{\text{ar}} = \mathcal{B}/\Theta V, \quad [P] \longmapsto [P(\mathcal{D})F_h] \quad (\text{APU21})$$

is well defined: replacing P by $P + hT$ changes its source representative by $\Theta T(\mathcal{D})\phi_*$. The original Mellin-jet map sends it to $j_h(g/h)[P] = [\nu][P]$. Since $[\nu]$ is the full invertible Taylor class, this proves injectivity on the original packet. Equivalently, with the retained corrected section $\sigma_h = \Psi_h[\nu]^{-1}$, it is $\Psi_h = \sigma_h[\nu]$. The complete endpoint-source arrow is therefore

$$\mathbb{C}^{d+r} \xrightarrow{J_0} E_h \xrightarrow{[\nu]} E_h \xrightarrow{\sigma_h} Q_{\text{ar}}, \quad v \longmapsto [(J_0 v)(\mathcal{D})F_h]. \quad (\text{APU22})$$

All inverse Taylor coefficients are those of the original $[\nu]^{-1}$; they have not been replaced by a constant. Since multiplication by $[\nu]$ commutes with the original $A(0)$, APU19 intertwines the displayed endpoint action with this actual theta-source action. On the transported gauge fibre the coefficient is $[\nu]J_0 v$, whose image under σ_h is the same source vector. This is the precise unit and endpoint comparison for the original rational pole extension.

Backward propagation through the entire finite scaling transport. Retain AP15–19b’s exact transport, for every complex a ,

$$C_{\text{ext},a}(u, t) = \Pi_{\text{ext}}(u, t)^{-1} \Pi_{\text{ext}}(u, t + ua), \quad \partial_a C_{\text{ext},a} = -C_{\text{ext},a} A_{\text{ext}}(t + ua).$$

Its invertible diagonal blocks and full upper-right integral are the ones in AP15; this paragraph propagates APU9 through that already existing finite map. Put $t_a = t + ua$. At fixed a , the exact two parameter derivatives are

$$\begin{aligned} \partial_u C_{\text{ext},a} &= -\Omega_u(u, t) C_{\text{ext},a} \\ &\quad + C_{\text{ext},a} (\Omega_u(u, t_a) + a\Omega_t(u, t_a)), \\ \partial_t C_{\text{ext},a} &= -\Omega_t(u, t) C_{\text{ext},a} + C_{\text{ext},a} \Omega_t(u, t_a). \end{aligned} \quad (\text{APU23})$$

To prove every term, differentiation of $\Pi_{\text{ext}}^{-1} \Pi_{\text{ext}} = I$ and APU14 gives

$$\partial_u \Pi_{\text{ext}}^{-1} = -\Omega_u \Pi_{\text{ext}}^{-1}, \quad \partial_t \Pi_{\text{ext}}^{-1} = -\Omega_t \Pi_{\text{ext}}^{-1}.$$

The derivative of the shifted factor is, by the ordinary chain rule and APU14,

$$\partial_u (\Pi_{\text{ext}}(u, t + ua)) = \Pi_{\text{ext}}(u, t + ua) (\Omega_u(u, t + ua) + a\Omega_t(u, t + ua)),$$

whereas its t -derivative is $\Pi_{\text{ext}}(u, t + ua) \Omega_t(u, t + ua)$. Multiplying these inverse and shifted derivatives proves APU23. In particular the $a\Omega_t$ term is the derivative of the actual shifted parameter and cannot be omitted. Equivalently, under the precise base map $F_a : S \rightarrow S$, $F_a(u, t) = (u, t + ua)$, the pulled-back connection has coefficients $\Omega_u(u, t_a) + a\Omega_t(u, t_a)$ and $\Omega_t(u, t_a)$; the matrix $C_{\text{ext},a}$ is the horizontal map from that pullback to the unshifted coefficient bundle, by APU23.

The original weighted-residue identity AP18 uses the rectangular matrix $\mathcal{R} = [0 \ W_{\text{res}}]$:

$$\mathcal{R}(u, t) C_{\text{ext},a}(u, t) = \mathcal{R}(u, t + ua).$$

It remains horizontal in both parameters. In fact its left-hand u -derivative is, by APU12 and APU23,

$$\begin{aligned} \mathcal{R}(u, t) \Omega_u(u, t) C_{\text{ext},a} + \mathcal{R}(u, t) \partial_u C_{\text{ext},a} \\ = \mathcal{R}(u, t + ua) (\Omega_u(u, t + ua) + a\Omega_t(u, t + ua)), \end{aligned}$$

which is the exact u -derivative of the right side by APU12 and the same chain rule. The t -derivative is $\mathcal{R}(u, t + ua) \Omega_t(u, t + ua)$, by the two cancelling unshifted terms in the identical calculation. Multiplication by the constant $2\pi i$ proves these same compatibilities for the positively oriented loop-period map $\mathcal{L}$. Thus the finite scaling, its full extension integral, both parameter derivatives, and both residue conventions all remain in the same original commuting diagrams.

For constant ν , the set P_ν is empty and every additional block, residue coordinate and loop row in APU7–23 is the unique empty map; the polynomial connection remains unchanged. For a nonempty pole set, all coefficient-face maps act on these matrices slot by slot. Constant zero insertion commutes with both parameter derivatives and every displayed coefficient map; hence the independent original support labels and their represented zeros are retained by the entire two-parameter calculation.

99.0.7 5. Entire finite scaling and its retained extension term

Let $C_a(u, t)$ be the original polynomial scaling transport, satisfying

$$\frac{dC_a}{da} = -C_a A(t + ua), \quad C_0 = I_d. \quad (\text{AP14})$$

It is the previously proved entire solution, including its full higher terms. Define an integral along the straight segment from 0 to a in the complex a -plane (equivalently the primitive of its entire integrand):

$$\begin{aligned} K_a &= - \int_0^a C_b(u, t) B_0 \exp(-(a-b)P) db, \\ C_{\text{ext},a} &= \begin{bmatrix} C_a & K_a \\ 0 & \exp(-aP) \end{bmatrix}. \end{aligned} \quad (\text{AP15})$$

Differentiating the integral gives $K'_a = -C_a B_0 - K_a P$ and $K_0 = 0$. Consequently

$$\frac{dC_{\text{ext},a}}{da} = -C_{\text{ext},a} A_{\text{ext}}(t + ua), \quad C_{\text{ext},0} = I_{d+r}. \quad (\text{AP16})$$

Existence and uniqueness for this finite polynomial-coefficient matrix ODE prove that these are the actual entire finite connection transports. The block integral retains the coupling into the original polynomial class. Both diagonal blocks are invertible, and the inverse has upper-right block $-C_a^{-1} K_a \exp(aP)$. The groupoid law is

$$C_{\text{ext},a}(u, t) C_{\text{ext},b}(u, t + ua) = C_{\text{ext},a+b}(u, t). \quad (\text{AP17})$$

It follows either by the shifted ODE and uniqueness, or from the commuting operator's formal flow $\exp(aL)F = e^{-as}F(u, t + ua, s)$. The latter is coefficientwise in a when F is rational; no claim that $e^{-as}F$ is itself a rational function at a nonzero complex a is needed. The finite matrix ODE supplies its entire cohomological continuation.

The residue quotient has the exact transport identity

$$\begin{bmatrix} 0 & W(u, t) \end{bmatrix} C_{\text{ext},a}(u, t) = \begin{bmatrix} 0 & W(u, t + ua) \end{bmatrix}, \quad (\text{AP18})$$

because $w(p; u, t + ua) = w(p; u, t)e^{-ap}$. In weighted residues the entire action is parameter translation; in the unchanged simple-pole frame the factor e^{-ap} remains. The exponentials and their polynomial extension K_a are both displayed, including the case when p is not real.

99.0.8 6. Small-loop periods, the actual unit gauge and dual maps

For a positively oriented small circle γ_p enclosing only p , the exact additional period is

$$\int_{\gamma_p} wF ds = 2\pi i (\text{Res}_w F)_p. \quad (\text{AP19})$$

Thus the extra periods are concrete loops, with their orientation and $2\pi i$ factor retained. Every original polynomial image has zero such loop period. For any original rapid-decay contour avoiding P_ν , the incoming polynomial period is still its old integral, with its original ray orientation and phase.

Choose the finite parts of the original d rapid-decay contours to avoid every point of P_ν , including zero when zero belongs to that set. Such detours leave their polynomial integrals unchanged, since those integrands are entire. Different detours for a rational integrand can add the small loops AP19; those are retained rows, not discarded contour ambiguities. At infinity w has the same decay on the specified rays as in the original polynomial period proof, and the simple-pole functions are $O(1/s)$, so all new integrals converge. On compact parameter subsets in an admitted u -sector and bounded t , the negative leading exponential dominates the lower terms and justifies differentiation.

In the unchanged AP6 frame these d contours followed by the r small loops give the full period matrix

$$\Pi_{\text{ext}} = \begin{bmatrix} \Pi_{\text{pol}} & V_{\text{pole}} \\ 0 & (2\pi i)W \end{bmatrix}, \quad (\text{AP19a})$$

$$\det \Pi_{\text{ext}} = \det \Pi_{\text{pol}} (2\pi i)^r \prod_p w(p).$$

Π_{pol} is the original full polynomial period matrix, whose nonzero determinant was proved by the monomial ray matrix and coefficient-connection transport. Hence AP19a is invertible: it realizes all $d+r$ analytic classes and all their loop periods. Integrals of D -exact forms vanish at the decaying endpoints or on closed loops. Differentiating with t therefore gives

$$\frac{d\Pi_{\text{ext}}}{dt} = -\Pi_{\text{ext}} A_{\text{ext}}(t)/u, \quad (\text{AP19b})$$

$$C_{\text{ext},a} = \Pi_{\text{ext}}(u, t)^{-1} \Pi_{\text{ext}}(u, t + ua).$$

The second identity follows from the same ODE and initial value as AP16, for fixed nonzero u in the admitted sector. No period matrix is evaluated at $u = 0$.

On the same localized complex define the actual gauge differential

$$D^\nu = \nu D \nu^{-1} = u \frac{d}{ds} + h - t - u \frac{\nu'}{\nu}. \quad (\text{AP20})$$

The cochain map is multiplication by ν in both degrees. Its inverse is multiplication by ν^{-1} in B_{loc} . The target weight is w/ν , and the identities

$$\begin{aligned} (w/\nu) D^\nu F &= u((w/\nu)F)', \\ (w/\nu)(\nu F) &= wF \end{aligned} \quad (\text{AP21})$$

show exact equality of every small-loop and every old rapid-decay period under this map. The target extra class $\nu/(s-p)$ need not have a pole as a rational function; its weighted form $(w/\nu)\nu/(s-p) = w/(s-p)$ retains the pole. The original image is ν times H_{pol} , not the unmodified polynomial frame.

The ordinary algebraic dual of AP5 is the exact sequence

$$0 \longrightarrow (\mathbb{C}^{P_\nu})^* \xrightarrow{\text{Res}_w^T} H_{\text{loc}}^* \xrightarrow{i^T} H_{\text{pol}}^* \longrightarrow 0. \quad (\text{AP22})$$

In AP6 the injected column for α is $(0, W^T \alpha)$. The dual connection is $\frac{d}{dt} + A_{\text{ext}}(t)^T/u$. Its action on that column is $(0, W^T \alpha')$: the derivative $-PW/u$ cancels PW/u , and the upper block is zero. Thus the loop-functional injection is explicitly horizontal for the trivial weighted-residue dual. Under the gauge the dual is the inverse transpose of multiplication by ν . This statement concerns the ordinary linear dual; the previous τ -base dagger and moment-line dual retain their separate, already calculated conjugation and weight-line maps. No positive pairing is inferred from AP22, and no original inverse Taylor unit is replaced by ν on a dual.

99.0.9 7. Exact relation to the formal contraction, including the endpoint

UG uses $\mathbb{C}[s][[u, t]]$ and $\mathbb{C}[s, \nu^{-1}][[u, t]]$, with coefficientwise completion. On the added pole module h is invertible because $\gcd(h, \nu) = 1$. Writing H for this inverse and $E = u \frac{d}{ds} - t$, its exact formal inverse is the ordered sum $\sum_{n \geq 0} (-HE)^n H$. That is the contraction proved in UG. AP3 instead fixes $u \neq 0$ first and calculates a cokernel of dimension r , nonzero when $r > 0$. For constant ν , $r = 0$ and the additional pole complex and its residue map are zero; localization adds no analytic or formal classes in that case.

The two operations are related by the original rational complexes and the localization arrow, but the formal completion has no evaluation homomorphism at an arbitrary nonzero complex u . A formal coefficient sequence may diverge there. Thus the previously displayed formal contraction is not evaluated to claim that AP3's residue classes vanish. AP3 gives exactly the missing cokernel.

There is a concrete endpoint calculation. For p in P_ν , $\gcd(h, \nu) = 1$ gives $h(p) \neq 0$. At $u = t = 0$ the class of $1/(s-p)$ modulo h is the original polynomial class

$$\left[\frac{1}{s-p} \right] = - \left[\frac{h(s) - h(p)}{(s-p)h(p)} \right] \quad \text{in } \mathbb{C}[s]/(h). \quad (\text{AP23})$$

Indeed multiplying the displayed polynomial by $s - p$ gives $1 - h(s)/h(p)$. This is the literal inverse of $s - p$ in the original algebra, with every jet of h retained. For formal u, t before the endpoint, $D(1/(s - p))$ gives

$$(h(p) - t) \left[\frac{1}{s - p} \right] = u \left[\frac{1}{(s - p)^2} \right] - \left[\frac{h(s) - h(p)}{s - p} \right]. \quad (\text{AP24})$$

The successive higher-pole relations AP4 and ordered formal inverse supply the remaining u, t coefficients. AP23 is not a rank- $(d + r)$ basis at $u = 0$. It explicitly describes how these rational lifts are represented in the original rank- d formal fibre.

The weighted residue factors also retain their parameter behavior: $w(p) = \exp((\Phi(p) - tp)/u)$. At fixed t with $\Phi(p) - tp \neq 0$ this has an essential singularity at $u = 0$. If that numerator vanishes, that particular value is one; its exact derivative is always $u d_t w(p) = -p w(p)$. For $p = 0$, $w(0)$ is independent of t : it is identically one when $\Phi(0) = 0$, and is $\exp(\Phi(0)/u)$ otherwise. Thus no universal singularity or t -dependence is asserted for every residue coordinate. Even when $w(p) = 1$, AP4 on higher pole orders uses $w^{(n)}(p)$, whose highest inverse- u term is $w(p)(h(p) - t)^n/u^n$. Because $h(p) \neq 0$, these contain unbounded inverse- u powers as the pole order increases near $t = 0$. Consequently when $r > 0$, AP2 does not define a coefficientwise continuous residue map on UG's completed pole module. For $r = 0$ its zero map is of course continuous. The obstruction to evaluating the nonzero-pole formal contraction is not replaced by a false assertion that every individual loop factor is singular.

There is also an exact map for the entire displayed endpoint matrix. Let Q_0 have p -th column the polynomial in AP23, expressed in the original degree- d frame, and put $J_0 = [I_d \ Q_0]$. Direct multiplication of AP23 gives

$$\begin{aligned} A Q_0 &= B_0 + Q_0 P, \\ J_0 A_{\text{ext}}(0) &= A J_0, \\ \ker J_0 &= \{(-Q_0 c, c) : c \in \mathbb{C}^r\}. \end{aligned} \quad (\text{AP25})$$

The map $c \mapsto (-Q_0 c, c)$ carries P to $A_{\text{ext}}(0)$, by the first identity. Thus the endpoint has an explicit invariant r -dimensional kernel and the original arithmetic quotient, rather than an unexplained rank comparison. Entire matrix exponentiation yields

$$J_0 C_{\text{ext},a}(0, 0) = \exp(-aA) J_0. \quad (\text{AP26})$$

Here $C_{\text{ext},a}(0, 0) = \exp(-aA_{\text{ext}}(0))$ is the matrix specialization of AP16; J_0 then maps it to actual formal-fibre cohomology. Multiplication by the full unit v_h after J_0 gives the gauge endpoint. It commutes with A since that unit is an element of the original algebra, so the same action diagram holds. The endpoint comparison therefore retains the full unit as well as all jets.

Completed scope: the original arithmetic polynomial cohomology injects into the analytic localization. The complete two-parameter connection, weighted-residue and oriented-loop maps, finite-scaling pullback including its shifted endpoint derivative, full Taylor gauge, dual and original theta-source endpoint have now been proved in APU1–23. All original additional pole classes and their finite-scaling extension integral remain in the same maps. The formal and analytic constructions retain their exact common maps and different coefficient operations. This does not supply a uniform θ -norm bound or an arithmetic Frobenius comparison not constructed in these equations.

99.0.10 Provenance and verification scope

Input proof: ACTUAL_TAYLOR_UNIT_FORMAL_GAUGE.md, SHA256 9ded2486160b76bf65f92d44b73cdd0c59a3ca7e5334f88682e10592d5a45b2f. Original scaling proof after the accepted integer-power-map clarification: ../f1_scaling_frobenius/ACTUAL_TAU_SCALING_AND_EXPONENTIAL_FLOW.md, SHA256 4e4cb66e3cbbff6379ae389ddaaad65045ac0ed380f17a87ac7c4241c45e6c08. The accompanying derivation supplied AP3's local-primitive construction and AP8–AP13's exact connection in the preceding calculation. This note supplies the full written continuation, AP15–AP18's entire extension transport, AP22's explicit dual and AP23–AP24's endpoint comparison. The independent reviewer supplied the determinant extension AP19a and the endpoint intertwiner AP25–AP26; the text incorporates their full proofs and includes the review's corrected $p = 0$ residue-factor exception explicitly. No new Lean execution or certified arithmetic-zero computation is claimed.

100 Complete independent review of analytic pole-residue transport

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

100.0.1 Independent review of analytic pole-residue transport

Date: 2026-09-13. This reviewer read the complete ANALYTIC_POLE_RESIDUE_TRANSPORT.md, originally AP1–24, its unnumbered assertions, and its provenance and scope paragraphs. The revised AP19a–b, AP25–26, and their complete surrounding proofs were then read as well. The formal-unit gauge and the original scaling proof were independently reviewed or derived in the adjoining work. This review changes neither the source proof nor its sources, and does not certify an arithmetic-zero computation, a metric estimate, an analytic evaluation of the formal inverse, or a Lean result.

100.0.2 Disposition and the one local edge case

Accept AP1–26, including AP19a–b, and their proofs. The weighted-residue exact sequence, the coupling into polynomial cohomology, the off-diagonal transport integral, the actual unit gauge, and the ordinary dual have the correct domains, signs, and matrix order. Neither repeated roots of h nor the multiplicities of ν need to be removed.

One unnumbered sentence in Section 7 was reported for correction before sealing this review. The claim that the full residue exponential and its t -derivative still contain t/u when its exponent vanishes requires an exception for a pole point $p = 0$. The exact derivative is $u\partial_t w(p) = -pw(p)$. If $p = 0$ and $\Phi(0) = 0$, then $w(0; u, t) = 1$ identically and its t -derivative is zero. If $p = 0$ and $\Phi(0)$ is nonzero, it is independent of t and has an essential singularity only in u . For p nonzero, the displayed two-parameter exponential retains its t/u dependence. This comment concerns only that local prose assertion; AP11, AP18, and all the numbered formulas already have the correct factors.

100.0.3 Pole quotient: all maps and exactness

For fixed u nonzero, the quotient $M = \mathbb{C}[s, \nu^{-1}]/\mathbb{C}[s]$ is the vector space of finite principal parts at the distinct roots of ν . Although ν can have repeated roots, localization allows every finite pole order at each such point. Polynomial differences are killed only in this quotient. Multiplication by the entire nonvanishing weight w does not define a rational multiplier, and the proof does not use it as one: its uses are local meromorphic products and contour integrands.

The residue functional descends to M because w times a polynomial is holomorphic at all the designated points. The identity $wDQ = u(wQ)'$ proves that its composite with D is zero, retaining u . If a principal part of Q at p starts with $c(s - p)^{-n}$, its derivative contributes the uncancellable highest pole $-unc(s - p)^{-n-1}$. Thus D is injective on M .

For a zero-residue F , each Laurent series wF has a meromorphic primitive H_p without a logarithm. The function $H_p/(uw)$ is meromorphic locally and satisfies $DQ_p = F$. Taking its finite principal part, and summing over the finitely many points, gives a rational Q with only allowed poles. The difference $DQ - F$ is rational and holomorphic at every finite point, hence polynomial. No global analytic primitive or rationality of w is assumed. A change of integration constant contributes a holomorphic germ because w never vanishes, so the principal part does not change.

The explicit lift $1/(w(p)(s - p))$ has weighted-residue vector exactly the p -th coordinate vector, including its nonzero phase and mass. This proves surjectivity. These arguments establish all of AP3. AP4 is the literal Taylor expansion of h and the Laurent-residue formula for w , so its factorials, derivative order, t term, and leading sign are correct.

100.0.4 Polynomial injection and the displayed basis

For nonzero polynomial Q of degree n , DQ has degree $n + d$, since h is monic and $d > 0$. Therefore D is injective on polynomials, and recursive leading-term subtraction gives a unique remainder of degree below d . For a rational Q with polynomial DQ , the preceding highest-pole argument first forces Q to be polynomial. Thus localization kills no original polynomial cohomology class.

AP3 now gives AP5 with the indicated kernel and surjection. Subtracting $\sum_p (\text{Res}_w F)_p / (w(p)(s - p))$ removes all weighted residues; reduction then leaves exactly a degree-below- d polynomial. Conversely, applying the residues to a linear relation among AP6's vectors kills every pole coefficient, and polynomial injectivity kills the rest. The dimension is therefore $d + r$ for u nonzero, with the original rank- d object explicitly injected. These statements include ν constant, when $r = 0$ and the additional maps and blocks have zero size. No squarefreeness of h is used.

100.0.5 Connection, frames, and entire transport

AP7's two nonzero commutators are $-u$ and $+u$, so L commutes with D . Its action on the last polynomial basis vector uses only $D(1) = h - t$; it is the companion block $A(t)$. On a simple pole, $-s/(s - p) = -1 - p/(s - p)$. Consequently the upper-right block of A_{ext} is the constant column e_0 repeated once per pole, with the positive sign in A_{ext} and the negative sign in L . All of AP8–10 follows without asserting that multiplication by s alone descends on the quotient.

The residue row is $[0, W]$, and $uW_t = -PW$. Thus $\text{Res}_w L = u\partial_t \text{Res}_w$, both by direct differentiation and by multiplying the block matrices. The normalized vector $r_p/w(p)$ has $L(r_p/w(p)) = -1/w(p)$: the two terms with p cancel exactly. AP13's diagonal frame change is therefore correct, without replacing the original W by identity.

For the source-to-target flow from the fibre at $t + ua$ to the fibre at t , the ODE must be $C'_{\text{ext},a} = -C_{\text{ext},a}A_{\text{ext}}(t + ua)$. Its upper-right block therefore obeys $K'_a = -C_a B_0 - K_a P$, with zero initial value. The integral in AP15 solves exactly this equation; in particular its C_b is on the left of B_0 and its final exponential is on the right. The integrand is entire in the integration variable and the finite matrix ODE gives the asserted entire continuation. The inverse block, shifted groupoid law AP17, and weighted-residue identity AP18 follow with the stated order and signs. Since W never vanishes for u nonzero, none of these operations silently discards a residue coordinate.

The formal flow on rational representatives is only coefficientwise in a . The note correctly obtains nonzero- a transport from finite matrices rather than treating $\exp(-as)$ as a rational cochain multiplier. The ODE matrix can extend to $u = 0$ without its $d + r$ representatives becoming a cohomology basis at that endpoint.

100.0.6 Contours, actual gauge, and ordinary dual

Counterclockwise small loops give exactly $2\pi i \text{Res}_w$, not the normalized residue alone. The original rapid-decay contours have their finite portions routed away from the designated poles, including zero if necessary. Polynomial periods are unchanged because their integrands are entire; different rational routings can change periods by precisely the retained small-loop periods. The infinite rays are unchanged, so their original rapid decay dominates the rational factors. Local uniform domination on the admitted u -sector and bounded parameter sets justifies the asserted differentiation in t .

In these actual contours the extended period matrix has the block form of AP19a. Its determinant is $\det(\Pi_{\text{pol}})(2\pi i)^r \prod_p w(p)$, with no missing factor or sign for the stated counterclockwise loops. The original nonzero polynomial determinant and nonvanishing of each $w(p)$ prove invertibility. Boundaries integrate to zero along these contours, so the connection calculation gives $\partial_t \Pi_{\text{ext}} = -\Pi_{\text{ext}} A_{\text{ext}}/u$. Consequently $\Pi_{\text{ext}}(u, t)^{-1} \Pi_{\text{ext}}(u, t + ua)$ solves AP16 with the correct initial value. This proves AP19b for fixed nonzero u and does not evaluate any period matrix at $u = 0$.

Leibniz differentiation verifies $D^\nu = u\partial_s + h - t - w'/\nu$. Multiplication by ν in both degrees is an isomorphism on the explicitly localized complexes. The equalities in AP21 prove exact equality of weighted periods, including all multiplicities in ν and the original constant in Φ . It is correct that the target representative $\nu/(s - p)$ can be polynomial: its weighted form still has the relevant simple pole. The image of the old polynomial subspace is represented by ν times that frame, not by a silently unchanged polynomial frame in the new differential.

Dualizing the finite-dimensional exact sequence gives AP22 with reversed arrows. The injected dual col-

umn is $(0, W^T \alpha)$. Acting by $\partial_t + A_{\text{ext}}^T/u$ gives $(0, W^T \alpha')$, since $W_t^T = -W^T P/u$ cancels the lower diagonal block, and the upper component remains zero. The inverse transpose is the correct forward transport of functionals under the gauge. This is an ordinary linear-dual statement; it neither supplies a Hermitian positivity assertion nor replaces the original τ -base conjugation or moment-line twist.

100.0.7 Formal endpoint and limits of the result

The coefficientwise formal inverse of the earlier note is not evaluated at a nonzero u here. The distinction is essential: AP3 directly computes its nonzero- u residue cokernel, whereas the formal pole complex is contractible because h is invertible on M and the perturbation raises parameter order. These are different coefficient operations on the same original rational complex, not contradictory dimension assertions.

For p a root of ν , $h(p)$ is nonzero. Multiplying AP23's displayed polynomial by $s - p$ gives $1 - h(s)/h(p)$, proving its exact inverse identity in the full quotient, including repeated roots. Directly setting the cohomology class of $D(1/(s - p))$ to zero gives AP24 with its positive u term and negative divided-polynomial term.

In particular, if Q_0 has these AP23 polynomials as columns, then $AQ_0 = B_0 + Q_0P$. The specialization map from the $d + r$ displayed lifts to the actual rank- d endpoint is $[I, Q_0]$, and it intertwines $A_{\text{ext}}(0)$ with A . This confirms the note's endpoint distinction without assigning $d + r$ independent classes to the formal special fibre.

The affirmative result is the fully computed analytic extension, its weighted residues, connection transport, actual-unit gauge, and linear dual, together with their precise original polynomial subobject. No uniform metric bound or unconstructed Frobenius identification follows from this review.

100.0.8 Revised endpoint and empty-pole clarification

The revised AP25–26 include the preceding explicit endpoint check. The kernel of $[I, Q_0]$ is precisely $\{(-Q_0c, c)\}$, and $A_{\text{ext}}(0)(-Q_0c, c) = (-Q_0Pc, Pc)$. Its dimension is r , including the zero-dimensional case, and the induced quotient action is the original A . At $u = t = 0$ the matrix ODE has constant coefficient $A_{\text{ext}}(0)$, so exponentiating the intertwiner proves AP26. The original full unit multiplier commutes with A on the full algebra, which also verifies the stated gauge endpoint without dropping any Taylor coefficient.

The corrected $p = 0$ discussion separates all exceptional cases accurately. For each existing pole p , the highest inverse- u term in $w^{(n)}(p)/w(p)$ is $(h(p) - t)^n/u^n$; its coefficient is nonzero at $t = 0$ because $h(p)$ is nonzero. In the usual u -adic scalar topology, one can see the noncontinuity explicitly even after dividing out $w(p)$: the source sequence $u^n/(s - p)^{2n+1}$ tends to zero, whereas its normalized residue at $t = 0$ has u -valuation $-n$, with nonzero leading coefficient $h(p)^{2n}/(2n)!$. Thus the weighted-residue operation is not a coefficientwise continuous extension to the earlier formal pole module. No claim that $w(p)$ itself is always singular is required.

The last argument presupposes at least one pole. A final local wording comment therefore asked that Section 7's "nonzero cokernel" and noncontinuous-residue assertions be explicitly qualified by $r > 0$. For ν constant, the pole module, residue cokernel, and residue map are all zero; the zero map is continuous. This is the complete degenerate case, not an exception to AP3 or any matrix formula.

100.0.9 Final acceptance seal

On 2026-09-13 I reread the revised pole-factor discussion and both explicit $r = 0$ qualifications. The $p = 0$ and empty-pole comments above are preserved as the historical review record; neither remains an outstanding correction.

The exact accepted proof is ANALYTIC_POLE_RESIDUE_TRANSPORT.md, SHA-256:

357923aead35c77f2fa98598fbc4ed8bc1f7cd6ebc04760da504a0ded765a652.

Final disposition: accept AP1–26, including AP19a–b and all accompanying scope statements, with no outstanding mathematical correction. This is a complete independent written-proof review of the residue exact sequence, full connection and period transport, actual-unit gauge, ordinary dual, and original formal endpoint. No numerical fixture, arithmetic-zero certificate, Lean replay, positive metric estimate, or additional Frobenius comparison is certified by this seal.

101 Complete all-degree principal-angle proof and literal tensor theta primitive

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

Source SHA-256. b0634428d69f80dedd4f68766ef9e6468c390eaac86dfe58b08c21c8fb896e03

101.0.1 All-degree principal angles of the original theta quotient sections

13 September 2026. This is a complete independent derivation of the nonlinear arithmetic determinant comparison in every quotient degree. All spaces are the original polynomial spaces, all projections use the actual common interpolated source Gram, and every change of representative is exhibited as a theta boundary. The earlier sealed AT and AW sources are unchanged.

101.0.2 1. Fixed original objects and the canonical projection relation

Retain a full actual finite zero packet h for $g = 2\xi$, an integer $k \geq 1$, its original tensor-sum annihilator $\chi = \chi_{h,k}$ of degree $q \geq 1$, and

$$E = \mathbb{C}[S]/(\chi), \quad H = \mathcal{P}_{2q}, \quad \mathcal{P}_N = \mathbb{C}[S]_{\leq N}, \quad \mathcal{P}_{-1} = 0. \quad (\text{AA1})$$

Use the original increasing-power remainder frame of E and the original source coordinate $S = k/2 + iu$. The two source densities are exactly

$$\begin{aligned} m_1(u) &= w_h^k(u), & w_h(u) &= \frac{|(g/h)(1/2 + iu)|^2}{2\pi}, \\ m_0(u) &= \frac{(\sqrt{2\pi})^k |\Gamma(k/4 + iu/2)|^2}{c_{k/4} 2\pi}, & c_a &= 2^{1-2a}\Gamma(2a). \end{aligned} \quad (\text{AA2})$$

Their literal masses μ_h^k and $(2\pi)^{k/2}$ remain in all Grams. Put $m_t = (1-t)m_0 + tm_1$, $0 \leq t \leq 1$, and let $M(t)$ be its common Gram on H . The source proofs establish positivity almost everywhere and every polynomial moment for the two densities. Therefore $M(t)$ and every restricted Gram below are positive definite. Inner products are conjugate-linear in their first argument, with $\langle x, y \rangle_t = x^* M(t) y$.

For $q-1 \leq N \leq 2q$, retain the exact sequence

$$0 \rightarrow \mathcal{P}_{N-q} \xrightarrow{B_N = \chi} \mathcal{P}_N \xrightarrow{J_N} E \rightarrow 0. \quad (\text{AA3})$$

Let P_N be the common-metric orthogonal projection onto $\mathcal{P}_N$, and Q_N the projection onto $\mathcal{R}_N = \chi \mathcal{P}_{N-q}$. In particular $Q_{q-1} = 0$. Since $\mathcal{R}_N \subseteq \mathcal{P}_N$, the two projections commute and $P_N Q_N = Q_N P_N = Q_N$. Hence

$$N_N := P_N - Q_N \quad \text{is the orthogonal projection onto} \quad K_N = \mathcal{P}_N \cap \mathcal{R}_N^\perp. \quad (\text{AA4})$$

Polynomial division gives $\dim K_N = q$. The original minimum section $R_N : E \rightarrow \mathcal{P}_N \subset H$ satisfies

$$J_N R_N = I_E, \quad \text{im } R_N = K_N, \quad G_N = R_N^* M(t) R_N > 0, \quad V_N = \det G_N. \quad (\text{AA5})$$

These objects retain their dependence on t . We suppress it only inside pointwise equations.

For any two cutoffs $q-1 \leq i \leq j \leq 2q$, both sections have remainder equal to their input. Thus $R_i - R_j$ has image in $\mathcal{R}_j$. Meanwhile R_j lies in K_j , orthogonal to that image. Orthogonal projection of R_i onto K_j consequently gives the exact relation

$$R_j = N_j R_i, \quad R_i^* M R_j = G_j, \quad G_i - G_j = (R_i - R_j)^* M (R_i - R_j) \succeq 0. \quad (\text{AA6})$$

No equality between the different canonical sections is assumed. The same formula is valid at $i = j$, with zero difference.

Let $H_j = B_j^* M B_j$, with every map understood through its original coefficient inclusion in H . The relation coefficient and its full energy are

$$\begin{aligned} X_{ij} &= H_j^{-1} B_j^* M R_i : E \rightarrow \mathcal{P}_{j-q}, \\ R_i - R_j &= B_j X_{ij}, \quad G_i - G_j = X_{ij}^* H_j X_{ij}. \end{aligned} \quad (\text{AA7})$$

Indeed $Q_j R_i = B_j H_j^{-1} B_j^* M R_i$, and the splitting in $\mathcal{P}_j$ shows that this is $R_i - R_j$. If the relation domain is zero, the formula uses its unique zero map and no inverse on a nonzero space. This is the actual source relation energy that will become the squared sine data.

101.0.3 2. Finite principal-angle calculation with all Gram factors

All square roots in this section are the positive Hermitian square roots in the fixed coefficient frame. Define the isometric frames

$$F_i = R_i G_i^{-1/2} : \mathbb{C}^q \rightarrow (H, M), \quad F_j = R_j G_j^{-1/2} : \mathbb{C}^q \rightarrow (H, M). \quad (\text{AA8})$$

They satisfy $F_i^* M F_i = F_j^* M F_j = I$; this equality retains the original Grams rather than assigning new source norms. Their exact cross matrix is

$$Z_{ij} = F_i^* M F_j = G_i^{-1/2} G_j G_j^{-1/2} = G_i^{-1/2} G_j^{1/2}. \quad (\text{AA9})$$

The order of its factors matters. Multiplication by its actual adjoint gives

$$A_{ij} := Z_{ij} Z_{ij}^* = G_i^{-1/2} G_j G_j^{-1/2}, \quad 0 < A_{ij} \preceq I. \quad (\text{AA10})$$

Its positivity follows from $G_j > 0$, and its upper bound from AA6. Also $I - A_{ij} = G_i^{-1/2} X_{ij}^* H_j X_{ij} G_i^{-1/2}$, retaining the complete source boundary energy.

Let $v_1, \dots, v_q$ be an orthonormal eigenbasis of A_{ij} , with eigenvalues $c_1^2, \dots, c_q^2$ in $(0, 1]$, including every multiplicity. Define

$$x_a = F_i v_a \in K_i, \quad y_a = c_a^{-1} N_j x_a \in K_j, \quad 1 \leq a \leq q. \quad (\text{AA11})$$

There is no division by zero because of AA10. Since $F_i^* M N_j F_i = Z_{ij} Z_{ij}^* = A_{ij}$, direct calculation gives

$$\langle x_a, x_b \rangle_t = \delta_{ab}, \quad \langle y_a, y_b \rangle_t = \delta_{ab}, \quad \langle x_a, y_b \rangle_t = c_b \delta_{ab}. \quad (\text{AA12})$$

For example the second equality follows from $\langle N_j x_a, N_j x_b \rangle_t = \langle x_a, N_j x_b \rangle_t = c_b^2 \delta_{ab}$, divided by $c_a c_b$. The y_a form a basis of K_j because they are q orthonormal vectors in that space.

Define $\theta_a \in [0, \pi/2)$ by $c_a = \cos \theta_a$. These are the complete principal angles of the two actual section spaces, as witnessed by the paired frames AA11–AA12. Their squared cosines are exactly the eigenvalues of AA10, with no interchange of noncommuting square roots.

If $c_a = 1$, then the orthogonal projection $N_j x_a$ has the full norm of x_a , so $x_a \in K_j$ and $y_a = x_a$. Conversely every $x \in K_i \cap K_j$ is fixed by $N_i N_j$ on K_i , and its coefficient vector is an eigenvector of AA10 of eigenvalue one. Hence

$$\#\{a : \theta_a = 0\} = \dim(K_i \cap K_j), \quad (\text{AA13})$$

including all repeated eigenvalues of one.

For every a with $s_a = \sin \theta_a > 0$, put $z_a = (y_a - c_a x_a)/s_a$. Equations AA12 imply that the vectors z_a are orthonormal, orthogonal to every x_b , and that different two-dimensional spaces $\text{span}(x_a, z_a)$ are orthogonal. They are also orthogonal to every common vector with $c_b = 1$. On each such plane, the difference of the original projections is exactly

$$(N_i - N_j)|_{\text{span}(x_a, z_a)} = \begin{pmatrix} s_a^2 & -s_a c_a \\ -s_a c_a & -s_a^2 \end{pmatrix}. \quad (\text{AA14})$$

This follows because N_i is projection onto x_a on that plane, while N_j is projection onto $y_a = c_a x_a + s_a z_a$. The trace is zero and the determinant is $-s_a^2$, giving eigenvalues $+s_a, -s_a$. On the common vectors and on $(K_i + K_j)^\perp$, the difference is zero. Thus if $r = \#\{a : \theta_a > 0\}$, its full spectrum on H is

$$\text{spec}(N_i - N_j) = \{+\sin \theta_a, -\sin \theta_a : \theta_a > 0\} \sqcup \{0^{[\dim H - 2r]}\}. \quad (\text{AA15})$$

This proves the complete finite angle-to-projection spectral relation, including zero angles, repeated positive angles, and the remaining zero eigenvalues.

Finally, taking determinants of AA10 gives

$$\prod_{a=1}^q \cos^2 \theta_a = \frac{V_j}{V_i}, \quad \log \frac{V_i}{V_j} = \sum_{a=1}^q -\log \cos^2 \theta_a \geq 0. \quad (\text{AA16})$$

Every determinant is computed in the unchanged remainder frame. In particular this identity retains the full original quotient metric, not merely its eigenvalue locations.

101.0.4 3. The two original cutoff pairs and their forced common direction

Use the original grouped pairs

$$(i_0, j_1) = (q-1, 2q), \quad (i_1, j_0) = (q, 2q-1). \quad (\text{AA17})$$

The second pair is ordered for $q \geq 2$; for $q = 1$ its two indices both equal one. Apply AA11–AA16 to both pairs, retaining all $2q$ angles, and define the original endpoint quantity

$$\begin{aligned} \mathcal{B}(t) &= \log \frac{V_{q-1}(t)V_q(t)}{V_{2q-1}(t)V_{2q}(t)} \\ &= \log \frac{V_{q-1}(t)}{V_{2q}(t)} + \log \frac{V_q(t)}{V_{2q-1}(t)} = \sum_{a=1}^{2q} x_a(t), \quad x_a = -\log \cos^2 \theta_a \geq 0. \end{aligned} \quad (\text{AA18})$$

At least one angle in the second pair is exactly zero. To prove this from the original spaces, both K_q and K_{2q-1} lie in

$$L = \mathcal{P}_{2q-1} \cap (\chi \mathcal{P}_0)^\perp, \quad \dim L = 2q - 1. \quad (\text{AA19})$$

They lie in that hyperplane because each is orthogonal to its own relation space, which contains $\chi \mathcal{P}_0$. The latter is a nonzero line inside $\mathcal{P}_{2q-1}$, so it cuts that $2q$ -dimensional space by exactly one dimension in a positive form. Since each K has dimension q , $\dim(K_q \cap K_{2q-1}) = 2q - \dim(K_q + K_{2q-1}) \geq 1$. Now AA13 proves the claim. At $q = 1$, the two one-dimensional spaces are identical, in agreement with their identical cutoffs.

Keep the complete angle list. At each t , remove one of these forced entries $x_a = 0$ only for the purpose of writing the following finite sum, and put

$$m = 2q - 1. \quad (\text{AA20})$$

The remaining m entries include any further zero angles and still sum to $\mathcal{B}(t)$. No continuous choice of the removed entry or of individual eigenvectors is needed: the next inequality is a pointwise symmetric inequality in this entire list. The smooth quantity differentiated below is the original log determinant, not individual angle branches.

101.0.5 4. Direct trace bound and finite concavity calculation

Define the unchanged relative operators

$$D = M(0)^{-1}M(1), \quad C(t) = M(t)^{-1}(M(1) - M(0)) = ((1-t)I + tD)^{-1}(D - I). \quad (\text{AA21})$$

The last identity follows by factoring $M(t) = M(0)((1-t)I + tD)$ in its actual order. The operator D is positive self-adjoint for $M(0)$, and $C(t)$ is self-adjoint for $M(t)$ because $M(t)C(t) = M(1) - M(0)$ is Hermitian. Let its extreme eigenvalues be $c_{\min}(t)$, $c_{\max}(t)$, and set $w(t) = c_{\max}(t) - c_{\min}(t) \geq 0$.

For any unit vector v , expansion in an orthonormal eigenbasis of $C(t)$ gives $\langle v, C(t)v \rangle_t = \sum c_j |v_j|^2$, between those two extremes. Apply this fact to the positive and negative eigenvectors in AA15. Each pair contributes at most $\sin \theta_a w(t)$ in absolute value. Summing and using the triangle inequality proves directly

$$|\mathrm{Tr}((N_i - N_j)C(t))| \leq \left(\sum_{a=1}^q \sin \theta_a \right) w(t). \quad (\text{AA22})$$

No external trace extremum theorem, or commutation with the section projections, is used.

The original determinant variation is $\frac{d}{dt} \log V_N = \mathrm{Tr}(N_N C(t))$. Its four original signs give exactly

$$\dot{\mathcal{B}} = \mathrm{Tr}((N_{q-1} - N_{2q} + N_q - N_{2q-1})C(t)). \quad (\text{AA23})$$

It follows either by differentiating the finite determinant ratio from the exact sequence, or from the retained AT12. Apply AA22 to the two pairs in AA17. Using AA18 and AA20 yields the full angle-profile bound

$$|\dot{\mathcal{B}}(t)| \leq \left(\sum_{a=1}^{2q} \sin \theta_a(t) \right) w(t) = \left(\sum_{a=1}^m \sqrt{1 - e^{-x_a(t)}} \right) w(t). \quad (\text{AA24})$$

For $x > 0$, direct differentiation of $f(x) = \sqrt{1 - e^{-x}}$ gives

$$f'(x) = \frac{e^{-x}}{2\sqrt{1 - e^{-x}}}, \quad f''(x) = -\frac{e^{-x}(2 - e^{-x})}{4(1 - e^{-x})^{3/2}} < 0. \quad (\text{AA25})$$

Thus its derivative decreases, so its secant slopes decrease, proving concavity on $(0, \infty)$. Iterating the two-point concavity inequality proves the finite equal-weight inequality $m^{-1} \sum f(y_a) \leq f(m^{-1} \sum y_a)$ for positive y_a . For nonnegative x_a , apply it to $y_a = x_a + \varepsilon$ and let $\varepsilon \downarrow 0$; continuity at zero, with $f(0) = 0$, gives the same result. Therefore AA24 implies

$$|\dot{\mathcal{B}}(t)| \leq m \sqrt{1 - e^{-\mathcal{B}(t)/m}} w(t), \quad m = 2q - 1. \quad (\text{AA26})$$

At $m = 1$ the finite concavity step is an equality. Additional zero angles in higher degree are still present in AA24; AA26 is the stated consequence using only their sum and the guaranteed one zero angle.

101.0.6 5. Strict positivity from the actual vertical-line moment source

Every term in AA18 is nonnegative. Suppose that $\mathcal{B}(t) = 0$ at one value of t . Then every angle of the first pair is zero, so AA13 makes its two q -dimensional spaces equal:

$$K_{q-1} = K_{2q}. \quad (\text{AA27})$$

The first is $\mathcal{P}_{q-1}$, because its relation domain is zero. It contains the original constant polynomial one. The second is orthogonal to $\chi \mathcal{P}_q$. Thus $1 \perp \chi \mathcal{P}_q$.

Write the original polynomial in full as $\chi(S) = \sum_{j=0}^q a_j S^j$, $a_q = 1$, and define its actual reflected-conjugate polynomial

$$\chi_k^\#(S) = \sum_{j=0}^q \overline{a_j}(k - S)^j. \quad (\text{AA28})$$

Its degree is q , with leading coefficient $(-1)^q \overline{a_q}$; this sign is retained. On the unchanged integration line, $\overline{S} = k - S$, and so

$$\chi_k^\#(S) = \overline{\chi(\overline{S})}, \quad \chi(S) \chi_k^\#(S) = |\chi(S)|^2. \quad (\text{AA29})$$

The polynomial product belongs to the literal relation subspace $\chi \mathcal{P}_q$. Orthogonality of one to that space would give

$$0 = \langle 1, \chi \chi_k^\# \rangle_t = \int_{\mathbb{R}} |\chi(k/2 + iu)|^2 m_t(u) du > 0, \quad (\text{AA30})$$

a contradiction. The strict inequality is the positive original Gram of the nonzero polynomial χ , and all integrals exist by the retained moments. This argument uses the actual source measure and vertical-line multiplication identity. It is not a claim about every abstract positive coefficient metric. We have proved

$$\mathcal{B}(t) > 0 \quad (0 \leq t \leq 1). \quad (\text{AA31})$$

The finite positive Grams and their inverses are smooth near the compact path, so $\mathcal{B}$ is smooth and attains a strictly positive minimum on it.

101.0.7 6. Nonlinear endpoint transport in every quotient degree

Let the full ordered positive spectrum of the original relative Gram be

$$0 < b_1 \leq \cdots \leq b_{2q+1}, \quad \kappa = b_{2q+1}/b_1. \quad (\text{AA32})$$

From AA21 its eigenvalues are $c_j(t) = (b_j - 1)/(1 - t + tb_j)$. Differentiating with respect to b_j gives $(1 - t + tb_j)^{-2} > 0$, so the same extreme indices apply for every t , including repeated values and values equal to one. Since each c_j is the derivative of $\log(1 - t + tb_j)$,

$$\int_0^1 w(t) dt = \log b_{2q+1} - \log b_1 = \log \kappa. \quad (\text{AA33})$$

For the fixed integer $m = 2q - 1$, define on $B > 0$

$$\Phi_m(B) = 2 \operatorname{arcosh}(e^{B/(2m)}), \quad \Phi'_m(B) = \frac{1}{m\sqrt{1 - e^{-B/m}}}. \quad (\text{AA34})$$

The derivative follows by differentiating $\cosh(\Phi_m(B)/2) = e^{B/(2m)}$, using the nonnegative real inverse branch of $\cosh$. The square root divisor is strictly positive on the original path by AA31. Multiply AA26 by AA34 and integrate the absolute derivative. Equation AA33 gives the all-degree nonlinear comparison

$$\left| 2 \operatorname{arcosh}(e^{\mathcal{B}(1)/(2m)}) - 2 \operatorname{arcosh}(e^{\mathcal{B}(0)/(2m)}) \right| \leq \log \kappa, \quad m = 2q - 1. \quad (\text{AA35})$$

The original values $\mathcal{B}(0) = \mathcal{B}_{h,k}^\Gamma$ and $\mathcal{B}(1) = \mathcal{B}_{h,k}^{\text{ar}}$ are kept. No monotonicity of $\mathcal{B}(t)$, individual angles, or individual eigenvectors was assumed.

An equivalent endpoint interval retains both branches explicitly. Set

$$A_0 = \operatorname{arcosh}(e^{\mathcal{B}(0)/(2m)}), \quad L = \frac{1}{2} \log \kappa. \quad (\text{AA36})$$

The endpoint inverse-cosh value lies in $[\max(0, A_0 - L), A_0 + L]$. Since $A \mapsto 2m \log \cosh A$ has derivative $2m \tanh A \geq 0$ for $A \geq 0$,

$$2m \log \cosh(\max\{0, A_0 - L\}) \leq \mathcal{B}(1) \leq 2m \log \cosh(A_0 + L). \quad (\text{AA37})$$

The lower bound may be zero while the actual endpoint is strictly positive. When $q = 1, m = 1$, the second pair has its one zero angle and AA35 is the previously proved one-dimensional formula. For any higher q , including the actual quartet dimension, the same proof applies. It establishes no uniform-in- k bound for κ .

The new estimate implies the earlier bound $|\mathcal{B}(1) - \mathcal{B}(0)| \leq m \log \kappa$: the derivative of the inverse function $B = 2m \log \cosh(\Phi/2)$ is $m \tanh(\Phi/2) \leq m$. Integrating that derivative between the two endpoint Φ values and using AA35 proves the assertion. The angle-profile inequality AA24 remains a still finer pointwise estimate, retaining every individual original Gram ratio.

101.0.8 7. The literal tensor theta boundary of the angle energy

This section supplies the source primitive behind AA7. Keep the original one-leg complex $C_+ = [V \xrightarrow{\Theta} \mathcal{B}]$ in degrees zero and one, with $D = -x\partial_x$, and the original functions satisfying

$$\mathcal{M}F_h = g/h, \quad \phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad h(D)F_h = \Theta\phi_*. \quad (\text{AA38})$$

The last identity follows by Mellin transformation: both sides transform to the exact g , and Mellin uniqueness on these source spaces identifies them. The original source intertwining $D\Theta = \Theta D$ lets all polynomial differential operators below act on the complex. Its inclusion in the original two-leg complex sends ϕ to $(\phi, 0)$ in degree zero and is identity in degree one, so the same primitive maps into the actual tau-base complex with its retained two-leg signs.

In the coefficient ring $\mathbb{C}[s_1, \dots, s_k]$, the cyclic definition of χ gives

$$\chi(s_1 + \dots + s_k) \in (h(s_1), \dots, h(s_k)). \quad (\text{AA39})$$

Indeed the tensor algebra $E_h^{\otimes k}$ is this polynomial ring modulo that ideal, and its unit is the cyclic vector used to define χ . Evaluating χ on the sum operator and that unit is zero by its actual annihilator definition.

The ideal expression can be chosen by a fully specified finite division. Start with $F_0 = \chi(s_1 + \dots + s_k)$; for $j = 1, \dots, k$, divide F_{j-1} by the literal monic $h(s_j)$, viewing the other variables as coefficients:

$$F_{j-1} = h(s_j)L_j + F_j, \quad \deg_{s_j} F_j < \deg h. \quad (\text{AA40})$$

Later divisions do not increase the already restricted degrees in earlier variables, because $h(s_j)$ has complex constant coefficients in those variables. Thus the final F_k lies in the span of the tensor remainder monomials, which are a basis of the quotient algebra. Its image in that algebra is zero by AA39, so $F_k = 0$. Summing the exact division identities proves

$$\chi(s_1 + \dots + s_k) = \sum_{j=1}^k h(s_j)L_j(s_1, \dots, s_k). \quad (\text{AA41})$$

Every original coefficient of h and χ remains in these finite quotient polynomials. This construction does not replace χ by a product of simple factors or discard any nilpotent multiplicity.

For a polynomial P in the original sum variable, define the degree- $k - 1$ tensor cochain

$$\begin{aligned} \mathcal{K}_\chi(P) &= \sum_{j=1}^k (-1)^{j-1} L_j(D_1, \dots, D_k) P(D_1 + \dots + D_k) \\ &\quad (F_h \otimes \dots \otimes F_h \otimes \phi_* \otimes F_h \otimes \dots \otimes F_h), \end{aligned} \quad (\text{AA42})$$

where the j -th position is ϕ_* in the degree-zero space V , and every other position is the displayed F_h in degree one. There are $j - 1$ degree-one factors before that position. The tensor differential therefore acts on it with sign $(-1)^{j-1}$; this cancels the explicit coefficient sign in AA42. It acts trivially on the other degree-one factors. By AA38, by commutation of the polynomial operators with the differential, and then by AA41, one obtains exactly

$$d\mathcal{K}_\chi(P) = P(D_1 + \dots + D_k)\chi(D_1 + \dots + D_k)F_h^{\otimes k} = \mathcal{V}_{h,k}(\chi P). \quad (\text{AA43})$$

This proves the primitive with its full tensor signs. In particular, for $x \in E$, regard $X_{ij}x$ from AA7 as its literal polynomial in S . Then

$$\mathcal{V}_{h,k}(R_i x - R_j x) = d\mathcal{K}_\chi(X_{ij}x), \quad G_i - G_j = X_{ij}^* H_j X_{ij}. \quad (\text{AA44})$$

Thus the angle energy is the Gram energy of this exact original relation, while its cohomology class is zero. The unchanged arithmetic observation still satisfies $J^{(k)}\mathcal{V}_{h,k}R_N = \eta_{h,k}$, with $\eta_{h,k}[P] = v_h^{\otimes k}P(A_h^{(k)})1$ and the full unit $v_h = j_h(g/h)$. Its further cohomology image is $\sigma_h^{\otimes k}\eta_{h,k}$ in the original $Q^{\otimes k}$. No source relation is dropped merely because those observations kill it.

At every nonempty original support label A , lift the displayed coefficient maps by $(A, v) \mapsto (A, fv)$, and send external absence τ to τ . The class of AA44 is the supported zero at the same label; its full source primitive and energy remain as written. This preserves the original cohomology over the tau base throughout the all-degree estimate.

101.0.9 8. Full review of the root AGT1–AGT19 source

The complete corrected tau_all_degree_angle_transport_20260913.tex was read at SHA-256 cc0c0c008b0532c5f120d1cea76b94e2d08153c87a694ce18775a5189c72d5f8. It is accepted without a further mathematical correction. The initial source-cutoff sentence now states $q - 1 \leq N \leq 2q$, making its inclusion $\mathcal{P}_N \subseteq H = \mathcal{P}_{2q}$ correct on the entire declared range.

The full acceptance covers the following calculations.

1. AGT1–AGT4 retain the actual packet, full Taylor unit, original source and cohomology observations, both full masses, original vertical line, positive finite Grams, and all four signed determinant terms. The bounded source codomain is now exact.
2. AGT5–AGT8 agree with the independent derivation AA6–AA16. In the root source the cross matrix is written in the opposite orientation, $U_j^* M U_i = G_j^{1/2} G_i^{-1/2}$; its adjoint-times-itself is precisely $G_i^{-1/2} G_j G_i^{-1/2}$. Thus both presentations give the same squared singular values without commuting the square-root factors. The displayed two-dimensional projection block, all unit-cosine common vectors, and the remaining zero spectrum are correct. The primitive behind its relation-valued difference is supplied explicitly by AA38–AA44 above.
3. AGT9–AGT11 retain both full angle lists and remove only one exactly proved zero scalar contribution. The common ambient space has dimension $2q - 1$, including $q = 1$. The trace bound is the sum of the paired positive and negative Rayleigh bounds, so it needs no mutual commutation and introduces no extra factor two.
4. AGT12–AGT13 use the precise involution with variable $k - S$ and conjugated coefficients. Its leading sign $(-1)^q$, its square, and its equality to complex conjugation on the original line are correct. The resulting integral is the full positive norm of the nonzero original polynomial χ , proving strict positivity on the actual moment path.
5. AGT14–AGT19 have the exact constant $m = 2q - 1$. The derivative and tangent-line proof include the remaining zero-angle values by continuity and the actual positive mean $\mathcal{B}/m$. The factor $1/m$ in the derivative of Φ_m cancels the factor m in the angle estimate. The integrated width equals the full original $\log \kappa$, including repeated eigenvalues and endpoint eigenvalues equal to one. Both inverse hyperbolic branches and the explicit endpoint interval are correct. The source states the valid all-degree application, including actual quartet quotients, and preserves the absence of a new uniform estimate for κ .

The separate complete PA1–PA29 derivation in tau_principal_angle_volume_independent_review_20260913.md, SHA-256 5f6a75afdbdf4dcd81781a336702ea6d6545fd8fd0a9b2e014a605e414b3198, was read in full. Its principal bases, projection spectra, positivity argument, and integrated constant agree with AA1–AA37. This provides an additional independent derivation, with its source scope retained; no finite numerical test is being substituted for these proofs.

101.0.10 9. Reading, source pins, and mathematical scope

The complete sealed AT source tau_arithmetic_determinant_transport_20260913.tex at SHA-256 24cf7ce5be6a43cc656641b516185df10b2e4d7824600ece657120d1c549deae and the complete AW source tau_relation_window_spectral_transport_20260913.tex at SHA-256 c79e76c087efd59871e3234ff44fb18964515dbd34f0318dffba6b3f1440f6ec were read in the preceding independent calculation. Their original projection and moment conventions are retained here. The full original arithmetic_input.tex and Tau_Base_Cohomology/NOTE.md were read earlier in this same audit and supply the stated theta complex, finite-packet unit, and tau-base tensor realization. AA6–AA44 provide the new finite angle, analytic transport, and explicit primitive proofs.

The companion receipt pins the final sources and the complete root-source acceptance above. These are closed written proofs and do not depend on a forthcoming supplement. No numerical or Lean execution, source normalization, remote mutation, or unproved uniform eigenvalue bound is claimed. The all-degree conclusion applies to the actual original moment Grams and includes every admissible quotient degree $q \geq 1$.

102 Complete independent principal-angle volume proof and integrated metric comparison

Source role. Complete written proof, with original source bytes and reversible notation/publication mapping retained.

102.0.1 Independent principal-angle calculation for the arithmetic four-volume

13 September 2026. This is a separate written derivation of the proposed canonical-section angle formula and its integrated metric comparison. No sealed source is edited.

102.0.2 1. Canonical sections in one original Hilbert space

Fix the original monic polynomial χ of degree $q \geq 1$, the original real weight k , and the literal finite polynomial space

$$\mathcal{H} = \mathcal{P}_{2q}, \quad E = \mathbb{C}[S]/(\chi), \quad J : \mathcal{H} \longrightarrow E \quad (\text{PA1})$$

with its fixed coefficient basis and remainder map. Let $M(t) > 0$ be a continuously differentiable Gram on this common space. All orthogonal projections and norms below use that Gram at the same parameter value. The adjoint in the coefficient formula R^*MR is the ordinary conjugate transpose in the retained bases; no coefficient basis is changed implicitly.

For $q - 1 \leq N \leq 2q$, let P_N project onto $\mathcal{P}_N$, and let Q_N project onto the original relation space $\chi\mathcal{P}_{N-q}$, with $Q_{q-1} = 0$. Since the latter is a subspace of the former, their projections commute and satisfy $P_N Q_N = Q_N P_N = Q_N$. Therefore

$$N_N = P_N - Q_N \quad (\text{PA2})$$

is exactly the orthogonal projection onto $K_N = \mathcal{P}_N \cap (\chi\mathcal{P}_{N-q})^\perp$. The original least-norm remainder section $R_N : E \rightarrow \mathcal{P}_N$ has $JR_N = I_E$, image K_N , and positive Gram

$$G_N = R_N^* M R_N > 0. \quad (\text{PA3})$$

These assertions follow from the direct orthogonal decomposition of the surjective remainder sequence; its kernel is multiplication by the unchanged monic χ .

If $i \leq j$, both $R_i x$ and $R_j x$ are in $\mathcal{P}_j$ and have remainder x . Their difference belongs to $\chi\mathcal{P}_{j-q}$, which is orthogonal to K_j . Hence

$$\boxed{R_j = N_j R_i}, \quad R_i^* M R_j = G_j, \quad G_i - G_j = (R_i - R_j)^* M (R_i - R_j) \succeq 0. \quad (\text{PA4})$$

The second identity follows by writing $R_i = R_j + (R_i - R_j)$; its last summand is orthogonal to $R_j E$. The same expansion gives the last identity with all cross terms accounted for.

102.0.3 2. Exact principal angles and the square-root order

Define the actual isometries

$$V_i = R_i G_i^{-1/2}, \quad V_j = R_j G_j^{-1/2}. \quad (\text{PA5})$$

Their domains have the usual coefficient inner product; their targets carry M . Thus $V_i^* M V_i = V_j^* M V_j = I$. Their cross-Gram and its two products, in their exact noncommutative orders, are

$$\begin{aligned}
V_i^* M V_j &= G_i^{-1/2} G_j^{1/2}, \\
(V_i^* M V_j)(V_j^* M V_i) &= G_i^{-1/2} G_j G_i^{-1/2}, \\
(V_j^* M V_i)(V_i^* M V_j) &= G_j^{1/2} G_i^{-1} G_j^{1/2}.
\end{aligned} \tag{PA6}$$

The first follows from (PA4), with $G_j G_j^{-1/2} = G_j^{1/2}$ in the adjacent factors. No commutation between G_i and G_j is used.

The singular values of the first matrix in (PA6) are the cosines of the principal angles between K_i and K_j . This can be seen directly. Choose an orthonormal eigenbasis a_ℓ of $V_i^* M N_j V_i = G_i^{-1/2} G_j G_i^{-1/2}$, and let its eigenvalues be c_ℓ^2 . By (PA3)–(PA4), $0 < c_\ell \leq 1$. Put

$$x_\ell = V_i a_\ell, \quad y_\ell = c_\ell^{-1} N_j x_\ell. \tag{PA7}$$

The x_ℓ form an orthonormal basis of K_i . The projection identity gives $\langle y_\ell, y_r \rangle = \delta_{\ell r}$ and $\langle x_\ell, y_r \rangle = c_r \delta_{\ell r}$. Since the c_ℓ values are positive, the y_ℓ form an orthonormal basis of K_j . These are principal bases. Set $\theta_\ell = \arccos c_\ell \in [0, \pi/2)$. Consequently

$$\text{spec}(G_i^{-1/2} G_j G_i^{-1/2}) = \{\cos^2 \theta_\ell : 1 \leq \ell \leq q\}. \tag{PA8}$$

The multiplicity of $\cos \theta = 1$ is exactly $\dim(K_i \cap K_j)$. Indeed equality $\|N_j x\| = \|x\|$ for an orthogonal projection is equivalent to $x \in K_j$; apply this on $x \in K_i$. The same multiplicity is $\dim \ker(R_i - R_j)$: a common vector has the same remainder in both sections, and conversely equal section values define a vector in the intersection. Thus all unit cosines are retained, including multiplicities arising from coinciding section subspaces.

Taking the determinant of the actual positive matrix in (PA8) gives

$$\log \frac{\det G_i}{\det G_j} = \sum_{\ell=1}^q -\log \cos^2 \theta_\ell. \tag{PA9}$$

All terms are finite and nonnegative, because the original section Grams are positive definite.

102.0.4 3. The two pairs and the forced unit cosine

Use exactly the pairs

$$(i_1, j_1) = (q-1, 2q), \quad (i_2, j_2) = (q, 2q-1). \tag{PA10}$$

For the second pair, both section spaces are contained in

$$\mathcal{L} = \mathcal{P}_{2q-1} \cap (\mathbb{C}\chi)^\perp, \quad \dim \mathcal{L} = 2q-1. \tag{PA11}$$

For K_q , this follows from its defining orthogonality to χ ; for K_{2q-1} , its relation space contains χ , so it has the same orthogonality. The dimension in (PA11) is exact because $\chi \in \mathcal{P}_{2q-1}$ is nonzero and its norm is positive. Both section spaces have dimension q . The identity $\dim(A \cap B) = \dim A + \dim B - \dim(A + B)$ therefore gives an intersection of dimension at least one. By (PA8), at least one angle in the second pair has cosine one. For $q = 1$, the second pair is literally $(1, 1)$, so its sole angle is zero and the whole pair contributes zero.

The original four-volume is precisely

$$\begin{aligned}
\mathcal{B}(t) &= \log \frac{\det G_{q-1}(t) \det G_q(t)}{\det G_{2q-1}(t) \det G_{2q}(t)} \\
&= \sum_{a=1}^2 \sum_{\ell=1}^q -\log \cos^2 \theta_{a,\ell}(t).
\end{aligned} \tag{PA12}$$

Remove one of the proved zero contributions from the second pair. There remain exactly $m = 2q - 1$ nonnegative slots, with every additional zero slot kept. This removal changes neither the value nor either

bound below. It is a pointwise assertion; no differentiability of a chosen angle enumeration at eigenvalue crossings is required.

102.0.5 4. Full projection-difference spectrum and derivative estimate

For a positive angle in (PA7), define $z_\ell = (y_\ell - c_\ell x_\ell) / \sin \theta_\ell$. The principal-basis identities show that the z_ℓ are orthonormal and orthogonal to K_i , and that distinct positive-angle two-planes are orthogonal. In the ordered basis (x_ℓ, z_ℓ) , the two projections and their difference have the exact matrices

$$N_i = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad N_j = \begin{pmatrix} c_\ell^2 & c_\ell s_\ell \\ c_\ell s_\ell & s_\ell^2 \end{pmatrix}, \quad N_i - N_j = \begin{pmatrix} s_\ell^2 & -c_\ell s_\ell \\ -c_\ell s_\ell & -s_\ell^2 \end{pmatrix}, \quad (\text{PA13})$$

where $s_\ell = \sin \theta_\ell$. The last matrix has trace zero and determinant $-s_\ell^2$, hence eigenvalues $+s_\ell, -s_\ell$. A zero-angle common vector has zero difference, and the orthogonal complement of the two spaces also has zero difference. Thus these are the complete nonzero eigenvalues with multiplicity. In particular

$$\text{Tr}(N_i - N_j)_+ = \text{Tr}(N_i - N_j)_- = \sum_{\ell=1}^q \sin \theta_\ell. \quad (\text{PA14})$$

Here the positive and negative parts are positive operators, and the latter is the negative of the operator on its negative spectral subspace.

Let $C = M^{-1}\dot{M}$, which is self-adjoint for the same M . Let $\omega(C) = \lambda_{\max}(C) - \lambda_{\min}(C)$. For any trace-zero self-adjoint D , subtracting the scalar $\lambda_{\min}(C)I$ leaves its trace pairing unchanged. The inequalities $0 \preceq C - \lambda_{\min}(C)I \preceq \omega(C)I$, applied to the two positive parts of D , give

$$|\text{Tr}(DC)| \leq \omega(C) \text{Tr} D_+ \quad \text{if } \text{Tr} D = 0. \quad (\text{PA15})$$

To verify the inequality without a commutation assumption, the trace of a product of two positive operators is nonnegative: it equals the trace of their positive conjugation $A^{1/2}BA^{1/2}$. Hence each of the two positive-part trace terms lies between zero and $\omega(C) \text{Tr} D_+$, and their difference has the asserted absolute bound.

The differentiability of the canonical section follows from its explicit positive-Gram inverse formula. Because $JR_N = I$, its derivative is a relation vector. Orthogonality to that relation space cancels the two section-derivative cross terms, giving

$$\dot{G}_N = R_N^* \dot{M} R_N, \quad \frac{d}{dt} \log \det G_N = \text{Tr}(N_N C), \quad N_N = R_N G_N^{-1} R_N^* M. \quad (\text{PA16})$$

The last formula is the orthogonal projection onto $R_N E$, since it is the identity there and annihilates its orthogonal complement. Cyclicity of the finite trace then proves the middle identity.

Using the two pairs (PA10), (PA12), (PA14)–(PA16), and the triangle inequality gives

$$|\mathcal{B}'(t)| \leq \omega(C(t)) \sum_{a=1}^2 \sum_{\ell=1}^q \sin \theta_{a,\ell}(t). \quad (\text{PA17})$$

This bound does not presume that the two projection differences commute, or that either one commutes with C .

For each of the m retained slots, set $b_r = -\log \cos^2 \theta_r \geq 0$. Then $\sum b_r = \mathcal{B}$ and $\sin \theta_r = f(b_r)$, where

$$f(b) = \sqrt{1 - e^{-b}}. \quad (\text{PA18})$$

It is continuous at zero and strictly concave on $(0, \infty)$, because

$$f''(b) = -\frac{e^{-b}}{2\sqrt{1 - e^{-b}}} - \frac{e^{-2b}}{4(1 - e^{-b})^{3/2}} < 0.$$

Concavity extends to the endpoint by continuity: apply the interior inequality to all arguments increased by a positive number and let that number decrease to zero. Jensen's inequality, which follows by iterating the defining two-point concavity inequality, therefore gives

$$\sum_{r=1}^m f(b_r) \leq m f(\mathcal{B}/m).$$

Combining this with (PA17) proves the proposed estimate with its exact constant:

$$\boxed{|\mathcal{B}'| \leq m \sqrt{1 - e^{-\mathcal{B}/m}} \omega(M^{-1} \dot{M}), \quad m = 2q - 1.} \quad (\text{PA19})$$

102.0.6 5. Strict positivity for the actual moment Grams

The original arithmetic and Gamma norms have the common vertical coordinate $S = k/2 + iu$ and the form

$$\langle P, R \rangle_{M(t)} = \int_{\mathbb{R}} \overline{P(k/2 + iu)} R(k/2 + iu) m_t(u) du. \quad (\text{PA20})$$

The original densities and their convex interpolation have the required finite moments and positive definite polynomial Grams. Write the unchanged polynomial as $\chi(S) = \sum_{j=0}^q a_j S^j$, retaining its coefficients, and define the exact reflected polynomial

$$\chi^\#(S) = \sum_{j=0}^q \overline{a_j} (k - S)^j. \quad (\text{PA21})$$

On the original vertical line, $k - S = \overline{S}$, so $\chi^\#(S) = \overline{\chi(\overline{S})}$. It has degree q , with leading coefficient $(-1)^q \overline{a_q}$; that sign is not removed. Hence $\chi \chi^\# \in \chi \mathcal{P}_q$ and

$$\langle 1, \chi \chi^\# \rangle_{M(t)} = \int |\chi(k/2 + iu)|^2 m_t(u) du = \|\chi\|_{M(t)}^2 > 0. \quad (\text{PA22})$$

All integrals are within the specified moment degree $2q$. If the first pair in (PA10) had every cosine equal to one, its two q -dimensional spaces would coincide. Its first space is exactly $\mathcal{P}_{q-1}$, and its second is $(\chi \mathcal{P}_q)^\perp$. The constant polynomial would then be orthogonal to $\chi \chi^\#$, contradicting (PA22). Thus at least one angle in the first pair is positive, and

$$\boxed{\mathcal{B}(t) > 0} \quad (\text{PA23})$$

for every actual moment Gram in this path. This proves strict positivity without a presumption about the zero locations or a discarded relation primitive. It also verifies the needed endpoint at $q = 1$, where the second pair contributes exactly zero.

102.0.7 6. Integrated arcosh comparison on the actual arithmetic/reference path

For $b > 0$, define

$$F_m(b) = 2 \operatorname{arcosh}(e^{b/(2m)}), \quad F'_m(b) = \frac{1}{m \sqrt{1 - e^{-b/m}}}. \quad (\text{PA24})$$

The derivative is obtained by differentiating the displayed exponential and arcosh; no rescaling of $\mathcal{B}$ or its original mass is performed. By (PA23), the chain rule applies along the entire actual path. Equation (PA19) gives

$$\left| \frac{d}{dt} F_m(\mathcal{B}(t)) \right| \leq \omega(M(t)^{-1} \dot{M}(t)). \quad (\text{PA25})$$

Now take exactly the convex source-metric interpolation $M(t) = (1 - t)M_\Gamma + tM_{\text{ar}}$, $0 \leq t \leq 1$, inherited from the two actual densities in (PA20). Put

$$A = M_\Gamma^{-1/2} M_{\text{ar}} M_\Gamma^{-1/2} > 0, \quad 0 < \lambda_1 \leq \dots \leq \lambda_{2q+1}, \quad \kappa = \lambda_{2q+1}/\lambda_1. \quad (\text{PA26})$$

This is the complete common-source relative Gram, not a quotient-metric substitute. Factoring $M(t) = M_\Gamma^{1/2}((1-t)I + tA)M_\Gamma^{1/2}$ shows that $M(t)^{-1}\dot{M}(t)$ is similar to $((1-t)I + tA)^{-1}(A - I)$. Its eigenvalues are

$$c_j(t) = \frac{\lambda_j - 1}{1 + t(\lambda_j - 1)}. \quad (\text{PA27})$$

Every denominator is positive. For fixed t , the derivative of this scalar expression with respect to λ is $(1 + t(\lambda - 1))^{-2} > 0$, so its largest and smallest values have the same indices as the original λ_j . Therefore

$$\begin{aligned} \int_0^1 \omega(M(t)^{-1}\dot{M}(t)) dt &= \int_0^1 \left(\frac{\lambda_{2q+1} - 1}{1 + t(\lambda_{2q+1} - 1)} - \frac{\lambda_1 - 1}{1 + t(\lambda_1 - 1)} \right) dt \\ &= \log \lambda_{2q+1} - \log \lambda_1 = \log \kappa. \end{aligned} \quad (\text{PA28})$$

The identity also includes any $\lambda_j = 1$, whose integrand is zero, and cases in which both extreme eigenvalues are above or below one.

Integrating (PA25) and using (PA28) gives precisely

$$\left| 2 \operatorname{arcosh}\left(e^{\mathcal{B}_{\text{ar}}/(2m)}\right) - 2 \operatorname{arcosh}\left(e^{\mathcal{B}_\Gamma/(2m)}\right) \right| \leq \log \kappa, \quad m = 2q - 1. \quad (\text{PA29})$$

Every endpoint volume is the original four-volume in (PA12). All section angles are strictly below $\pi/2$ because every finite quotient Gram is positive definite. The forced unit-cosine slot is retained through the exact common-space argument (PA11). For $q = 1$, $m = 1$ and the formula uses the single nontrivial pair. If $\kappa = 1$, the two source Grams differ by one positive scalar; all quotient Grams acquire that same scalar and their four-volume ratio is unchanged, consistently giving zero on both sides of (PA29).

The proposed formulas are accepted. This calculation proves their exact finite metric geometry and their application to the original positive moment interpolation. It supplies no bound on κ beyond its computed source definition, and no extra arithmetic conclusion is assigned to that quantity.

103 Complete independent acceptance proof of the literal tensor theta primitive

Source role. Complete independently accepted supporting calculation, with every original prose and mathematical payload retained and exact delimiter-transcription inverses.

Source SHA-256. a78384fe3a1cff8398713f89181c38c62351315d6f32aca314d357e457938de4

103.0.1 Acceptance addendum: the full all-degree angle derivation and theta primitive

13 September 2026. The complete work/tau_all_degree_angle_independent_review_20260913.md, equations AA1–AA44 and all prose, was read for this addendum. Accepted source SHA-256: b0634428d69f80dedd4f68766ef9e6468c390eaac86dfe58b08c21c8fb896e03.

The original output/split_zero_rh_tandem_2026-09-12/tex/arithmetic_input.tex was previously read completely and its current pin was checked again: a50b0fb587b644c4ea94dba45b2b423d038f2bfbfe7fef188543939ba850e58d2. It supplies the unchanged spaces, Euler inverses, original Gaussian, theta factor, and full finite-packet unit used below. The earlier independent PA1–PA29 calculation is tau_principal_angle_volume_independent_review_20260913.md, SHA-256 5f6a75afdbdfd4dcd81781a336702ea6d6545fd8fd0a9b2e014a605e414b3198.

AA1–AA37 agree with that independent principal-angle derivation. The relation coefficient in AA7 keeps its actual domain; the positive square roots in AA9–AA10 occur in the correct order; AA13 and AA15 retain every unit cosine and all remaining zero eigenvalues. The second pair's common hyperplane gives the exact one-angle reduction to $m = 2q - 1$, including its identical-cutoff case when $q = 1$. The strict moment

positivity in AA28–AA31 retains the leading sign of the reflected polynomial. AA33 integrates the actual full-source spectral width, and the two inverse-cosh branches in AA36–AA37 have the stated domains. No further correction is required in those calculations.

Section 7 was checked separately as follows.

1. The identity $h(D)F_h = \Theta\phi_*$ in AA38 has exactly the original Mellin transform $g = 2\xi$ on both sides. The source statement $H_{\phi_*} = 1$ gives $\mathcal{M}\Theta\phi_* = g$, while multiplication by the original h cancels the displayed quotient g/h . Mellin uniqueness in the stated source space therefore proves the identity. There is no extra Taylor-unit factor in this identity: the full unit belongs to the later arithmetic jet observation, where the review retains it.
2. In the tensor algebra, the sum operator is multiplication by $s_1 + \cdots + s_k$, and its cyclic vector is the literal unit. Thus the defining annihilation equation is the vanishing of the actual element $\chi(s_1 + \cdots + s_k)$ modulo the ideal generated by the original $h(s_j)$. This proves AA39, including repeated roots and the full cyclic multiplicities.
3. Division in AA40 is valid over the polynomial coefficient ring in the other variables because each divisor $h(s_j)$ is monic. Its division operations multiply earlier-variable coefficients only by the complex coefficients of that divisor and add or subtract such coefficients. Therefore later divisions cannot raise a previously restricted degree in an earlier variable. At the final step every variable degree is less than $\deg h$. The corresponding tensor monomials are a basis of the quotient: one-variable monic remainders form a basis, and their external products form the tensor basis. A remainder in their span with zero quotient image is consequently the zero polynomial. Telescoping the actual division identities gives AA41 with no leftover term.
4. In the j -th summand of AA42, the j -th tensor factor is ϕ_* in degree zero. The preceding $j - 1$ factors are all F_h in degree one. Thus the only nonzero term of the tensor differential carries precisely the sign $(-1)^{j-1}$; it cancels the displayed coefficient sign in that summand. Every other factor is in the top degree of the two-term complex, where the differential is zero. All D_j have cohomological degree zero and commute with the differential because $D\Theta = \Theta D$. Applying the differential therefore gives exactly

$$\sum_{j=1}^k L_j(D_1, \dots, D_k) P(D_1 + \cdots + D_k) h(D_j) F_h^{\otimes k}.$$

AA41 turns this sum into $P(\sum D_j)\chi(\sum D_j)F_h^{\otimes k}$, which is the unchanged $\mathcal{V}_{h,k}(\chi P)$. This proves AA43 with every tensor sign and the original theta factor retained. For $k = 1$, the same division gives $L_1 = 1$ because the cyclic annihilator is the original monic h , and the formula reduces to the one-leg identity without any tensor sign.

5. Substituting the literal polynomial $P = X_{ij}x$ from AA7 proves the first equation of AA44. Its second equation is the independently checked orthogonal source energy. That energy uses the specified common interpolated coefficient Gram $M(t)$; at $t = 1$ it is the ordinary arithmetic $\mathcal{V}_{h,k}$ norm, and along the path it is the stated arithmetic/reference interpolated norm. Neither equality identifies those two norms. The actual theta primitive exists as the displayed source cochain at every parameter value, independently of which of those specified norms is being evaluated.
6. Inclusion of the one-leg complex into the first leg of the two-leg complex commutes with the differential: the second coefficient is zero, so the original difference differential is still Θ on that image. The supported reconstruction retains its admitted mask, sends represented zero amplitudes to supported zeros, and sends external absence to τ . Consequently this ordinary coefficient inclusion does not require identifying a missing support leg with a new represented amplitude. The explicit primitive and its full energy remain attached before taking the supported quotient.

The full AA1–AA44 review is accepted at the pin above, including its added deterministic division and theta primitive. No mathematical correction is requested. This addendum records a written proof review; it makes no claim of a new finite test, Lean execution, remote operation, or fresh reading of the separate root AGT file. No sealed source was changed.

104 Which completion retains the arithmetic jets?

This section extends the Hilbert/jet calculation of the September 12 orthogonal-boundary note. All changes of topology are specified maps on the same arithmetic functions. The theta relation space,

the operator $D = -x\partial_x$, and $g = 2\xi$ are retained.

104.1 Logarithmic coordinates and the original measure

Let $\mathcal{B}, V, \Theta$ have the definitions in Section 6. Put $\mathcal{H} = L^2(\mathbb{R}_+, dx)$. The map

$$\mathcal{L}F(y) = e^{y/2}F(e^y), \quad \mathcal{L}^{-1}f(x) = x^{-1/2}f(\log x)$$

is unitary from $\mathcal{H}$ to $L^2(\mathbb{R}, dy)$, since $dx = e^y dy$. Direct differentiation gives

$$\mathcal{L}D\mathcal{L}^{-1} = \frac{1}{2} - \partial_y, \quad \mathcal{M}F(\rho) = \int_{\mathbb{R}} (\mathcal{L}F)(y)e^{(\rho-1/2)y} dy. \quad (\text{JT1})$$

On $\mathcal{H}$, D denotes the closed maximal distributional operator which $\mathcal{L}$ identifies with $1/2 - \partial_y$ on the Sobolev domain $H^1(\mathbb{R})$. For an integer $r \geq 0$, let $\mathcal{H}^{(r)}$ be the domain of the first r powers of D in $\mathcal{H}$, with norm $\|F\|_r^2 = \sum_{k=0}^r \|D^k F\|_{\mathcal{H}}^2$. The Mellin-line transform makes this the norm with density $w_r(t) = \sum_{k=0}^r |1/2 + it|^{2k}$ relative to $dt/(2\pi)$.

Theorem 104.1 (Finite differential graph norms and the complete jet graph). *Let Z be a nonempty finite packet of actual nontrivial zeros with full multiplicities, $E_Z = \mathbb{C}[t]/h_Z$, and $J_Z : \mathcal{B} \rightarrow E_Z$ the complete Mellin-jet map. For every finite r ,*

$$\overline{\text{span}\{D^j f_0 : j \geq 0\}}^{\mathcal{H}^{(r)}} = \mathcal{H}^{(r)}, \quad f_0 = \Theta\phi_*, \quad (\text{JT2})$$

$$\overline{\{(F, J_Z F) : F \in \mathcal{B}\}}^{\mathcal{H}^{(r)} \oplus E_Z} = \mathcal{H}^{(r)} \oplus E_Z. \quad (\text{JT3})$$

Thus J_Z is not closable in this norm. The completed theta-boundary graph is $\mathcal{H}^{(r)} \oplus 0$; its quotient in (JT3) is E_Z through $[(F, u)] \mapsto u$.

Proof. For each $0 < c < \pi/4$, the actual source gives $|g(1/2 + it)| \leq C_c e^{-c|t|}$. Indeed $e^{z/2}f_0(e^z)$ is holomorphic in $|\text{Im } z| < \pi/4$: its Gaussian series and derivatives converge uniformly on compact subsets since $\text{Re}(e^{2z}) > 0$. On smaller horizontal strips it decays faster than every exponential at the positive end. Poisson gives $Jf_0 = f_0$, so analytic continuation gives $e^{z/2}f_0(e^z) = e^{-z/2}f_0(e^{-z})$; this controls the negative end. Shift the Fourier contour to height c or $-c$. The vertical integrals vanish by that decay, proving the bound.

The measure $d\mu_r = w_r(t)|g(1/2 + it)|^2 dt/(2\pi)$ has a positive exponential moment. If $u \in L^2(\mu_r)$ is orthogonal to every polynomial, $d\nu = \bar{u} d\mu_r$ is a finite complex measure with a smaller positive exponential moment, by Cauchy–Schwarz. Its Fourier transform is analytic in a strip, and every derivative at zero vanishes. Analytic continuation makes it zero there. Fourier uniqueness gives $\nu = 0$, hence $u = 0$. For this uniqueness step, convolve with Gaussian approximate identities: each convolution is in L^2 , since $\|\nu * \gamma_\epsilon\|_2 \leq \|\nu\|_{\text{TV}} \|\gamma_\epsilon\|_2$; its transform is zero, so Plancherel makes it zero, and weak convergence then gives $\nu = 0$. Polynomials are therefore dense in $L^2(\mu_r)$. Multiplication by $g(1/2 + it)$ is an isometry onto $L^2(w_r dt/(2\pi))$: divide almost everywhere, since this nonzero analytic function vanishes on a discrete, measure-zero set. The Mellin transform of $D^j f_0$ is $(1/2 + it)^j g(1/2 + it)$, proving (JT2).

Every theta polynomial has zero J_Z -jet. Thus the closure in (JT3) contains $(h, 0)$ for every h . The actual packet section $R_{\text{ref}} : E_Z \rightarrow \mathcal{B}$ satisfies $J_Z R_{\text{ref}} = 1$. Approximate $R_{\text{ref}} u$ in $\mathcal{H}^{(r)}$ by theta polynomials $p_n(D)f_0$. Then $(R_{\text{ref}} u - p_n(D)f_0, u) \rightarrow (0, u)$. This proves (JT3). For $u \neq 0$ it prevents closability. The boundary and quotient statements follow from the coordinate projections. $\square$

Corollary 104.2 (Differential on the completed graph). *The continuous map*

$$(D, A) : \mathcal{H}^{(r+1)} \oplus E_Z \longrightarrow \mathcal{H}^{(r)} \oplus E_Z, \quad (F, u) \mapsto (DF, Au) \quad (\text{JT4})$$

extends the original $(F, J_Z F) \mapsto (DF, J_Z DF)$. On the quotient by the boundary closure it is exactly $A = M_t$.

Proof. The norm definitions bound $D : \mathcal{H}^{(r+1)} \rightarrow \mathcal{H}^{(r)}$; the jet identity $J_Z D = A J_Z$ follows by retaining the complete Taylor polynomial of $s\mathcal{M}F(s)$. Apply (JT3). $\square$

Its split observation records $(e_{\mathcal{H}}, u^\bullet)$ when the Hilbert component tends to its supported zero and the jet survives. The projections compare this point to $e_{\mathcal{H}}$ and to $u^\bullet$; they do not identify it with (τ, τ) .

104.2 Exponential weights and exact jet norms

For $a \geq 0$, retain the original functions and introduce

$$\mathcal{H}_a = L^2(\mathbb{R}_+, e^{2a|\log x|} dx), \quad \|F\|_a^2 = \int_{\mathbb{R}} |\mathcal{L}F(y)|^2 e^{2a|y|} dy. \quad (\text{JT5})$$

The identity inclusions $\mathcal{B} \hookrightarrow \mathcal{H}_a \hookrightarrow \mathcal{H}_0$ are continuous. Source seminorms with powers exceeding $a + 1/2$ control both ends. Smooth functions compactly supported in log coordinates prove density.

Theorem 104.3 (Exact threshold, including the boundary). *Put $\ell_{\rho,k}(F) = (\mathcal{M}F)^{(k)}(\rho)/k!$ and $b = \operatorname{Re} \rho - 1/2$, with $k \geq 0$. The functional on $\mathcal{B}$ extends continuously to $\mathcal{H}_a$ if and only if $|b| < a$. Its exact squared norm is*

$$\|\ell_{\rho,k}\|^2 = \frac{(2k)!}{(k!)^2} \left(\frac{1}{[2(a-b)]^{2k+1}} + \frac{1}{[2(a+b)]^{2k+1}} \right). \quad (\text{JT6})$$

Proof. Inner products are conjugate-linear in their first argument. The Riesz vector in log coordinates must be

$$r_{\rho,k}(y) = \frac{y^k}{k!} e^{(\bar{\rho}-1/2)y} e^{-2a|y|}.$$

Its norm squared is $(k!)^{-2} \int y^{2k} e^{2by-2a|y|} dy$. The two half-lines converge exactly when $|b| < a$; their gamma integrals give (JT6). If $|b| \geq a$, testing any putative Riesz representative against compactly supported smooth functions forces it to be this same non-square-integrable density, a contradiction. The equality case is included: one end has no exponential decay. $\square$

Theorem 104.4 (Complete confluent Cauchy Gram). *For distinct centres ρ_i with $|\operatorname{Re} \rho_i - 1/2| < a$ and orders $0 \leq k < m_i$, let $J_a : \mathcal{H}_a \rightarrow \mathbb{C}^d$ be their Taylor-jet map. In the original Taylor coordinates its Gram $C_a = J_a J_a^*$ is*

$$(C_a)_{(i,k),(j,l)} = \frac{(k+l)!}{k!l!} \left(\frac{1}{(2a-z_{ij})^{k+l+1}} + \frac{(-1)^{k+l}}{(2a+z_{ij})^{k+l+1}} \right), \quad z_{ij} = \rho_i + \bar{\rho}_j - 1. \quad (\text{JT7})$$

It is positive definite. The exact right inverse $S_a = J_a^ C_a^{-1}$ satisfies*

$$J_a S_a = 1, \quad \|S_a u\|_a^2 = u^* C_a^{-1} u, \quad \|F\|_a^2 = \|(1 - S_a J_a)F\|_a^2 + (J_a F)^* C_a^{-1} (J_a F). \quad (\text{JT8})$$

Proof. The entry is $\langle r_{\rho_i,k}, r_{\rho_j,l} \rangle_a$; integrating $y^{k+l} e^{z_{ij}y-2a|y|} / (k!l!)$ on both half-lines proves (JT7) with its stated sign. The vectors are independent. After removing their common nonzero factor, a dependence is an exponential polynomial $\sum_i P_i(y) e^{\bar{\rho}_i y} = 0$. For each i , apply $\prod_{j \neq i} (\partial_y - \bar{\rho}_j)^{m_j}$. On the i -th polynomial factor every nonzero constant plus derivative is invertible on the finite-degree polynomial space; hence $P_i = 0$. Thus $C_a > 0$. Now $S_a J_a$ is the orthogonal projection onto $\operatorname{range} J_a^* = (\ker J_a)^\perp$. Multiplying the specified matrices proves all of (JT8). $\square$

For an actual packet the unchanged theta subspace lies in $\ker J_a$. Consequently there is an onto continuous quotient map

$$\mathcal{H}_a / \overline{\Theta V}^{\mathcal{H}_a} \longrightarrow \mathbb{C}^d, \quad [F] \mapsto J_a F, \quad \ker = (\ker J_a) / \overline{\Theta V}^{\mathcal{H}_a}. \quad (\text{JT9})$$

Its surjectivity follows from (JT8). Define the retained coordinate map

$$T : E_Z \longrightarrow \mathbb{C}^d, \quad T[p] = (p^{(k)}(\rho_i)/k!)_{i,k}.$$

Then $J_a|_{\mathcal{B}} = TJ_Z$, and the exact representative difference is $R_{\text{ref}}T^{-1} - S_a : \mathbb{C}^d \rightarrow \ker J_a$. Here R_{ref} is the original source map; S_a is a Hilbert map, with no claim it lies in $\mathcal{B}$. In E_Z coordinates the observation Gram is $C_E = T^{-1}C_a(T^{-1})^*$ and the right inverse is S_aT .

104.3 The energy term carried by the weighted topology

Theorem 104.5 (Weighted boundary identity on the actual representatives). *On $\mathcal{B}$, with $(\Sigma H)(x) = \text{sgn}(\log x)H(x)$,*

$$\langle DF, H \rangle_a + \langle F, DH \rangle_a - \langle F, H \rangle_a = 2a \langle F, \Sigma H \rangle_a. \quad (\text{JT10})$$

*For an actual packet representative $R : E_Z \rightarrow \mathcal{B}$ with $DR - RA = B = \Theta k$, put $G_a = R^*R$, $T_a = R^*\Sigma R$. Adjoints use exactly $\mathcal{H}_a$. Then*

$$A^*G_a + G_aA - G_a = 2aT_a - (B^*R + R^*B), \quad -G_a \leq T_a \leq G_a. \quad (\text{JT11})$$

For $Au = \rho u \neq 0$,

$$2 \operatorname{Re} \rho - 1 = 2a \frac{u^*T_a u}{u^*G_a u} - 2 \operatorname{Re} \frac{\langle Ru, Bu \rangle_a}{\|Ru\|_a^2}. \quad (\text{JT12})$$

Proof. In log coordinates integrate $-(\bar{f}h)'e^{2a|y|}$ on the two half-lines. Source decay kills the terms at infinity; those at zero cancel because the weight is continuous there. The weak derivative of the weight is $2a \operatorname{sgn}(y)e^{2a|y|}$. This proves (JT10) with its positive sign. Substitute $DR = RA + B$ and move both boundary terms to obtain (JT11). Multiplication by sign is a self-adjoint contraction, proving the form bounds. Evaluation on u proves (JT12). $\square$

At $a = 0$, (JT11) is the source boundary-control formula. At $a > 0$, the topology making a jet continuous has its explicitly retained energy term $2aT_a$. Off-line jets cannot remain continuous as $a \downarrow 0$. For line-centred jets, all $a > 0$ work but (JT6) diverges as $a \downarrow 0$. These are exact comparisons on the same Mellin map and differential, without a weight theorem assumed.

104.4 The tesserine coordinate in the actual weight form

Retain $c_{-+} = 4(\beta - 1/2)$, $c_{--} = 4i\gamma$ for $\rho = \beta + i\gamma$. For $p > 1$ and $|\psi| = 1$,

$$z = \psi \exp\left(\frac{\log p}{4}(c_{-+} + c_{--})\right), \quad \frac{u^*(A^*G + GA - G)u}{u^*G u} = \frac{c_{-+}}{2}, \quad |b| < a \iff |c_{-+}| < 4a. \quad (\text{JT13})$$

The first equality is exactly $z = \psi p^{\rho-1/2}$; the second is evaluation on $Au = \rho u$. Thus the original sector, local holonomy radius, arithmetic weight form and jet-continuity strip have specified comparison maps. The scalar evaluations do not replace the original matrix or its support-labelled source.

Part II

Complete counterfactual, mixed-support and boundary calculations

105 The object, its actual elements, and its assembly

Put $U = \{s : 0 < \Re s < 1, \Re s \neq 1/2\}$ and retain the original $g = 2\xi$, source V , target $\mathcal{B}$, operator $D = -x\partial_x$, and map Θ defined in full in the following construction. Let $\mathcal{P}_U$ consist of all monic polynomials whose roots lie in U , including 1. The construction starts with actual functions:

$$\mathcal{B}_U = \{F \in \mathcal{B} : \exists p \in \mathcal{P}_U, p(D)F \in \Theta V\}, \quad C_U = [V \xrightarrow{\Theta} \mathcal{B}_U], \quad \mathfrak{T}_U = \bigoplus_{k \geq 0} C_U^{\otimes k}. \quad (\text{T0.1})$$

The differential, multiplication, maps, topologies, full local coordinates and every finite presentation of this object are proved below. In particular, (T0.1) specifies a subspace of the original functions and a differential graded algebra, rather than introducing free numerical variables to which necessary conditions are assigned. An element is a finite sum of finite tensors of actual original source functions and target functions satisfying the displayed annihilator equation. Its differential applies the original theta map with the original Koszul signs.

The complete object includes its maps into the original two-leg tau diagram and its arithmetic, geometric and norm observations. We specify exactly what one object with these maps means. Let

$$C_\tau^{\text{raw}} = [V_+ \oplus V_- \xrightarrow{(\phi, \psi) \mapsto \Theta(\phi - \widehat{\psi})} \mathcal{B}], \quad i : C_U \longrightarrow C_\tau^{\text{raw}}, \quad (\text{T0.2})$$

where $i^0 v = (v/2, -\widehat{v}/2)$ and $i^1 F = F$. The minus leg has the action $t = 1 - D$, the plus and target legs have $t = D$, and Fourier uses $e^{-2\pi i x v}$. Thus i is an injective cochain map: its differential on v is $\Theta(v/2 + \widehat{v}/2) = \Theta v$, and Fourier's Euler identity proves its $A = \mathbb{C}[t]$ linearity. Tensoring these literal inclusions over $\mathbb{C}$ gives the injective homomorphism of differential graded algebras

$$T(i) : \mathfrak{T}_U \hookrightarrow T_{\mathbb{C}}(C_\tau^{\text{raw}}). \quad (\text{T0.3})$$

Injectivity follows because every inclusion of vector spaces admits a linear retraction: extend a basis, project onto the original basis, and tensor the retractions. This is a proof of injectivity, not a claim that these auxiliary retractions preserve the Euler action.

The arithmetic sheaf observation is the actual balanced diagram

$$\mathcal{A}_U \xrightarrow{a} C_\tau \xrightarrow{c} C_g = [\mathcal{O}_U \xrightarrow{g} \mathcal{O}_U], \quad C_{\ker} \hookrightarrow C_\tau, \quad c \circ C_{\ker} = 0, \quad (\text{T0.4})$$

with the all-polynomial complexes, all arrows, and their exact cohomology constructed in (CAU.1)–(CAU.33). Here balancing means sheafification of $\mathcal{O}_U \otimes_A$; it is a specified observation of the original source. Independent tensor variables always tensor over $\mathbb{C}$, as in (T0.1), not over A or a single analytic stalk.

The connection from (T0.1) to this diagram is also explicit. At a polynomial p , a degree-one cycle of the original complex

$$[V \xrightarrow{(\Theta, p(D))} \mathcal{B} \oplus V \xrightarrow{(p(D), -\Theta)} \mathcal{B}]$$

is (F, ϕ) with $p(D)F = \Theta\phi$. Send it to $F \in \mathcal{B}_U$. Its boundaries map to ΘV . Under the transitions $p \mid P$, the first coordinate F is unchanged. Consequently its induced map to $H^1(C_U)$ is the identity on

$$T_U Q = \bigcup_{p \in \mathcal{P}_U} \ker(p(D) : Q \rightarrow Q), \quad Q = \mathcal{B}/\Theta V. \quad (\text{T0.5})$$

Composition with (TO.2), balancing, and Mellin is exactly the map in (TO.4), as is checked on these representatives in CAU.

Define $\mathbf{C}_U$ to be the following single represented diagram. Start with the source vertices and arrows (TO.1)–(TO.4), including the all-polynomial vertices and transitions of CAU. Adjoin the finite polynomial source, full tensor jet, conormal, cyclic and metric observation vertices and their arrows in (AG19)–(AG38) and the subsequent exact continuation of those formulas. Common source vertices are identified by the literal function equalities in (AG12), (AG20), (AG22) and (AG26), and by the representative map preceding (TO.5). Retain the proper source-label and support arrows of (CAU.28)–(CAU.32).

The original all-packet observation also retains $\Omega = \{0 < \Re s < 1\}$ and $L = \Omega \setminus U$. For $X = \Omega, L$ put $\mathcal{B}_X = q^{-1}(T_X Q)$ using the same all-polynomial torsion definition as (TO.5), and $C_X = [V \rightarrow \mathcal{B}_X]$. Include the actual cochain inclusions $C_U \rightarrow C_\Omega \rightarrow C_+ = [V \rightarrow \mathcal{B}]$, with identity in degree zero and the original inclusions in degree one. The full calculation (MCF41)–(MCF41g) proves $T_\Omega Q = T_U Q \oplus T_L Q$ by its exact Bezout maps, and proves the cochain quotient and all proper-source comparisons. Thus critical and offcritical full packets occur on their specified domains while (TO.7) retains its offcritical detector.

For every actual full-order packet h in Ω , every $n \geq 1$, and every coefficient mask $A \subseteq I_n = \{0, \dots, n-1\}$, also adjoin the original independent carrier $D_{E_h, n} = G(E_h)^n$, every labelled face $E_h[A] = \bigoplus_{i \in A} E_h$, and the source faces $C_\Omega[A]$ and $C_{W, S}^\Omega[A]$, together with their original U -subcomplexes and their maps into $C_{W, S}[A]$. The section for a packet rooted in U lands in C_U 's degree-one term; a general packet in Ω uses the degree-one term of C_Ω , as proved in (MCF41e). Here $E_h = \mathbb{C}[x]/(h)$; the scalar ring $\mathbb{C}[x]$ acts on C_U by $x \mapsto D$ and is identified with the earlier Euler ring $\mathbb{C}[t]$ by $x \mapsto t$ at that Euler-ring vertex. The coefficient variable t in the negacyclic observation $E_h[t]/(t^n + 1)$ is a separate tagged coordinate from x and from the earlier Euler-ring variable bearing the same glyph. The additional generators are the amplitude and complete-mask maps, negacyclic product, synchronization and localization map and its specified nonunital section, coefficient extraction and insertion, signed coefficient Frobenius, and every zero-insertion arrow between faces. Include the coordinatewise original quotient, full-unit packet section, divisor, arithmetic action and theta-boundary homotopies, together with the strict free-resolution realization which can be balanced over $\mathbb{C}[x]$. Their complete formulas and proofs are the mixed-support and cochain attachments included below. In particular, the finite section s_h remains a complex-linear observation; it is not silently tensored over $\mathbb{C}[x]$ as a module morphism. The nonempty original leg label $\emptyset \neq S \subseteq \{+, -\}$ and the coefficient mask A remain independent indices. Every coefficient face, including its represented zero and the empty face, remains a vertex; no colimit over the face-filling arrows is taken.

Include also the original quadratic mixed carrier, its exact synchronization quotient and prime branches, and the original higher lattice zero fibres with their specified threshold and localization maps, as constructed in the accompanying full-carrier proofs. Retain also the original chain-to-ideal identifications $j \mapsto p^{n-j}(\mathbb{Z}/p^n\mathbb{Z})$ and $j \mapsto \epsilon^{n-j}k[\epsilon]/(\epsilon^n)$. For the power-indexed ideals $I_a = (p^a)$ or $I_a = (\epsilon^a)$, $0 \leq a \leq n$, their separate product is $I_a I_b = I_{\min(n, a+b)}$, in addition to their stated sum and intersection operations. These ideal-product degrees remain distinct from the spectral nilpotent filtration below. Their connections to the independent coefficient carrier are those explicit maps. The nilpotent filtrations, their graded quotients, and the additional Tate-scaling operators of (MW1)–(MW22) are further observation vertices and arrows. The reconstruction identity (MW19) retains the unchanged original arithmetic dilation at the same vertex. Include the original marked-product family with coefficient differentials $u\partial_{s_i} + h(s_i) - t_i$, its ordered exterior complex, its marked-fibre theta map, the specified finite-field coefficient realizations and their geometric sheaves, and its original complex connection and period observations. The marked-product boundary calculation below constructs these maps, the full u -connection and its period determinant. Its coefficient specializations have their stated source and target; the represented category imposes only the proved comparison relations. Adjoin also the four original common-source projections and signed trace obser-

vations of (SP1)–(SP13). Close all arrows under composition. Close the complex-linear amplitude complexes under their specified finite ordered tensor products over $\mathbb{C}$ and Koszul permutations, and the ringed-space complexes under their specified external tensor products and base maps. For the mixed semiring carriers and support spaces retain only their explicitly defined products and the proved coefficient-face tensor attachments. No complex tensor product or Koszul action is inferred on a semiring carrier, prime branch or lattice-zero set from its underlying-set observation.

This specifies a set-sized indexing category and one representation of it. For its complex and sheaf vertices the target is the category of ringed spaces with the specified module complexes and base-map/semilinear cochain morphisms defined in CAU. External tensor words carry product bases. Its polynomial and Hilbert vertices have their displayed vector-space domains and linear maps; forms and scalar norm values are typed observations. A common target for all evaluations is the category of their underlying sets, with each original structure retained in its vertex label and each displayed function as an arrow. This set-valued representation with marked structural data does not declare a nonlinear norm evaluation to be a linear or cochain morphism. Concretely, form the free path category on the stated vertices and arrows, then divide its paths by precisely their proved composition, tensor-interchange and common-source equalities. Assign each vertex its displayed actual space and each arrow its displayed map. Every defining relation holds as an equality of those maps by the proofs cited above; hence the assignment factors through the path relations and is a well-defined functor. This functor is $\mathbf{C}_U$. Its explicit generating source chain is $C_U \rightarrow C_\Omega \rightarrow C_+$. The offcritical tensor sources come from C_U , all nontrivial full-packet tensor sources from C_Ω , and the ambient source observations retain C_+ . The graded cochain attachment (CFA.38) also retains the actual Hom-complex vertices and their differential. A proved homotopy has the relation $f - g = dH + Hd$ with its specified degree-minus-one map H ; it does not impose the false equality $f = g$ on the original degree-zero paths.

The universal assertion for this assembly concerns the actual maps: any compatible realization of these same generating spaces and maps extends uniquely to the represented category, by sending a path to the composite of its maps and a tensor word to the specified tensor product. Well-definedness is precisely the stated path relations; uniqueness follows because every arrow is generated in this manner. No colimit over quotient observations is taken. Such a colimit would identify classes with images in zero targets and erase the very fibres the programme constructs. Only the directed inclusion colimits explicitly proved in CAU and AG are used.

106 The absolute base and the two distinct zero fibres

The base of this represented object is the constructed pointed monoid blueprint $\mathfrak{b}_\tau = \text{Spec}\{\tau, 1\}$, with absorbing τ and empty-sum relation $\emptyset \equiv \tau$. At a commutative coefficient ring R , its split carrier is $G(R) = \{\tau\} \sqcup R^\bullet$, with $e_R = 0_R^\bullet \neq \tau$. Supported addition and multiplication are the operations in R , while τ is the additive identity and multiplicative absorber. At a labelled linear arrow $f : E \rightarrow F$ the lifted arrow is

$$\tau \longmapsto \tau, \quad (\lambda, x) \longmapsto (\lambda', f(x)). \quad (\text{T0.6})$$

For a linear arrow its additivity and supported scalar compatibility follow by applying the linear identities for f ; compositions give the lift of the composite. An element killed by an arrow lands at $(\lambda', 0)$ and retains support. For the conjugate-linear reflected-conjugate operator and for conjugation, the scalar is conjugated in the semilinear rule proved in (AG38). The Fourier reflection retains its complex-linear map and the base involution $s \mapsto 1 - s$. For multiplication the rule is $x^\bullet y^\bullet = (xy)^\bullet$, with absorbing τ ; the product identities prove compatibility. These rules give the pointed structural arrows of $\mathbf{C}_U$. Numerical norm evaluations remain the specified observations and are not asserted additive.

For independent coefficients, the coordinatewise lift of a linear map preserves every coefficient mask, including coordinates with zero image. Face filling is a different specified arrow: for $A \subseteq$

B , zero insertion sends the zero e_A of the labelled additive face group to e_B . If A is empty and B is nonempty, it sends the all-absent coefficient tuple to a supported-zero tuple. It is therefore not declared to preserve the global absent point. Both maps occur in the represented underlying-set category with their respective structural types. The Cartesian product semiring has intersection of coefficient supports under multiplication; the negacyclic semiring has their cyclic sumset. These are two marked structures with their actual formulas, not an identification of their products. The negacyclic product is an arrow of the finite algebra observation. The cochain tensor algebra uses its original concatenation into the next tensor degree; no degree-zero cochain multiplication $C_U \otimes C_U \rightarrow C_U$ is inferred from that finite product.

For the scalar carrier $G(R)$, the amplitude/support map is injective: support zero identifies τ , while support one and amplitude identify $r^\bullet$. The scalar maps continue to be $G(\mathbb{Z}) \rightarrow G(\mathbb{C})$ and $\mathbb{Z} \rightarrow \mathbb{C}$. The lower arithmetic ring is the entire infinite ring $\mathbb{Z}$. Applying (T0.6) to the four point chart $+$, $- < \eta < \sigma$ leaves its original central amplitude $\mathcal{B}$, its two theta legs, and its zero σ amplitude. It does not identify relative cohomology with the zero amplitude at σ .

107 Exactly what survives and how every offcritical zero enters

The complete calculation gives an isomorphism with an explicit inverse on original functions:

$$H^1(C_U) = T_U Q \xrightarrow{[F]} [\mathcal{M}F] \sim \bigoplus_{\substack{\rho \in U \\ g(\rho)=0}} \mathcal{O}_{\mathbb{C},\rho}/(g). \quad (\text{T0.7})$$

For finite support Z , put $h = \prod_{\rho \in Z} (s - \rho)^{m_\rho}$ with each actual full order. A prescribed full jet α has the unique remainder polynomial P satisfying $[P]_\rho = [(g/h)^{-1} \alpha_\rho]$; its preimage is

$$[F_\alpha], \quad F_\alpha = S_h \Theta(P(D)\phi_*), \quad \mathcal{M}F_\alpha = (g/h)P. \quad (\text{T0.8})$$

Here S_h is the iterated original Euler inverse and $\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}$. CAU proves that every inverse acts on its required moment-zero domain, that the result belongs to the original $\mathcal{B}$, and that changes of representatives are actual theta boundaries. The complete unit g/h is retained in (T0.8).

The local element 1 at any actual offcritical zero is nonzero modulo (g) . Formula (T0.8) therefore gives a nonzero arithmetic class, not merely a parameter bearing that zero's name. Conversely, the original finite-jet kernel calculation proves that a nonzero class in (T0.5) has a root of g in its annihilator support. Thus this construction is exhaustive in both directions. The exclusion of zeros outside the open strip is the original arithmetic input for $g = 2\xi$; within that input, vanishing of $H^1(C_U)$ excludes every counterexample to RH.

The entire object is retained when this marked cohomology vanishes: its theta relations, scalar unit, diagonal tau source and meromorphic comparison kernel remain actual parts of the represented diagram. The precise arithmetic detector is (T0.7), not an assertion that all those background spaces vanish. Its tensor powers are

$$H^j(C_U^{\otimes k}) = \begin{cases} (T_U Q)^{\otimes k}, & j = k, \\ 0, & j \neq k. \end{cases} \quad (\text{T0.9})$$

AG proves this with the full explicit tensor contraction. For a nonzero class u , a functional taking u to 1 proves $u^{\otimes k} \neq 0$. A contradiction to any universally forced component of $\mathbf{C}_U$ therefore excludes its originating offcritical class. The following amplification calculation uses these exact nonvanishing maps.

108 The norm observations are values on this same object

All Hilbert, phase and finite quotient forms in the calculation come from evaluating the original functions represented above. For a full packet and polynomial P they begin with the identity

$$\|P(D_1, \dots, D_k)F_h^{\otimes k}\|_{L^2(d^k x)}^2 = \int_{\mathbb{R}^k} |P(1/2+it_1, \dots, 1/2+it_k)|^2 \prod_i \frac{|(g/h)(1/2+it_i)|^2}{2\pi} d\mathbf{t}. \quad (\text{T0.10})$$

Successive monic division gives their relation spaces and the theta primitive (AG21). Orthogonal minimization within precisely these finite relation spaces defines their matrices G , their canonical lifts and their volume determinants. These quantities are thereby coupled through the same F_h ; none is an independently adjustable entry in the construction.

Conormal logarithmic derivatives and other observations made before the theta quotient retain their target in the full ambient tensor source of (T0.3). Closure of $\mathcal{B}_U$ under those extra operations is not presumed. Hilbert completions likewise remain observations with their proved arrows. In particular the FKG calculation gives actual nonzero observations of canonical lifts whose Hilbert norms tend to zero; it proves their exact algebraic quotient and their Hausdorff reduction separately. Replacing (T0.7) by that Hausdorff reduction is not an arrow that preserves the arithmetic detector.

Every original coefficient, conormal, phase, control and volume restriction is thus a proved identity or inequality on these specified vertices and arrows. The complete proof inputs are included later in this manuscript. The next calculation tests their joint quantitative content against the surviving tensor class, including all error terms.

109 One anchored offcritical assembly of the original tau complex

We construct a single diagram from the original source complexes, with a marked arithmetic image and with its other fibres still attached. Its index set does not require naming an actual zero. In particular, the construction makes sense with no decision about the existence of an offcritical zero. The analytic input consists of the exact original calculations (BK.1)–(BK.24), the finite derived comparison (DP.1)–(DP.8), and the original two-leg maps (DC.17)–(DC.23).

109.1 The source-indexed complex and its canonical directed limit

Keep $A = \mathbb{C}[t]$, $D = -x\partial_x$, the original even Schwartz space V with $\phi(0) = 0$ and $\int \phi = 0$, and the original rapid-at-both-ends space $\mathcal{B}$ of (BK.1). All tensor products in this section are algebraic. The operators and entire functions are

$$\begin{aligned} \Theta\phi(x) &= 2 \sum_{n \geq 1} \phi(nx), & \mathcal{M}F(s) &= \int_0^\infty F(x)x^s \frac{dx}{x}, \\ Q &= \mathcal{B}/\Theta V, & g(s) &= 2\xi(s), & \mathcal{M}\Theta\phi &= gH_\phi. \end{aligned} \quad (\text{CAU.1})$$

Here $g = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ and $H_\phi = 2\pi^{s/2}M_+\phi/(s(s-1)\Gamma(s/2))$ with its original entire continuation. The Fourier transform uses $e^{-2\pi i x \nu}$. Set

$$U = \{s \in \mathbb{C} : 0 < \Re s < 1, \quad \Re s \neq \tfrac{1}{2}\}, \quad \mathcal{P}_U = \{p \in \mathbb{C}[t] : p \text{ monic and every root lies in } U\}. \quad (\text{CAU.2})$$

The constant polynomial 1 belongs to this set. Order it by divisibility. It is directed because pP is a common upper bound of p and P . No condition $p \mid g$ is imposed on this index set.

For every $p \in \mathcal{P}_U$ define the following original-source complex in degrees zero, one, and two:

$$\mathcal{K}_p = [V \xrightarrow{v \mapsto (\Theta v, p(D)v)} \mathcal{B} \oplus V \xrightarrow{(F, \phi) \mapsto p(D)F - \Theta\phi} \mathcal{B}]. \quad (\text{CAU.3})$$

The differential squares to zero because $D\Theta = \Theta D$. For $P = rp$, the transition $\iota_{p,P}$ is the identity on degree zero and has the formulas

$$(F, \phi) \mapsto (F, r(D)\phi), \quad F \mapsto r(D)F \quad (\text{CAU.4})$$

in degrees one and two. Applying both differentials verifies the cochain identity, and $\iota_{P,R}\iota_{p,P} = \iota_{p,R}$ because the polynomial multipliers multiply. Thus (CAU.3)–(CAU.4) are one specified functor from the directed category $\mathcal{P}_U$ to complexes of A -modules, not a set of requested properties.

The original Θ is injective and every nonzero $p(D)$ is injective on $\mathcal{B}$ and V . The exact cohomology maps are

$$H^0 \mathcal{K}_p = 0, \quad H^1 \mathcal{K}_p \xrightarrow{\sim} Q[p], \quad [(F, \phi)] \mapsto [F], \quad H^2 \mathcal{K}_p \xrightarrow{\sim} Q/pQ. \quad (\text{CAU.5})$$

Indeed a cycle has $p(D)F = \Theta\phi$, exactly the torsion condition. The source ϕ is unique. If $F = \Theta v$, injectivity of Θ gives $\phi = p(D)v$, so the cycle is the displayed boundary. Conversely every torsion class has such a representative and gives a cycle. The degree-two quotient is $\mathcal{B}/(p(D)\mathcal{B} + \Theta V)$, which is exactly Q/pQ . Under (CAU.5), (CAU.4) induces the literal inclusion $Q[p] \subset Q[P]$ in degree one, and $[q] \mapsto [r(D)q]$ in degree two.

Define the actual directed colimit complex

$$\mathcal{K}_U = \operatorname{colim}_{p \in \mathcal{P}_U} \mathcal{K}_p, \quad T_U Q = \bigcup_{p \in \mathcal{P}_U} Q[p]. \quad (\text{CAU.6})$$

Its universal property is explicit: a cochain map $\mathcal{K}_U \rightarrow L$ is uniquely the same as cochain maps $f_p : \mathcal{K}_p \rightarrow L$ satisfying $f_p \iota_{p,P} = f_P$. To construct it, represent a colimit vector by $x \in \mathcal{K}_p$ and send it to $f_p(x)$. The common-upper-bound relation makes this independent of the representative, and the cochain assertion follows at that stage. Conversely restriction gives the compatible family. Filtered colimits of vector spaces are exact: an element and any relation involving it occur at finitely many stages, and a common upper stage witnesses the required kernel or image identity. This also proves that cohomology commutes with this colimit.

In fact

$$H^1 \mathcal{K}_U = T_U Q, \quad H^i \mathcal{K}_U = 0 \quad (i \neq 1). \quad (\text{CAU.7})$$

Only degree two remains to prove. The original finite-jet calculation (BK.8)–(BK.11) identifies Q/pQ with $A/(p, j_p g)$ by the Mellin jet. At a root ρ of p of order n , let $m = \operatorname{ord}_\rho g$, allowing $m = 0$. The local factor of this cokernel is $\mathbb{C}[z]/(z^{\min(n,m)})$, with $z = s - \rho$; this records the actual unit of g in the Mellin map, although the ideal alone is generated by this power. For $P = p^L$, the transition on degree two is multiplication by p^{L-1} . At ρ this multiplier has zero order $(L-1)n$, while the target cokernel is killed by $z^{\min(Ln,m)}$. Choose L so that $(L-1)n \geq m$ at every one of the finitely many roots with $m > 0$. Every local component then maps to zero. Components with $m = 0$ were zero already. Thus each degree-two class is killed at a later stage, proving (CAU.7). This argument never assumes that $p(D)$ is onto its original test space.

109.2 The exact Mellin identification, including every actual zero

Let $\mathcal{N}_U = (\mathcal{O}_{\mathbb{C}}/(g))|_U$. The notation $\Gamma_c(U, \mathcal{N}_U)$ means sheaf sections with compact support in U . The zeros of the nonzero entire function g form a discrete closed set. Each compact subset of U meets that set in finitely many points. A local section at one of these points extends uniquely by zero outside a sufficiently small disc containing no other zero: on the punctured disc g is a unit and the quotient sheaf is zero. These extensions glue, since their restrictions agree on overlaps. Consequently there is the canonical identification

$$\Gamma_c(U, \mathcal{N}_U) = \bigoplus_{\rho \in U: g(\rho)=0} \mathcal{O}_{\mathbb{C},\rho}/(g). \quad (\text{CAU.8})$$

The direct sum specifies finite support and keeps the full stalk quotient.

The original Mellin map gives a canonical isomorphism

$$\mathfrak{m} : T_U Q \xrightarrow{\sim} \Gamma_c(U, \mathcal{N}_U), \quad [F] \longmapsto ([\mathcal{M}F]_\rho)_\rho. \quad (\text{CAU.9})$$

We prove all assertions, rather than presupposing a spectral identification. If $p(D)F = \Theta\phi$, then

$$p(s)\mathcal{M}F(s) = g(s)H_\phi(s). \quad (\text{CAU.10})$$

Away from the roots of p , this says that $\mathcal{M}F$ is locally a multiple of g . Hence the proposed section has finite support in U . Changing F by an original theta boundary changes its Mellin transform by gH , so the map is well-defined and A -linear.

For injectivity, suppose the section in (CAU.9) is zero. At a root ρ of p of order n , write $p = a(z)z^n$ and $g = u(z)z^m$, with $a(0)u(0) \neq 0$, allowing $m = 0$. The vanishing section says that $\mathcal{M}F = gB$ for an analytic germ B if $m > 0$; it says the same when $m = 0$ because g is then a unit. Equation (CAU.10) and cancellation in the local analytic domain give $H_\phi = pB$. Thus every jet of H_ϕ of order less than the corresponding multiplicity in p is zero. The proved original range identity (BK.8) gives $\phi = p(D)\psi$ for $\psi \in V$. Then $p(D)(F - \Theta\psi) = 0$, and injectivity on $\mathcal{B}$ gives $F = \Theta\psi$. This proves injectivity.

For surjectivity, take a finitely supported section α of (CAU.8), with support Z , and put

$$p_Z(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}, \quad m_\rho = \text{ord}_\rho g, \quad k_Z(s) = g(s)/p_Z(s). \quad (\text{CAU.11})$$

The quotient k_Z is entire, and its germ at each $\rho \in Z$ is a unit. The function g , every multiplicity, and this entire quotient are retained. Choose the unique polynomial P of degree less than $\deg p_Z$ whose jets satisfy

$$[P]_\rho = [k_Z^{-1}\alpha]_\rho \quad \text{in } \mathcal{O}_{\mathbb{C},\rho}/(s - \rho)^{m_\rho}. \quad (\text{CAU.12})$$

Existence and uniqueness follow from the polynomial Chinese remainder map: relatively prime factors have Bezout polynomials, whose products construct the orthogonal idempotents; multiplication by these idempotents and summation realizes any prescribed finite set of Taylor polynomials. The kernel is (p_Z) , and degree reduction gives the unique representative.

Use the original vector $\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}$, for which $H_{P(D)}\phi_* = P$. The Mellin transform of $\Theta(P(D)\phi_*)$ is gP and vanishes to every order specified by p_Z . The exact original range identity for $\mathcal{B}$ in (BK.8) therefore supplies its unique inverse under $p_Z(D)$:

$$F_\alpha = S_{p_Z}\Theta(P(D)\phi_*) \in \mathcal{B}, \quad p_Z(D)F_\alpha = \Theta(P(D)\phi_*), \quad \mathcal{M}F_\alpha = k_Z P. \quad (\text{CAU.13})$$

Here S_{p_Z} is the composite of the original full-plane Euler inverses at the roots with their full multiplicities. Uniqueness makes the composite independent of the order of those factors. Formula (CAU.12) gives $[\mathcal{M}F_\alpha]_\rho = \alpha_\rho$. Away from Z the quotient by p_Z is a unit at every zero of g , so the other stalk classes are zero. This proves surjectivity. The empty support gives the zero class. Any alternative polynomial lift differing by $p_Z R$ changes F_α by $\Theta(R(D)\phi_*)$, so its class in Q is unchanged. Thus (CAU.13) constructs the inverse to (CAU.9) on the original functions and relations.

In particular, for every actual $\rho \in U$ the element 1 of $\mathcal{O}_{\mathbb{C},\rho}/(g)$ has a nonzero preimage in $T_U Q$. Indeed g vanishes there, so $1 \notin (g)$, and (CAU.9) is injective. Every nilpotent coefficient at that zero is carried by the same inverse. This exhaustiveness assertion is a proved map at every actual zero; it is not an assertion that such a ρ exists.

109.3 The anchored sheaf diagram and its retained diagonal and kernel

Sheafify $\mathcal{O}_U \otimes_A$ applied termwise to (CAU.6), and denote the resulting complex by $\mathcal{A}_U$. Its stalks are the corresponding tensor products because tensor products commute with filtered colimits. Every

analytic stalk is torsion-free over the PID A , hence flat by the directed-union-of-finite-free-modules proof in (BK.12). Therefore

$$H^1 \mathcal{A}_U = \mathcal{O}_U \otimes_A T_U Q, \quad H^i \mathcal{A}_U = 0 \quad (i \neq 1). \quad (\text{CAU.14})$$

The natural sheaf map induced by Mellin identifies this degree-one sheaf with $\mathcal{N}_U$. To check it exactly, (CAU.8)–(CAU.9) identify $T_U Q$ as an A -module with the direct sum of $A/(t - \rho)^{m_\rho}$. At a point s_0 , tensoring a summand gives $\mathcal{O}_{s_0}/(s - \rho)^{m_\rho}$ through the original map $a \otimes [P(t)] \mapsto [aP(s)]$. It is zero if $s_0 \neq \rho$, and is the full quotient if $s_0 = \rho$. The Mellin identification retains the unit k_Z used in (CAU.12)–(CAU.13), so this is the actual germ of the map to $\mathcal{O}_{s_0}/(g)$. It is an isomorphism at every stalk and hence an isomorphism of sheaves.

Use the original two-leg complex, with $t = D$ on V_+ and $t = 1 - D$ on V_- , and its analytic comparison:

$$C_\tau = [\mathcal{V}_+ \oplus \mathcal{V}_- \xrightarrow{(\phi, \psi) \mapsto \Theta(\phi - \hat{\psi})} \mathcal{B}], \quad C_g = [\mathcal{O}_U \xrightarrow{g} \mathcal{O}_U]. \quad (\text{CAU.15})$$

Their terms are in degrees zero and one and are restricted to U . The comparison $c : C_\tau \rightarrow C_g$ sends (ϕ, ψ) to $H_{\phi - \hat{\psi}}$ and sends F to $\mathcal{M}F$; on balanced tensors these formulas are multiplied by their analytic coefficient. The identity in (CAU.1) proves it is a cochain map.

There is a cochain map from every $\mathcal{K}_p$ to the original unbalanced joint complex, compatible with (CAU.4), given by

$$v \mapsto \left(\frac{1}{2}v, -\frac{1}{2}\hat{v}\right), \quad (F, \phi) \mapsto F, \quad F \text{ in degree two} \mapsto 0. \quad (\text{CAU.16})$$

The differential of the first image is exactly Θv because Fourier squares to the identity on even functions. The half factors in (CAU.16) are part of this displayed map; no amplitude is discarded. The map is compatible with every transition because their first degree-one coordinate is unchanged. Taking the colimit and balancing therefore gives $a : \mathcal{A}_U \rightarrow C_\tau$.

Write $C_{\ker} = \ker c$. As proved by the explicit lifts in (DC.20)–(DC.22), there is a short exact sequence of the original complexes $0 \rightarrow C_{\ker} \rightarrow C_\tau \xrightarrow{c} C_g \rightarrow 0$. The single anchored diagram we use is

$$\mathfrak{T}_U^{\text{coh}} := \left(\mathcal{A}_U \xrightarrow{a} C_\tau \xrightarrow{c} C_g, \quad C_{\ker} \hookrightarrow C_\tau, \quad \{\mathcal{O}_U \otimes_A \mathcal{K}_p \rightarrow \mathcal{A}_U\}_{p \in \mathcal{P}_U} \right). \quad (\text{CAU.17})$$

The tensor notation in the final family means its sheafification. This is a representation of the complex-linear path category of the following fully specified quiver with relations: vertices A, C, G, R and one vertex P_p for every $p \in \mathcal{P}_U$; arrows $P_p \rightarrow P_P$ for $p \mid P$, arrows $P_p \rightarrow A$, and $A \rightarrow C \rightarrow G, R \rightarrow C$. Relations identify composites of divisibility arrows, require $P_p \rightarrow A$ to be compatible with them, and require $R \rightarrow C \rightarrow G = 0$. The representation assigns respectively $\mathcal{A}_U, C_\tau, C_g, C_{\ker}$ and the displayed balanced source complexes, with precisely the maps above. The quiver is a set-sized category, since $\mathcal{P}_U$ is a set. Its colimit vertex has the proved universal property following (CAU.6). This specifies one object in a diagram category and its actual entries and arrows, rather than an object defined by satisfying a list of conditions.

The composite ca is a quasi-isomorphism. Both its source and target have cohomology only in degree one, and its degree-one map is the isomorphism (CAU.14) to $\mathcal{N}_U$. With the original notation $\mathcal{M} = \mathcal{O}_U \otimes_A Q, \beta : \mathcal{M} \rightarrow \mathcal{N}_U$, and $\mathcal{K} = \ker \beta$, its degree-one factorization is

$$\mathcal{N}_U \xrightarrow{j} \mathcal{M} \xrightarrow{\beta} \mathcal{N}_U, \quad \beta j = 1. \quad (\text{CAU.18})$$

It is the canonical original inclusion of the full torsion summand. Indeed each local class in its image is annihilated by some polynomial, whereas every nonzero polynomial is invertible on $\mathcal{K}$ by BK. Thus it has zero $\mathcal{K}$ component, and β is an isomorphism on that torsion summand. This identifies the actual map induced by (CAU.16), not just an abstract summand of equal length.

For clarity the entire middle term is retained in (CAU.17). On the original joint degree-zero amplitude make the reversible change

$$u = \phi - \hat{\psi}, \quad v = \frac{1}{2}(\phi + \hat{\psi}), \quad \phi = v + \frac{1}{2}u, \quad \psi = \hat{v} - \frac{1}{2}\hat{u}. \quad (\text{CAU.19})$$

Its differential is Θu ; the v component is the full diagonal. Together with the original canonical splitting $\mathcal{M} = \mathcal{N}_U \oplus \mathcal{K}$, it proves

$$C_\tau \simeq \mathcal{V}_+[0] \oplus \mathcal{N}_U[-1] \oplus \mathcal{K}[-1], \quad C_{\ker} \simeq \mathcal{V}_+[0] \oplus \mathcal{K}[-1]. \quad (\text{CAU.20})$$

These are derived identifications of the explicitly retained complexes. The marked arithmetic image of (CAU.17) is $\text{im } H^1(a)$, which by (CAU.18) is $j\mathcal{N}_U$. Its support is therefore exactly the actual zero divisor of g in U , with its scheme multiplicities. The support of the entire middle term is not being substituted for this specified arithmetic support. In particular the nonzero meromorphic kernel and the diagonal are present even at points where this arithmetic image is zero.

109.4 Full finite observations and all tensor jets of the same diagram

For each $p \in \mathcal{P}_U$ let $E_p = A/(p)$ and let j_p denote full Taylor reduction. The original Mellin maps define the following cochain map, with every factor of g retained:

$$\mathcal{K}_p \longrightarrow [\mathcal{O}_U \xrightarrow{(g,p)} \mathcal{O}_U^2 \xrightarrow{(p,-g)} \mathcal{O}_U], \quad v \mapsto H_v, \quad (F, \phi) \mapsto (\mathcal{M}F, H_\phi), \quad F \mapsto \mathcal{M}F. \quad (\text{CAU.21})$$

On balanced tensors it is $\mathcal{O}_U$ -linear. Applying either differential gives the same expression by (CAU.1) and $\mathcal{M}p(D)F = p(s)\mathcal{M}F$. It induces the original maps to the kernel and cokernel of multiplication by $j_p g$ on E_p ; equivalently its analytic degree-one target is $\mathcal{N}_U[p]$. The local conversion between these two presentations, for $p = a(z)z^n$ and $g = u(z)z^m$, is

$$[v] \longmapsto [(g/p)v], \quad z^{\max(n-m,0)}\mathcal{O}/z^n\mathcal{O} \xrightarrow{\sim} z^{\max(m-n,0)}\mathcal{O}/z^m\mathcal{O}, \quad (\text{CAU.22})$$

with the exact multiplier $(u/a)z^{m-n}$ and inverse $(a/u)z^{n-m}$ on those specified powers. This is a well-defined isomorphism because changing a representative by p changes the product by g , and the source kernel condition makes the product holomorphic. It includes zero factors when $m = 0$ and includes every repeated-zero order. Thus every finite factor of the all-polynomial index is computed, including those which observe no actual zero. In fact (CAU.21), after balancing, is a quasi-isomorphism at every p : the degree-one map is (CAU.22), the degree-two map is the same Mellin identification $\mathcal{O}/(p, g)$, and both degree-zero groups vanish. Flatness and (CAU.5) justify these cohomology calculations for the original balanced source, so no chain-level kernel has been assumed zero.

For an actual finite monic divisor $h \mid g$ with roots in U , the finite packet is the prescribed quotient $A_h = A/(h) \simeq \Gamma(U, \mathcal{O}_U/(h))$. It is obtained from the marked image by the reduction $\mathcal{N}_U \rightarrow \mathcal{O}_U/(h)$ and from the original source by $[F] \mapsto j_h \mathcal{M}F$. Retain the entire quotient $k = g/h$; its germ at a root of h is a unit exactly when h contains the full multiplicity of g there. Both degrees of its derived observation are retained by

$$E_h^{\text{free}} = [\mathcal{O}_U \xrightarrow{h} \mathcal{O}_U] \quad \text{in degrees } -1, 0, \quad - \otimes_{\mathcal{O}_U} E_h^{\text{free}}. \quad (\text{CAU.23})$$

This is a tensor operation on every vertex and arrow of (CAU.17), so it is an observation of the single diagram. On its analytic vertex C_g the total complex in degrees $-1, 0, 1$ is

$$\mathcal{O}_U \xrightarrow{a \mapsto (ha, ga)} \mathcal{O}_U^2 \xrightarrow{(b, c) \mapsto gb - hc} \mathcal{O}_U. \quad (\text{CAU.24})$$

It maps to $[\mathcal{O}_U/(h) \xrightarrow{0} \mathcal{O}_U/(h)]$ in degrees zero and one by $(b, c) \mapsto [b]$ and $d \mapsto [d]$. This is a quasi-isomorphism because it tensors the free complex C_g with the quasi-isomorphism $E_h^{\text{free}} \rightarrow \mathcal{O}_U/(h)$; alternatively its degree-zero cycles are exactly (b, kb) , modulo (ha, ga) , and its degree-one quotient is $\mathcal{O}/(g, h) = \mathcal{O}/(h)$. Under the map to the torsion in $\mathcal{N}_U$ its degree-zero class is $[b] \mapsto [kb]$. The multiplier $k = g/h$ is not dropped.

On the full joint vertex the same observation also retains its diagonal. By (BK.8)–(BK.9), $\mathcal{V}_+/h\mathcal{V}_+ \simeq \mathcal{O}_U/(h)$ through H , and h is injective on $\mathcal{V}_+$. Using (CAU.20) and the contractibility of $[\mathcal{K} \xrightarrow{h} \mathcal{K}]$ therefore gives

$$H^0(C_\tau \otimes E_h^{\text{free}}) \simeq (\mathcal{O}_U/(h))^2, \quad H^1(C_\tau \otimes E_h^{\text{free}}) \simeq \mathcal{O}_U/(h). \quad (\text{CAU.25})$$

In the original plus/minus jet coordinates the degree-zero comparison is $(\alpha, \beta) \mapsto \alpha - \beta$; its kernel is the full diagonal (α, α) . Thus the finite observation does not confuse the joint source with the one-leg complex.

For $h \mid H$, the quotient transition of these observations is the cochain map $E_H^{\text{free}} \rightarrow E_h^{\text{free}}$ equal to H/h in degree -1 and the identity in degree zero. Its cochain identity is $h(H/h) = H$. All transitions of the total diagram are obtained by tensoring this exact map.

To specify all endpoints of these arrows, first adjoin to the seed diagram a vertex (v, h) with value $D_v \otimes_{\mathcal{O}_U} E_h^{\text{free}}$ for every existing vertex v of value D_v and every admitted h . Adjoin the maps $f \otimes 1$ for each original arrow f , the transition maps $1 \otimes (E_H^{\text{free}} \rightarrow E_h^{\text{free}})$, and their cohomology vertices and induced arrows, including the finite quotient vertices in (CAU.24)–(CAU.25). Their relations are exactly the commuting squares supplied by tensor functoriality and by cohomology. This internal tensor operation over $\mathcal{O}_U$ is an explicitly adjoined observation; it is not identified with the external tensor operation in the next paragraph.

Finally close this represented diagram under finite ordered external tensor products over $\mathbb{C}$, with the specified symmetry maps and Koszul signs. The ambient category is graded by the nonnegative integer r : degree- r values are sheaf complexes on U^r , with the coefficient sheaf equal to the tensor product over $\mathbb{C}$ of the pulled-back coefficient sheaves; degree zero is the point with unit $\mathbb{C}$. Permutations use their actual coordinate permutations on U^r . This is a single canonical enlargement: its vertices are finite words of existing vertices, including the empty word; arrows are generated by tensoring the existing arrows with identities, by permutations, and by the displayed finite-observation maps. Their relations are composition, identity, tensor interchange, and the Koszul permutation relations. The value of a word is the literal external tensor product of its original complexes; its differential is

$$d(x_1 \otimes \cdots \otimes x_r) = \sum_{i=1}^r (-1)^{\sum_{j<i} |x_j|} x_1 \otimes \cdots \otimes dx_i \otimes \cdots \otimes x_r. \quad (\text{CAU.26})$$

This construction has the explicit free symmetric monoidal universal property: a tensor-compatible extension of the original represented diagram must have these values and arrows on every word, and the displayed relations make that extension unique. Pairwise interchange of the two differential terms proves $d^2 = 0$ with these signs. For finite packets $h_1, \dots, h_r$, their tensor observation is exactly

$$A_{h_1} \otimes_{\mathbb{C}} \cdots \otimes_{\mathbb{C}} A_{h_r} = \frac{\mathbb{C}[s_1, \dots, s_r]}{(h_1(s_1), \dots, h_r(s_r))}. \quad (\text{CAU.27})$$

Successive monic division in each variable proves the isomorphism: the monomials with $0 \leq j_i < \deg h_i$ give bases on both sides and the map takes the tensor basis to that basis. At specified actual centres it retains all jets $0 \leq j_i < \text{ord}_{\rho_i} h_i$; when each selected divisor contains the full multiplicity, these are exactly all jets $0 \leq j_i < m_{\rho_i}$. It retains every one-variable multiplier $g(s_i)/h_i(s_i)$ from (CAU.24). The total derived observation is the tensor of the two-term observations, so every degree and every tensor nilpotent survives in its prescribed summand. Tensoring over a field is exact: a basis extends a basis of a subspace and splits every vector-space short exact sequence. This proves the cohomological tensor assertion without an unproved flatness claim about a completed analytic tensor product. The tensor sheaves here are sheaves of modules over the literal tensor product of the pulled-back analytic coefficient sheaves; no formal or analytic completion of the original source is implicit.

109.5 All proper source and original leg-support fibres, and the exact actions

The diagram has its original label enlargement as part of the same construction. For every D -invariant subspace $W \subset V$ and every nonempty original leg mask $S \subset \{+, -\}$, include the original complex $C_{W,S}$ with central term $\mathcal{B}$, plus source W if $+$ $\in S$, minus source $\widehat{W}$ if $- \in S$, and differential $\Theta\phi - \Theta\widehat{\psi}$ on the present sources. Give the two sources the actions D and $1 - D$, respectively. Balancing and restriction to U are the same operations used above. For $W \subset W'$ and $S \subset S'$, inclusion on each present source and the identity on $\mathcal{B}$ is a cochain map; the differentials agree term by term. These maps compose literally and are included as arrows in the represented category of (CAU.17). The map to C_g is the original signed H map in degree zero and Mellin in degree one, so these arrows commute with that comparison.

For the joint mask, the change (CAU.19) has $u, v \in W$ and proves $H^0 C_{W,\{+,-\}} = W$ and $H^1 C_{W,\{+,-\}} = Q_W$, where $Q_W = \mathcal{B}/\Theta W$. Each one-leg mask has zero degree-zero cohomology and the same Q_W in degree one; on the minus leg the actual differential is $-\Theta\widehat{\psi}$. The proper-label transition retains the exact original sequence

$$0 \longrightarrow V/W \xrightarrow{[\phi] \mapsto [\Theta\phi]} Q_W \longrightarrow Q \longrightarrow 0. \quad (\text{CAU.28})$$

Injectivity of Θ and the quotient definitions prove exactness; flatness retains it after balancing. Thus every additional proper-label class and its specified vanishing under transition remain in this single diagram. No field-vector assertion for its larger kernel is substituted for the proved assertion about the full source V .

On a support fibre the total carrier is the original disjoint union with external absence. Every displayed linear map f lifts as

$$\tau \mapsto \tau, \quad (W, S, x) \mapsto (W', S', f(x)), \quad e_{W,S} = (W, S, 0). \quad (\text{CAU.29})$$

For a fixed source and target label its supported-zero fibre is exactly $\{(W, S, x) : f(x) = 0\}$, while only external τ maps to external τ . Composition of these lifts follows from composition of the linear maps. Thus the supported part has the actual Grothendieck category of elements: at a fixed cochain degree and open set its objects are the labelled amplitude elements, and its arrows are exactly the represented maps carrying one element to the other. Forgetting the amplitude gives the label projection on this supported part. The single external τ is adjoined to its carrier outside that projection, with the pointed actions in (CAU.29). It is not identified with a labelled object (W, S, τ) of a category of elements. No zero fibre has been replaced by that external point.

These are the original leg-mask fibres. The independent coefficient slots of the original PS construction have an additional index $A \subseteq I_n$, retained jointly with (W, S) . Their face complex is $C_{W,S}[A] = \bigoplus_{i \in A} C_{W,S}$, with every arrow and differential acting in each active coordinate. Consequently the transition to the full source has kernel $(V/W)^A$: injectivity, image, and surjectivity in (CAU.28) are checked in each coordinate. Zero insertion between coefficient faces commutes with every linear cochain arrow because a new coordinate has value zero on both composites. It fills a labelled supported zero and does not change the independent outer leg label S . The mixed cochain attachment below proves the complete packet-section, boundary, balancing and tensor comparisons on these faces. Their disjoint labelled carrier and synchronization are additional represented vertices; the single synchronized lift $G(E^n)$ is not used in place of the independent carrier $G(E)^n$.

The symmetries and actions are also actual arrows. To type their base maps precisely, the enlargement with these arrows uses the category whose objects are ringed spaces with their specified module complexes and whose morphisms consist of a specified base map and the indicated semilinear cochain map. Composition uses the composite base map and the composite semilinear map. Ordinary arrows of (CAU.17) have the identity base map; reflection and conjugation have their displayed base maps. This is the Grothendieck extension of that represented diagram by the following actual action maps. Dilation $R_a F(x) = F(x/a)$, $a > 0$, sends the label W to $R_a W$; on the plus source

and target it acts by R_a , and on the minus source it acts by $aR_{1/a}$. The latter lies in $\widehat{R_a W} = aR_{1/a}\widehat{W}$, by direct Fourier substitution. It commutes with the differentials and Mellin takes it to a^s . It acts on (CAU.3) by R_a in each original coordinate and hence commutes with its polynomial transitions and with (CAU.16).

For the reflection $r(s) = 1 - s$ put $JF(x) = x^{-1}F(1/x)$ and $p^r(s) = (-1)^{\deg p}p(1 - s)$, which is again monic in $\mathcal{P}_U$. The r -semilinear chain map from the (W, S) vertex to $(\widehat{W}, \text{swap } S)$ sends

$$(\phi, \psi) \mapsto (-\psi, -\phi), \quad F \mapsto JF. \quad (\text{CAU.30})$$

The theta identity $J\Theta = \Theta^\wedge$ proves the chain identity with the displayed signs, and its square is the identity. On (CAU.3), writing $\epsilon_p = (-1)^{\deg p}$, the corresponding map to $\mathcal{K}_{p^r}$ is

$$v \mapsto \widehat{v}, \quad (F, \phi) \mapsto (JF, \epsilon_p \widehat{\phi}), \quad F \mapsto \epsilon_p JF. \quad (\text{CAU.31})$$

Indeed $\widehat{p(D)v} = p(1 - D)\widehat{v} = \epsilon_p p^r(D)\widehat{v}$ and $p^r(D)JF = \epsilon_p Jp(D)F$. These equalities verify both differentials. For $P = rp$, one has $r^r = \epsilon_r r(1 - s)$ and $\epsilon_P = \epsilon_r \epsilon_p$, which proves compatibility of (CAU.31) with (CAU.4). Formula (CAU.16) intertwines (CAU.31) with (CAU.30) exactly. In (CAU.19) coordinates reflection acts by $(u, v) \mapsto (\widehat{u}, -\widehat{v})$, retaining the diagonal.

On the adjoined finite observations the required cochain map is $r^* E_h^{\text{free}} \rightarrow E_{h^r}^{\text{free}}$, with multiplier $\epsilon_h = (-1)^{\deg h}$ in degree -1 and multiplier 1 in degree zero; indeed $h^r = \epsilon_h h(1 - s)$. On (CAU.24) this sends its three coordinates to $\epsilon_h r(a)$, $(r(b), \epsilon_h r(c))$, and $r(d)$, respectively. Substitution into both differentials proves the cochain identity. For $h \mid H$, the identity $(H/h)^r = \epsilon_{H/h}(H/h)(1 - s)$ and $\epsilon_H = \epsilon_h \epsilon_{H/h}$ proves compatibility with the quotient transition of the observation complexes. Thus the reflection on every observed vertex is typed by its pullback and retains the signs forced by monic polynomial reflection.

Complex conjugation acts on the original functions and all coefficients, takes $p(s)$ to $\overline{p(\overline{s})}$, and commutes with the differentials because the theta sums, D , and g have the corresponding real structure. It commutes with Fourier on the even source spaces. Together with (CAU.30) it gives the original reflected-conjugate operation $s \mapsto 1 - \overline{s}$ on the packet. Direct substitution proves

$$JR_a J = aR_{1/a}, \quad r R_a = aR_{1/a} r \quad (\text{CAU.32})$$

on the labelled chain maps, with the scalar a acting on every term. These are the actual semidirect relations, not a commuting-action replacement. All analytic actions agree because $a^{1-s} = a(a^{-1})^s$ and $g(1 - s) = g(s)$.

At an actual zero ρ of order m_ρ the finite arithmetic action obtained from this single diagram is precisely

$$a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho[v] = [(s - \rho)v] \text{ in } \mathcal{O}_\rho/(g). \quad (\text{CAU.33})$$

It is multiplication by the Taylor expansion of a^s modulo the full original ideal, so every coefficient and nilpotent order is specified. The finite residue and its weight-one dual action are the original maps (OCQ.26)–(OCQ.30) applied to these same factors; their source inclusion is (CAU.18), and their tensor extensions are fixed by (CAU.26). Thus (CAU.17), enlarged by its explicitly defined label, action, and tensor arrows, is one anchored original-programme object. Its marked arithmetic support is exactly $\mathcal{N}_U$, and (CAU.13) provides a nonzero original-source lift of every nonzero class of each actual offcritical packet. The construction asserts neither that this support is nonempty nor that it is empty.

109.6 The exact attachment to the single arithmetic tensor algebra

The arithmetic tensor algebra (AG14) is attached to (CAU.17) by an explicit source-level map, with no claim that all operations on the ambient test space preserve its arithmetic subspace. Retain its

original definitions

$$\mathcal{B}_U = q^{-1}(T_U Q) \subset \mathcal{B}, \quad C_U = [V \xrightarrow{\Theta} \mathcal{B}_U], \quad \mathfrak{T}_U = \bigoplus_{k \geq 0} C_U^{\otimes_{\mathbb{C}} k}. \quad (\text{CAU.34})$$

These agree exactly with (AG2) and (AG14), since $[F] \in Q[p]$ means $p(D)F \in \Theta V$. Each term has the original topology as a subspace when a topological observation is taken; the displayed DGA itself uses the algebraic tensors specified in AG.

It is essential not to project all of $\mathcal{K}_p^1$ into $\mathcal{B}_U$: an arbitrary F in that degree need not have a torsion class. The exact connecting complex is the good truncation

$$Z_p = \{(F, \phi) : p(D)F = \Theta\phi\}, \quad \tau_{\leq 1}\mathcal{K}_p = [V \xrightarrow{(\Theta, p(D))} Z_p]. \quad (\text{CAU.35})$$

The map $Z_p \rightarrow q^{-1}(Q[p])$, $(F, \phi) \mapsto F$, is a linear isomorphism: existence of ϕ is the defining condition on its target and uniqueness follows from injectivity of Θ . It intertwines the displayed differential with Θ . The transitions (CAU.4) preserve it and become literal inclusions of these target subspaces. Directed exactness consequently proves the cochain isomorphism and the anchored zigzag

$$\mathcal{K}_U \longleftarrow \operatorname{colim}_p \tau_{\leq 1}\mathcal{K}_p \xrightarrow{\sim} C_U \xrightarrow{\sigma} C_\tau^{\text{orig}}, \quad \sigma^0(v) = (\tfrac{1}{2}v, -\tfrac{1}{2}\widehat{v}), \quad \sigma^1(F) = F. \quad (\text{CAU.36})$$

Here C_τ^{orig} is the original unbalanced joint complex; its balancing is (CAU.15). The left arrow is the inclusion of the good truncation into the directed complex and is a quasi-isomorphism by (CAU.7). The middle arrow is the actual cochain isomorphism just proved, since the union of $q^{-1}(Q[p])$ is $\mathcal{B}_U$. The right arrow is injective in both degrees and is a cochain map by (CAU.16). The two maps from the middle complex into the full tau complex agree literally. Balancing preserves this zigzag and its quasi-isomorphism because all the analytic stalks are flat over A . Thus it is the exact source-level attachment of AG's arithmetic complex to the arithmetic vertex of (CAU.17).

Tensoring the right arrow and taking the direct sum gives one injective unital differential graded algebra map

$$\mathfrak{T}_U \hookrightarrow T(C_\tau^{\text{orig}}) := \bigoplus_{k \geq 0} (C_\tau^{\text{orig}})^{\otimes_{\mathbb{C}} k}, \quad x_1 \otimes \cdots \otimes x_k \mapsto \sigma(x_1) \otimes \cdots \otimes \sigma(x_k). \quad (\text{CAU.37})$$

Its multiplicativity follows from concatenation, its compatibility with the differential follows term by term from (CAU.26), and its injectivity follows by extending bases over $\mathbb{C}$ in every cochain degree before tensoring. The degree-zero tensor unit maps to the same unit. It has the tensor-algebra universal property: every cochain map from C_U into the underlying complex of a unital DGA extends uniquely to a unital DGA map by multiplying the images of the tensor factors, since the Leibniz identity is exactly the signed formula (CAU.26). In particular (CAU.37) is the unique such extension of the specified original source inclusion σ .

Adjoining (CAU.36)–(CAU.37) as arrows to the same represented diagram identifies its arithmetic tensor vertex with the already constructed single DGA (AG14). All its finite packet lifts in (AG6)–(AG13) have the same Mellin image as (CAU.12)–(CAU.13); equality of their classes follows from the injectivity proved in (CAU.9). The ambient vertex retains the full $\mathcal{B}$ and both original tau legs. Accordingly the original logarithmic-derivative and conormal observations remain attached to their actual ambient domains. No closure of $\mathcal{B}_U$ under those operations is asserted, and no observation is silently retyped as an endomorphism of the arithmetic tensor algebra.

110 The single arithmetic carrier and its divisor–tensor gluing

Put $U = \{s \in \mathbb{C} : 0 < \Re s < 1, \Re s \neq 1/2\}$. The original objects are

$$\begin{aligned} V &= \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \int \phi = 0\}, \\ \mathcal{B} &= \{F \in C^\infty(\mathbb{R}_+) : \sup_{x>0} x^b |D^j F(x)| < \infty \ (b \in \mathbb{Z}, j \geq 0)\}, \\ D &= -x\partial_x, \\ \Theta\phi(x) &= 2 \sum_{n \geq 1} \phi(nx), \quad Q = \mathcal{B}/\Theta V, \quad q : \mathcal{B} \rightarrow Q, \quad \mathcal{M}F(s) = \int_0^\infty F(x)x^s \frac{dx}{x}. \end{aligned}$$

The original theta and Euler inverse calculations (A1)–(A9) prove that Θ is injective, commutes with D , and that every nonzero polynomial $p(D)$ is injective on $\mathcal{B}$. For roots of p in the open strip they also prove

$$p(D)\mathcal{B} = \ker(j_p \mathcal{M}), \quad p(D)V = \ker(j_p H), \quad \mathcal{M}\Theta\phi = gH_\phi, \quad g = 2\xi, \quad H_{P(D)\phi_*} = P, \quad (\text{AG1})$$

where $\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}$. The maps j_p in this formula are the complete Taylor jets, including every nilpotent coefficient through the indicated multiplicity. The following construction takes place inside these original test function spaces. Their topologies are the displayed Schwartz topologies and their inherited subspace topologies.

110.1 A definition that does not presuppose a list of zeros

Let $\mathcal{P}_U$ be the multiplicative set of monic polynomials all of whose roots lie in U , including 1. Define the actual spaces

$$\begin{aligned} T_U Q &= \{u \in Q : p(D)u = 0 \text{ for some } p \in \mathcal{P}_U\}, \\ \mathcal{B}_U &= \{F \in \mathcal{B} : p(D)F \in \Theta V \text{ for some } p \in \mathcal{P}_U\}, \\ C_U &= [V \xrightarrow{\Theta} \mathcal{B}_U] \subseteq [V \xrightarrow{\Theta} \mathcal{B}]. \end{aligned} \quad (\text{AG2})$$

The complex has its original degrees zero and one. Products of annihilating polynomials show that both displayed sets are vector spaces and D -modules. For example, if $p(D)u = 0$ and $r(D)v = 0$, then $(pr)(D)(au + bv) = 0$; D commutes with both polynomials. The inverse image under q of $T_U Q$ is exactly $\mathcal{B}_U$. Consequently

$$H^0(C_U) = 0, \quad H^1(C_U) = T_U Q, \quad 0 \rightarrow V \xrightarrow{\Theta} \mathcal{B}_U \xrightarrow{q} T_U Q \rightarrow 0 \quad (\text{AG3})$$

is the actual exact sequence, with the original arrows.

Here is its precise finite-packet presentation. For any $p \in \mathcal{P}_U$, the map

$$Q[p(D)] \longrightarrow \ker(M_{j_p g} : E_p \rightarrow E_p), \quad [F] \longmapsto j_p H_\phi, \quad p(D)F = \Theta\phi, \quad E_p = \mathbb{C}[s]/(p), \quad (\text{AG4})$$

is a $\mathbb{C}[s]$ -linear isomorphism. To check every arrow, ϕ is unique by injectivity of Θ . Replacing F by $F + \Theta\psi$ replaces ϕ by $\phi + p(D)\psi$, whose p -jet changes by zero by (AG1). The target condition follows from $j_p \mathcal{M}(p(D)F) = 0$. A zero source jet gives $\phi = p(D)\psi$ by (AG1); injectivity of $p(D)$ then gives $F = \Theta\psi$. Conversely a target vector has a polynomial representative P , and $j_p(gP) = 0$ allows the unique inverse $F = S_p^{\mathcal{B}} \Theta(P(D)\phi_*)$. Changing P by pR changes this inverse by $\Theta(R(D)\phi_*)$. These operations are inverse and commute with D , again by its injectivity and (AG1).

At a root ρ of p of order n , use the literal coordinate $z = s - \rho$. If g has order $m \geq 0$ there, its full local jet has the form $z^m u(z)$, $u(0) \neq 0$, with the convention that it is zero modulo z^n when $m \geq n$. The inverse of the unit is the finite geometric expansion of its nilpotent part. Thus

$$\ker(M_g : \mathbb{C}[z]/z^n \rightarrow \mathbb{C}[z]/z^n) = z^{\max(n-m, 0)} \mathbb{C}[z]/z^n. \quad (\text{AG5})$$

This kernel is zero when $m = 0$, and is killed by z^m when $m > 0$. Chinese remainders and (AG4) imply that every $u \in T_U Q$ is killed by the polynomial consisting of the actual roots of g in its finite annihilator, with their full orders. Adding the finite orbits under conjugation and $s \mapsto 1 - s$ still gives an annihilator whose roots lie in U .

Let $\mathcal{D}_U$ denote these finite invariant full-order packet polynomials, with 1 included. Divisibility makes it a directed set: the least common multiple is the polynomial on the union of the two supports, retaining each full order once. This directed set is now a presentation of (AG2), rather than its definition.

110.2 The exact divisor arrows and their arithmetic units

For $h \in \mathcal{D}_U$, $h \neq 1$, retain

$$\begin{aligned} E_h &= \mathbb{C}[s]/h, & d_h &= \deg h, & A_h &= M_s, \\ v_h &= g/h, & v_h &= j_h v_h, & \varepsilon_h &= v_h^{-1}, \\ F_h &= S_h^{\mathcal{B}} \Theta \phi_*, & \mathcal{T}_h P &= P(D)F_h. \end{aligned} \quad (\text{AG6})$$

Thus $h(D)F_h = \Theta \phi_*$ and $\mathcal{M}F_h = v_h$. The notation F_h denotes this actual inverse function, not an unconstructed functional calculus. Complete root orders imply $v_h(\rho) \neq 0$ on the packet, proving the asserted unit property. Write r_h for the unique remainder representative of degree $< d_h$, and define

$$s_h = \mathcal{T}_h r_h M_{\varepsilon_h}, \quad J_h = j_h \mathcal{M}, \quad \sigma_h = q s_h. \quad (\text{AG7})$$

Then $J_h s_h = I$, $J_h \Theta = 0$, and

$$h(D)s_h u = \Theta(r_h(\varepsilon_h u)(D)\phi_*), \quad Ds_h - s_h A_h = \Theta \phi_* \ell_h, \quad \ell_h(u) = [s^{d_h-1}]r_h(\varepsilon_h u). \quad (\text{AG8})$$

For the second identity, the difference $sr_h(\varepsilon_h u) - r_h(\varepsilon_h A_h u)$ is divisible by h , has degree at most d_h , and has quotient exactly $\ell_h(u)$. Applying $\mathcal{T}_h$ proves it.

The image of σ_h is exactly $Q[h(D)]$. In fact (AG4) identifies the latter with E_h , since $j_h g = 0$. Applying its map to $\sigma_h u$ gives $\varepsilon_h u$ by the first identity of (AG8), an invertible map of E_h . Injectivity of σ_h also follows from $J_h s_h = I$ and $J_h \Theta = 0$. Hence

$$\mathcal{B}_U = \Theta V + \bigcup_{h \in \mathcal{D}_U} s_h E_h, \quad T_U Q = \varinjlim_{h \in \mathcal{D}_U} (E_h, \iota_{hH}), \quad (\text{AG9})$$

with the following explicit transition arrows. The $h = 1$ terms mean $E_1 = 0$, $s_1 = 0$, and ΘV ; no inverse unit is required in the zero space.

For $h \mid H$, put $b = H/h$; b and h are coprime. Let

$$\pi_{Hh} : E_H \twoheadrightarrow E_h, \quad [P]_H \mapsto [P]_h, \quad \iota_{hH} : E_h \hookrightarrow E_H \quad (\text{AG10})$$

be respectively restriction of jets and insertion of zero jets at the added centres. Chinese remainder division proves $\pi \iota = I$, $\iota \pi = M_{e_{hH}}$, where e_{hH} is the idempotent equal to one on the old local factors and zero on the added ones. Both maps commute with multiplication by s . The map π is a unital algebra map; ι preserves products and is $\mathbb{C}[s]$ -linear, with $\iota(1) = e_{hH}$. Define the different, raw numerator map

$$\mu_b : E_h \rightarrow E_H, \quad [P]_h \mapsto [bP]_H, \quad \mu_b = \iota M_{[b]_h}, \quad \iota = \mu_b M_{[b]_h}^{-1}. \quad (\text{AG11})$$

These identities follow on every old factor by multiplication by the full unit $[b]_h$, and on every added factor by its full-order zero. They prove well-definedness and injectivity of μ_b .

The analytic and unit identities are exactly

$$\begin{aligned} v_h &= bv_H, & b(D)F_H &= F_h, & \mathcal{T}_H(bP) &= \mathcal{T}_hP, \\ \pi v_H &= [b]_h^{-1}v_h, & \pi\varepsilon_H &= [b]_h\varepsilon_h, & J_H\mathcal{T}_hP &= \iota J_h\mathcal{T}_hP, \\ s_H\iota &= s_h, & \sigma_H\iota &= \sigma_h, & \ell_H\iota &= \ell_h. \end{aligned} \quad (\text{AG12})$$

The function identity follows by applying the injective $h(D)$ to $b(D)F_H$ and F_h . The jet identity holds at the old centres by equality of the entire functions, and at added centres because v_h vanishes there to their full orders. For the section identity, $br_h(\varepsilon_h u)$ has degree $< d_H$ and its product with v_H has complete H -jet ιu . Since v_H is a unit, this is precisely $r_H(\varepsilon_H \iota u)$. The last identity follows either from monicity of b and its leading coefficient, or by subtracting (AG8) for these equal sections. These arguments also prove the composition laws $\iota_{HK}\iota_{hH} = \iota_{hK}$ and $\mu_{K/H}\mu_{H/h} = \mu_{K/h}$.

In particular the directed limit in (AG9) is explicitly

$$E_U := \bigoplus_{\substack{\rho \in U \\ g(\rho)=0}} \mathbb{C}[z_\rho]/z_\rho^{m_\rho}, \quad s \cdot u_\rho = (\rho + z_\rho)u_\rho, \quad \sigma_U : E_U \xrightarrow{\sim} T_U Q. \quad (\text{AG13})$$

All vectors have finite support. The direct sum is closed under coordinatewise products, but has no prescribed global unit when the set of roots is infinite. No nilpotent coordinate is removed. The map $s_U : E_U \rightarrow \mathcal{B}_U$ is defined by the coherent s_h ; the formula $\mathcal{B}_U = \Theta V \oplus s_U E_U$ is an equality of vector spaces proved by $J_h s_h = I$. It is not asserted to be a D -equivariant splitting.

110.3 One differential graded arithmetic object

Define the algebraic differential graded tensor algebra

$$\mathfrak{T}_U = \bigoplus_{k \geq 0} C_U^{\otimes k}, \quad C_U^{\otimes 0} = \mathbb{C}, \quad (x_1 \otimes \cdots \otimes x_k)(y_1 \otimes \cdots \otimes y_l) = x_1 \otimes \cdots \otimes x_k \otimes y_1 \otimes \cdots \otimes y_l. \quad (\text{AG14})$$

On homogeneous tensors retain the literal differential

$$d(x_1 \otimes \cdots \otimes x_k) = \sum_{i=1}^k (-1)^{\sum_{j < i} |x_j|} x_1 \otimes \cdots \otimes dx_i \otimes \cdots \otimes x_k. \quad (\text{AG15})$$

Every $|x_i|$ is its original cochain degree, zero or one. The two orders of applying the differential at distinct positions have opposite signs, and $d^2 x_i = 0$, proving $d^2 = 0$. Separating this sum at the concatenation point proves $d(xy) = (dx)y + (-1)^{|x|}x(dy)$. Concatenation is associative on pure tensors and hence by linearity. Thus (AG14) is one actual differential graded algebra embedded in the corresponding tensor algebra of the original theta complex. The operator $D_{\text{tot}} = \sum_i D_i$ commutes with d and is a derivation for concatenation. It is zero on the length-zero term.

Every tensor uses finitely many entries, so (AG9) and a common packet containing their supports prove

$$C_U^{\otimes k} = \varinjlim_{h \in \mathcal{D}_U} [V \rightarrow \Theta V + s_h E_h]^{\otimes k}. \quad (\text{AG16})$$

These are literal inclusions into the same tensor test-function complex, rather than isomorphisms of unspecified carriers.

There is a direct proof of its complete cohomology. For $F = \Theta\phi + s_U u$, define $tF = \phi$ and $pF = s_U u$; on degree zero put $p = 0$. Uniqueness of the decomposition makes these linear maps well defined. Then $dt + td = I - p$, with t zero on degree zero, and p is a cochain projection onto $s_U E_U$ in degree one. On a length- k tensor set

$$t_k = \sum_{i=1}^k p^{\otimes(i-1)} \otimes t \otimes I^{\otimes(k-i)}, \quad (\text{AG17})$$

where the action of the degree- -1 map t includes the sign $(-1)^{\sum_{j < i} |x_j|}$ on each homogeneous input. Computing $dt_k + t_k d$ cancels every term involving different positions, by precisely these signs. The remaining terms are $\sum_i p^{\otimes(i-1)} \otimes (I - p) \otimes I^{\otimes(k-i)} = I - p^{\otimes k}$ by telescoping. Consequently, in each length k ,

$$H^j(C_U^{\otimes k}) = \begin{cases} (T_U Q)^{\otimes k}, & j = k, \\ 0, & j \neq k, \end{cases} \quad H^\bullet(\mathfrak{T}_U) = \bigoplus_{k \geq 0} (T_U Q)^{\otimes k} \quad (\text{AG18})$$

with concatenation and the degree k retained. A cocycle has only finitely many length components, so cohomology commutes with this direct sum directly. The projection in (AG18) is the original $q^{\otimes k}$ and is D_{tot} -equivariant. The contraction t_k is only the explicit complex-linear proof of its quasi-isomorphism. It introduces no equivariant section into $\mathcal{B}$: such a section would send any h -torsion vector to an element killed by the injective $h(D)$ and hence to zero.

110.4 The finite original source and metric diagrams

For $k \geq 1$ and $M \geq k(d_h - 1)$, put

$$\begin{aligned} \mathcal{P}_M^{(k)} &= \mathbb{C}[s_1, \dots, s_k]_{\leq M}, \quad I_{h,k} = (h(s_1), \dots, h(s_k)), \quad E_h^{(k)} = E_h^{\otimes k}, \quad U_{h,k} = v_h^{\otimes k}, \\ \mathcal{T}_h^{(k)} P &= P(D_1, \dots, D_k) F_h^{\otimes k}, \quad J_{h,k,M} P = U_{h,k}[P]_{I_{h,k}}. \end{aligned} \quad (\text{AG19})$$

Thus the following entire diagram has its given source, quotient, and original cohomology arrow:

$$\begin{array}{ccccc} \mathcal{P}_M^{(k)} & \xrightarrow{\mathcal{T}_h^{(k)}} & \mathcal{B}_U^{\otimes k} & \xrightarrow{q^{\otimes k}} & (T_U Q)^{\otimes k} \\ J_{h,k,M} \downarrow & & & & \uparrow \sigma_h^{\otimes k} \\ E_h^{(k)} & \xrightarrow{I} & E_h^{(k)} & \xrightarrow{I} & E_h^{(k)}. \end{array} \quad (\text{AG20})$$

To prove commutativity, divide P successively by the monic $h(s_i)$; its remainder is represented by a linear combination of separate-variable monomials of degree $< d_h$ in each variable. The difference from the numerator of $s_h^{\otimes k}(U_{h,k}[P])$ belongs to $I_{h,k}$. Every relation $\sum_i h(s_i)P_i$ has the explicit primitive

$$\sum_{i=1}^k (-1)^{i-1} P_i(\mathbf{D})(F_h^{\otimes(i-1)} \otimes \phi_* \otimes F_h^{\otimes(k-i)}). \quad (\text{AG21})$$

The $i-1$ preceding factors have degree one; (AG15) supplies the second sign $(-1)^{i-1}$. Its differential is therefore exactly $\mathcal{T}_h^{(k)}(\sum_i h(s_i)P_i)$. Conversely its complete jet vanishes precisely when $P \in I_{h,k}$, since $U_{h,k}$ is a unit. This proves all the kernel assertions used by the diagram. Monic division lowers total degree, so at degree M the relation coefficients have degree at most $M - d_h$.

For $h \mid H$ and $b = H/h$, put $B_b(\mathbf{s}) = \prod_i b(s_i)$ and $N = M + k \deg b$. The diagram of divisor arrows is exactly

$$\begin{array}{ccc} \mathcal{P}_M^{(k)} & \xrightarrow{\times B_b} & \mathcal{P}_N^{(k)} \\ J_{h,k,M} \downarrow & & \downarrow J_{H,k,N} \\ E_h^{(k)} & \xrightarrow{\iota_{hH}^{\otimes k}} & E_H^{(k)}, \end{array} \quad \mathcal{T}_H^{(k)}(B_b P) = \mathcal{T}_h^{(k)} P. \quad (\text{AG22})$$

This follows first on pure monomials from (AG12), and then on all polynomials by linearity. It sends the smaller relation space into the larger one and hence agrees with the actual cochain inclusion.

All norms in this diagram are values of the original functions. Mellin–Fourier Plancherel in $x = e^y$ gives exactly

$$\|\mathcal{T}_h^{(k)} P\|_{L^2(d^k x)}^2 = \int_{\mathbb{R}^k} |P(1/2 + it_1, \dots, 1/2 + it_k)|^2 \prod_{i=1}^k w_h(t_i) dt, \quad w_h(t) = \frac{|v_h(1/2 + it)|^2}{2\pi}. \quad (\text{AG23})$$

The one-variable normalization is seen directly from $F(x) \mapsto e^{y/2}F(e^y)$, which is unitary for dx and dy , followed by Fourier measure $dt/(2\pi)$. Applying it in every variable proves (AG23). The entire multiplier $\prod_i v_h(s_i)$ is nonzero, so $\mathcal{T}_h^{(k)}$ is injective: a zero Mellin product on an open set makes the polynomial zero there and hence everywhere. Thus the Gram matrix in (AG23) is positive definite. The actual mass is $\mu_h^k, \mu_h = \int w_h > 0$. The numerator map in (AG22) is an isometry for these specified source forms, because its actual functions are equal. It does not state that the bare coordinate insertion preserves Euclidean metrics or every minimized quotient metric.

For completeness the exact minimized comparison is as follows. Let $\mathcal{L}_{h,k,M} = \mathcal{T}_h^{(k)}(I_{h,k} \cap \mathcal{P}_M^{(k)})$, with its inherited Hilbert inner product, and let $P_{h,k,M}$ be its orthogonal projection. Then

$$\begin{aligned} R_{h,k,M} &= (I - P_{h,k,M})s_h^{\otimes k}, \quad G_{h,k,M} = R_{h,k,M}^* R_{h,k,M}, \\ W_{h,k,M} &= (A_h^{(k)})^* G_{h,k,M} + G_{h,k,M} A_h^{(k)} - k G_{h,k,M}. \end{aligned} \quad (\text{AG24})$$

Indeed every source lift of a fixed jet differs from $s_h^{\otimes k}$ by exactly $\mathcal{L}_{h,k,M}$; orthogonal projection is its unique minimum. The section has numerator of total degree at most $k(d_h - 1)$, so it belongs to the declared source. Surjectivity follows from this section. With $\iota_k = \iota_{hH}^{\otimes k}$ and the degrees in (AG22), set

$$\mathcal{F} = \mathcal{L}_{H,k,N} \cap \mathcal{L}_{h,k,M}^\perp, \quad Z = P_{\mathcal{F}} R_{h,k,M}.$$

The inclusion of relation spaces in (AG22) implies that the difference of their projections is precisely $P_{\mathcal{F}}$. Their common section is $s_H^{\otimes k} \iota_k = s_h^{\otimes k}$ by (AG12). Therefore

$$\begin{aligned} R_{H,k,N} \iota_k &= R_{h,k,M} - Z, \\ \iota_k^* G_{H,k,N} \iota_k &= G_{h,k,M} - Z^* Z, \\ \iota_k^* W_{H,k,N} \iota_k &= W_{h,k,M} - ((A_h^{(k)})^* Z^* Z + Z^* Z A_h^{(k)} - k Z^* Z). \end{aligned} \quad (\text{AG25})$$

Orthogonality proves the second line; $A_H^{(k)} \iota_k = \iota_k A_h^{(k)}$ and expansion prove the third. When $k = 1$ and $M = n + d_h$, both relation spaces are $\Theta \text{span}\{\phi_*, D\phi_*, \dots, D^n \phi_*\}$. Then $Z = 0$, so (AG25) is the exact one-leg metric and control compression equality. In general the displayed $Z^* Z$ is retained.

Tensor concatenation also retains its source norm exactly. For $P \in \mathcal{P}_M^{(k)}$ and $Q \in \mathcal{P}_L^{(l)}$, set $P \boxtimes Q = P(s_1, \dots, s_k)Q(s_{k+1}, \dots, s_{k+l})$. Then

$$\begin{aligned} \mathcal{T}_h^{(k+l)}(P \boxtimes Q) &= \mathcal{T}_h^{(k)}P \otimes \mathcal{T}_h^{(l)}Q, \\ J_{h,k+l,M+L}(P \boxtimes Q) &= J_{h,k,M}P \otimes J_{h,l,L}Q. \end{aligned} \quad (\text{AG26})$$

Fubini gives the product of the two squared norms; polarization gives the full tensor inner product. Thus the map on the Hilbert tensor of these finite polynomial sources is isometric onto its specified product subspace of $\mathcal{P}_{M+L}^{(k+l)}$. Different packets are first inserted into their least common multiple by (AG22); equality of the actual functions makes the result independent of this presentation. Multiplication of the factors $b(s_i)$ proves that (AG22) and (AG26) commute, including their degree shifts. The symmetric coefficient projection is the literal average $\frac{1}{k!} \sum_{\sigma \in S_k} \sigma$. At top cochain degree its realization is the signed cochain average $\frac{1}{k!} \sum_{\sigma} \text{sgn}(\sigma) T_{\sigma}$, since interchanging degree-one factors contributes the other factor $\text{sgn}(\sigma)$. Concatenation followed by this specified projection supplies the symmetric product; no isometry of that projection is presumed.

110.5 The cyclic sources and every conormal depth in the same diagram

Retain the original finite local algebras

$$B_{h,k,r} = \mathbb{C}[\mathbf{s}]/I_{h,k}^r, \quad A_{h,k,r} = B_{h,k,r}^{S_k}, \quad U_{h,k,r} = [\prod_i v_h(s_i)]_{I_{h,k}^r}, \quad r \geq 1. \quad (\text{AG27})$$

At an ordered root tuple ρ , with multiplicities m_i , their local presentation is

$$\mathbb{C}[z_1, \dots, z_k]/(z_1^{m_1}, \dots, z_k^{m_k})^r.$$

The basis consists exactly of $z^{\mathbf{a}}$ with $\sum_i [a_i/m_i] \leq r-1$: ideal membership is equivalent to choosing r generator factors whose exponents are bounded by $\mathbf{a}$. The highest surviving total degree is $D_\rho + (r-1)M_\rho$, where $D_\rho = \sum_i (m_i-1)$ and $M_\rho = \max_i m_i$. Put every one of the $r-1$ allowed blocks at an index attaining the maximum and retain each remainder exponent m_i-1 to attain it. Its multinomial coefficient in the corresponding power of $\sum_i z_i$ is nonzero. Thus the exact sum nilpotency order is $1 + D_\rho + (r-1)M_\rho$. The separate-variable Chinese remainder theorem proves the stated local presentations: the local ideals are pairwise comaximal, and their products, intersections, and r th powers agree.

Consequently, with $S = \sum_i s_i$,

$$\begin{aligned} \ell_{h,k,\lambda,r} &= \max_{\sum_i \rho_i = \lambda} \{1 + D_\rho + (r-1)M_\rho\}, \\ \chi_{h,k,r}(T) &= \prod_{\lambda} (T - \lambda)^{\ell_{h,k,\lambda,r}}, \quad C_{h,k,r} = \mathbb{C}[T]/\chi_{h,k,r}, \\ \alpha_{h,k,r} : C_{h,k,r} &\hookrightarrow A_{h,k,r}, \quad [P] \mapsto [P(S)], \quad \eta_{h,k,r} = M_{U_{h,k,r}} \alpha_{h,k,r}. \end{aligned} \quad (\text{AG28})$$

Intersecting the local annihilator ideals takes the maximum at each collided sum, proving that α is an injective unital algebra map. The full Taylor unit U is invertible on every local factor, so η is an injective $\mathbb{C}[T]$ -module map. It is not called a unital algebra map. At $r = 1$ its analytic source is the exact restriction

$$\mathcal{V}_{h,k}P = \mathcal{T}_h^{(k)}P(S), \quad J_h^{\otimes k} \mathcal{V}_{h,k}P = \eta_{h,k,1}[P], \quad \|\mathcal{V}_{h,k}P\|^2 = \int_{\mathbb{R}} |P(k/2 + iu)|^2 w_h^{*k}(u) du. \quad (\text{AG29})$$

The last equality is (AG23) with $u = \sum_i t_i$, eliminating one coordinate with absolute Jacobian one, which is exactly the definition of the convolution. Higher r in (AG27) are full Taylor observations of this same analytic Mellin multiplier; they are not new cohomology quotients killing the original theta relations, since those relations need only vanish to depth one. The truncation maps record their further jets.

For fixed h , tensor regrouping has an exact all-depth form:

$$\begin{aligned} \Delta_{k,l,r} : C_{h,k+l,r} &\hookrightarrow \prod_{a=0}^{r-1} (C_{h,k,a+1} \otimes C_{h,l,r-a}), \\ [P(T)] &\longmapsto ([P(T_1 + T_2)])_{a=0}^{r-1}. \end{aligned} \quad (\text{AG30})$$

Each component is well defined: a product of r generators from the two blocks has either at least $a+1$ first-block generators or at least $r-a$ second-block generators. Hence $I_{h,k+l}^r \subseteq I_{h,k}^{a+1} + I_{h,l}^{r-a}$, giving an algebra quotient to the corresponding two-block algebra. The scalar map in (AG30) factors through its cyclic subalgebras. On a pair of local sum factors the nilpotency order is the sum of their orders minus one: expand $(z+w)^n$ in $\mathbb{C}[z,w]/(z^A, w^B)$ and retain $\binom{A+B-2}{A-1} z^{A-1} w^{B-1} \neq 0$. The maximal order at a total sum in all components of (AG30) is therefore the maximum, over tuples and a , of

$$1 + D_{\text{first}} + D_{\text{second}} + aM_{\text{first}} + (r-1-a)M_{\text{second}}.$$

The maximum over a is attained at an endpoint and equals $1 + D_{\text{total}} + (r-1) \max(M_{\text{first}}, M_{\text{second}})$. This is exactly (AG28), proving that the kernel before taking the quotient is $(\chi_{h,k+l,r})$ and thus proving injectivity. For $r = 1$ the product has one factor and gives the familiar injection $C_{h,k+l,1} \hookrightarrow C_{h,k,1} \otimes C_{h,l,1}$. In every component the full unit maps to $U_{h,k,a+1} \otimes U_{h,l,r-a}$. Accordingly

$$\Xi_a \eta_{h,k+l,r} = (\eta_{h,k,a+1} \otimes \eta_{h,l,r-a}) \Delta_a, \quad (\text{AG31})$$

where Ξ_a is the just-proved quotient of the full joint algebras. Grouping three blocks gives the components indexed by $a + b + c = r - 1$ and evaluation at $T_1 + T_2 + T_3$ in either order. This proves associativity of these gluing maps with all depths and all their nilpotent coefficients retained.

For divisor inclusion, the local old factors of $B_{H,k,r}$ are exactly those of $B_{h,k,r}$: the extra $b(s_i)$ are units there, so the generated ideals and all their powers coincide. Restriction π_r and zero insertion ι_r therefore give

$$\pi_r \iota_r = I, \quad \iota_r \pi_r = M_{e_r}, \quad \iota_r U_{h,k,r} = e_r B_b U_{H,k,r}, \quad \pi_r U_{H,k,r} = (\pi_r B_b)^{-1} U_{h,k,r}. \quad (\text{AG32})$$

They commute with the depth truncations. The e_r are the idempotents equal to one on tuples entirely in the old support and zero on every other tuple; permutations preserve this set, so these maps also preserve the invariant algebras. The exact polynomial map through depth r is

$$\mu_{b,r} : B_{h,k,r} \hookrightarrow B_{H,k,r}, \quad [P] \mapsto [B_b^r P], \quad \mu_{b,r} = \iota_r M_{[B_b^r]}, \quad (\text{AG33})$$

where the multiplier on the right is taken in $B_{h,k,r}$. To prove well-definedness on generators, for $\sum_i a_i = r$ one has $B_b^r \prod_i h(s_i)^{a_i} = \prod_i H(s_i)^{a_i} \prod_i b(s_i)^{r-a_i} \in I_{H,k}^r$. On an added tuple at least one $b(s_i)$ belongs to the corresponding local generator ideal, so B_b^r vanishes modulo its r th power. On old tuples it is a unit. These facts prove (AG33), injectivity, and image $e_r B_{H,k,r}$. The complete arithmetic identity is

$$U_{H,k,r} \mu_{b,r} [P] = \iota_r [B_b^{r-1} U_{h,k,r} P], \quad \mathcal{T}_H^{(k)}(B_b^r P) = \mathcal{T}_h^{(k)}(B_b^{r-1} P). \quad (\text{AG34})$$

It follows from (AG32) on old factors and from zero on added ones; the analytic identity follows directly from $v_h = b v_H$. The analytic equality in (AG34) is asserted for each specified polynomial P before passage to a finite quotient. Its two functions are not defined from $[P]$ alone; changing the polynomial representative retains the corresponding actual source relation. Under truncation from $r + 1$ to r , the raw map satisfies $\text{red } \mu_{b,r+1} = \mu_{b,r} M_{[B_b]} \text{red}$. Thus its extra multiplier is explicitly part of the depth diagram. In particular the one-power physical map must not be declared to descend at every depth: for $k = 1$ and a proper inclusion, $bh^r = Hh^{r-1}$ is not divisible by H^r for $r > 1$, since b and h are coprime. This tests the claim on the actual packet polynomials themselves.

At depth one the physical divisor image of a cyclic vector is the precise vector

$$\iota_1 \eta_{h,k,1} [P] = e_1 B_b U_{H,k,1} [P(S)] \quad \text{in } E_H^{\otimes k}. \quad (\text{AG35})$$

This is always the common-carrier arrow, including collisions of old and added sum eigenvalues. It belongs to the larger cyclic module $\eta_{H,k,1} C_{H,k,1}$ exactly when $e_1 B_b [P(S)] \in \alpha_{H,k,1} C_{H,k,1}$, since U_H is a unit. No such membership is imposed by the gluing. An exact common-source pullback, available without imposing it, is

$$\mathcal{Z}_{hH,k} = \{(x, y) \in C_{h,k,1} \oplus C_{H,k,1} : \iota_1 \eta_{h,k,1} x = \eta_{H,k,1} y\}. \quad (\text{AG36})$$

Both projections are injective by injectivity of the displayed maps; their images are exactly the cyclic vectors whose specified physical jets agree. This states the full agreement relation inside (AG20), rather than substituting an unsupported scalar transition. The CRT restriction and insertion maps compose by their explicit local-factor formulas. They commute with the block quotients in (AG31), because restriction or insertion of old tuples and truncation of their local monomial ideals commute coordinate by coordinate.

There is also a scalar restriction in the reverse direction at every depth. Every old tuple occurs in the larger packet with unchanged orders, so $\chi_{h,k,r} \mid \chi_{H,k,r}$. Let $\pi_C : C_{H,k,r} \twoheadrightarrow C_{h,k,r}$ be polynomial remainder. Evaluation and (AG32) give the exact squares

$$\pi_r \alpha_{H,k,r} = \alpha_{h,k,r} \pi_C, \quad M_{[B_b]_{I_{h,k}^r}} \pi_r \eta_{H,k,r} = \eta_{h,k,r} \pi_C. \quad (\text{AG36a})$$

Thus even this backwards arithmetic observation retains its full extra multiplier.

The forward cyclic image admits complete complementary coordinates, with no membership assumption in (AG35). Here is the original full-unit retraction, with its proof. On each sum factor of $A_{H,k,r}$, let $N = S - \lambda$, $\ell = \ell_{H,k,\lambda,r}$, and choose a tuple and a highest surviving monomial z^{a^*} attaining degree $\ell - 1$, as in the proof of (AG28). On this specific local factor let θ extract its coefficient. For $X = T - \lambda$, define

$$\Pi_\lambda^0(v) = \sum_{j=0}^{\ell-1} \theta(N^{\ell-1-j}v)X^j, \quad p_\lambda(X) = \Pi_\lambda^0(e_\lambda(S)U_{H,k,r}), \quad \Pi_\lambda = p_\lambda^{-1}\Pi_\lambda^0. \quad (\text{AG36b})$$

Here e_λ is the complete scalar CRT idempotent and the polynomials on the right are reduced modulo X^ℓ . Since $N^\ell = 0$, coefficient comparison gives $\Pi_\lambda^0(Nv) = X\Pi_\lambda^0(v)$. Moreover

$$p_\lambda(0) = \left(\prod_i v_H(\rho_i) \right) \frac{(\ell-1)!}{\prod_i a_i^{*!}} \neq 0.$$

In fact terms of positive total degree in the unit would exceed the maximal surviving degree of the chosen local factor, while the remaining multinomial coefficient is the one displayed. This proves invertibility by the finite geometric series and shows that $\Pi_\lambda\eta(P) = P$ on each local scalar factor. Combining these maps by scalar CRT gives the exact $\mathbb{C}[T]$ -linear retraction $\Pi_H : A_{H,k,r} \rightarrow C_{H,k,r}$. Put $K_H = \ker \Pi_H$ and $Q_H = I - \eta_H\Pi_H$. Direct multiplication gives the inverse module isomorphisms

$$A_{H,k,r} \longleftrightarrow C_{H,k,r} \oplus K_H, \quad v \longmapsto (\Pi_H v, Q_H v), \quad (c, z) \longmapsto \eta_H c + z. \quad (\text{AG36c})$$

They are the retained original coefficient changes; no orthogonality for the arithmetic form is inferred. The complete forward insertion is consequently the injection

$$(X_{hH}, Y_{hH}) : C_{h,k,r} \hookrightarrow C_{H,k,r} \oplus K_H, \quad (\text{AG36d})$$

$$X_{hH} = \Pi_H \iota_r \eta_h, \quad Y_{hH} = Q_H \iota_r \eta_h, \quad \iota_r \eta_h = \eta_H X_{hH} + Y_{hH}.$$

The last equality follows from (AG36c); if both coordinates vanish, injectivity of $\iota_r \eta_h$ forces the input to vanish. Its image is wholly cyclic exactly when $Y_{hH} = 0$. Under another divisor insertion the whole map is transformed by (AG36c), so both coordinates, including the cross maps from K_H , remain present.

For clarity the raw polynomial arrows also have their exact compatibility with the distributed-depth quotients. Write $B_b = B_1 B_2$ for its first and second blocks. On their stated finite quotients,

$$\Xi_a^H \mu_{b,r}^{(k+l)} = (\mu_{b,a+1}^{(k)} \otimes \mu_{b,r-a}^{(l)}) M_{B_1^{r-a-1} B_2^a} \Xi_a^h. \quad (\text{AG36e})$$

Both sides multiply a polynomial representative by $B_1^r B_2^r$ before the same block reduction; this proves equality and retains every additional power. The arithmetic identity (AG34) supplies its corresponding actual source-function equality.

110.6 Reflection and the retained split zero

For an invariant packet use the original involutions $P^\dagger(s) = \overline{P(1-\bar{s})}$ and $j_{\mathcal{B}}F(x) = x^{-1}\overline{F(1/x)}$. The latter is antiunitary for dx by substitution $y = 1/x$. Its Mellin transform is $(\mathcal{M}F)^\dagger$ by the same substitution, and $Dj_{\mathcal{B}} = j_{\mathcal{B}}(1-D)$ by differentiation. Since $h^\dagger = (-1)^{d_h}h$ and $g^\dagger = g$, $v_h^\dagger = (-1)^{d_h}v_h$. The full jet argument and degree bound used in (AG12) now give $j_{\mathcal{B}}s_h = s_h j_h$. The CRT maps commute with reflection, since old support and added support are separately invariant. The raw numerator map carries the exact sign

$$(\mu_{b,r}P)^\dagger = (-1)^{kr(d_H-d_h)}\mu_{b,r}(P^\dagger), \quad (\text{AG37})$$

as follows from $B_b^\dagger = (-1)^{k(d_H - d_h)} B_b$. Thus no sign has been removed from the original arithmetic unit. These involutions, with reversal $S \mapsto k - \bar{S}$, intertwine the divisor CRT, scalar-evaluation and depth-truncation arrows just constructed. In the complementary coordinates (AG36c) their exact action is $(c, z) \mapsto (\Pi_H j(\eta_H c + z), Q_H j(\eta_H c + z))$. No commutation of the chosen coefficient extractor with reflection is assumed. Before any parity consequence, the full-unit map has the exact law $j_A \eta_{h,k,r} = (-1)^{kd_h} \eta_{h,k,r} j_C$, because $U_{h,k,r}^\dagger = (-1)^{kd_h} U_{h,k,r}$. For the present off-critical invariant packets d_h is even: $\rho \mapsto 1 - \bar{\rho}$ has no fixed centre in U and pairs equal full multiplicities. The sign is therefore one here.

Finally apply the original split lift to every proved linear arrow. For a vector space X put $G(X) = \{\tau\} \sqcup \{x^\bullet : x \in X\}$, $e_X = 0_X^\bullet$, with τ the additive identity and $x^\bullet + y^\bullet = (x + y)^\bullet$. For $L : X \rightarrow Y$, its specified lift is

$$G(L)(\tau) = \tau, \quad G(L)(x^\bullet) = (Lx)^\bullet. \quad (\text{AG38})$$

Checking two supported inputs proves additivity and scalar compatibility; a case involving τ follows from the given identity and absorbing rules. Thus composition and every commutative diagram above lift exactly. Products lift by $x^\bullet y^\bullet = (xy)^\bullet$ and make τ absorbing; the same check applies to concatenation and to the multiplicative arrows of their proved types. A retained support label is carried by $(\lambda, x) \mapsto (\lambda, Lx)$ at each such arrow. In particular the differential of (AG21) remains the represented theta boundary $\mathcal{T}_h^{(k)}(\sum_i h(s_i) P_i)$; it is the subsequent map $G(q^{\otimes k})$ that sends this boundary to the supported zero e . Every inserted zero jet remains a supported zero. External absence is always τ . These lifts produce the split form of the single actual object (AG14), with its divisor, tensor, cohomology, full-jet and metric observation diagrams intact. The conjugate-linear reflection uses its corresponding semilinear lift, with $G(j)(c^\bullet x^\bullet) = \bar{c}^\bullet G(j)(x^\bullet)$. The square of the lifted differential is the lift of the zero linear map: it sends a supported input to the supported zero in the indicated degree, while fixing τ . This is the original split-zero identity, not a replacement of e by τ .

All positive matrices, convolution densities, minimum representatives and control forms appearing here are defined by (AG19)–(AG25) from the fixed $g = 2\xi$ and its original test functions. The construction does not assign independent values to these quantities. It supplies the exact common arithmetic carrier on which their previously proved analytic and control formulas are evaluated.

111 Full mixed carriers, their faces, prime branches, and depth maps

MFC.1. Conventions and the original split scalar. All rings in this attachment are commutative with identity and are nonzero. All semiring homomorphisms preserve the specified zero and unit unless a different category is explicitly named. A semiring ideal contains zero, is closed under addition, and absorbs multiplication by arbitrary elements; no subtractivity requirement is imposed. A prime ideal is a proper ideal whose complement is multiplicatively closed. The length of a strict prime chain is its number of strict inclusions. For a ring R , write

$$G(R) = \{\tau_R\} \sqcup \{r^\bullet : r \in R\}, \quad e_R = 0_R^\bullet, \quad 1_{G(R)} = 1_R^\bullet. \quad (\text{MFC.1})$$

The union is disjoint. Its operations are

$$r^\bullet + s^\bullet = (r + s)^\bullet, \quad r^\bullet s^\bullet = (rs)^\bullet, \quad \tau_R + x = x, \quad \tau_R x = \tau_R. \quad (\text{MFC.2})$$

In particular, a cancellation of supported amplitudes produces e_R , not τ_R . These operations make a commutative semiring. On supported entries the laws are the ring laws. In a sum an occurrence of τ_R can be deleted, and a product with an occurrence of τ_R equals τ_R ; these observations prove both associativities in every other case. For distributivity the new cases are $\tau_R(x + y) = \tau_R = \tau_R x + \tau_R y$ and $x(\tau_R + y) = xy = x\tau_R + xy$. The amplitude and support maps

$$\begin{aligned} p_R : G(R) &\longrightarrow R, & p_R(\tau_R) &= 0_R, & p_R(r^\bullet) &= r, \\ \chi_R : G(R) &\longrightarrow \mathbb{B}, & \chi_R(\tau_R) &= 0, & \chi_R(r^\bullet) &= 1 \end{aligned} \quad (\text{MFC.3})$$

are unital semiring homomorphisms; here $\mathbb{B} = \{0, 1\}$ has join as addition and meet as multiplication. Indeed (MFC.2) proves the amplitude identities, and a sum is absent exactly when both terms are absent, whereas a product is absent exactly when at least one factor is absent.

MFC.2. Independent Cartesian faces and their entire fibres. Let I be a nonempty finite set and R_i a nonzero ring for each $i \in I$. Put

$$P_I = \prod_{i \in I} G(R_i), \quad R_I = \prod_{i \in I} R_i, \quad p = \prod_i p_{R_i}, \quad s(x) = \{i : x_i \neq \tau_{R_i}\}. \quad (\text{MFC.4})$$

Both operations of P_I are coordinatewise. The map $s : P_I \rightarrow \mathcal{P}(I)$ is a unital semiring homomorphism for union and intersection on $\mathcal{P}(I)$, by the last two assertions of MFC.1 in each coordinate. Its exact face over $A \subseteq I$ is

$$s^{-1}(A) = \prod_{i \in A} \{r_i^\bullet : r_i \in R_i\} \times \prod_{i \notin A} \{\tau_{R_i}\}. \quad (\text{MFC.5})$$

The ordering of factors is the original ordering indexed by I ; the displayed expression specifies each coordinate rather than changing that ordering. For $r = (r_i) \in R_I$, put $J(r) = \{i : r_i \neq 0_{R_i}\}$. For each $A \supseteq J(r)$ define

$$x(r, A)_i = \begin{cases} r_i^\bullet & i \in A, \\ \tau_{R_i} & i \notin A. \end{cases} \quad p^{-1}(r) = \{x(r, A) : J(r) \subseteq A \subseteq I\}. \quad (\text{MFC.6})$$

To prove equality, an absent coordinate of any preimage must have zero amplitude; hence its mask contains $J(r)$. At an active coordinate its amplitude forces the unique supported entry $r_i^\bullet$. Conversely each displayed tuple has amplitude r . Distinct masks give distinct tuples, including at zero amplitude. Consequently

$$|p^{-1}(r)| = 2^{|I| - |J(r)|}, \quad (p, s) : P_I \hookrightarrow R_I \times \mathcal{P}(I) \text{ has image } \{(r, A) : J(r) \subseteq A\}. \quad (\text{MFC.7})$$

In particular the amplitude-zero fibre has all $2^{|I|}$ faces. These statements retain supported zeros on every proper face.

MFC.3. Synchronized inclusion and the precise failed collapse. The original synchronized inclusion is

$$j : G(R_I) \hookrightarrow P_I, \quad j(\tau_{R_i}) = (\tau_{R_i})_i, \quad j(r^\bullet) = (r_i^\bullet)_i. \quad (\text{MFC.8})$$

It is injective: the absent image differs from every fully supported image, and amplitudes distinguish fully supported images. Applying (MFC.2) coordinatewise proves preservation of sum, product, zero, and unit. Its image is exactly $s^{-1}(\{\emptyset, I\})$. Thus the square

$$\begin{array}{ccc} G(R_I) & \xrightarrow{j} & P_I \\ \chi_{R_I} \downarrow & & \downarrow s \\ \mathbb{B} & \xrightarrow{\delta} & \mathcal{P}(I) \end{array} \quad \delta(0) = \emptyset, \quad \delta(1) = I \quad (\text{MFC.9})$$

is a pullback of semirings. Explicitly, an element of the fibre product is a pair (ϵ, x) with mask empty when $\epsilon = 0$ and full when $\epsilon = 1$. In the first case it comes uniquely from τ_{R_i} ; in the second case its amplitudes give its unique preimage $r^\bullet$. This bijection respects all operations by (MFC.8), proving the asserted universal property. Also $pj = p_{R_I}$.

For $I = \{1, 2\}$, there is no semiring homomorphism

$$q : P_I \longrightarrow G(R_1 \times R_2), \quad p_{R_1 \times R_2} q = p, \quad q(x) \text{ supported whenever } s(x) \neq \emptyset. \quad (\text{MFC.10})$$

Indeed let $x = (1_{R_1}^\bullet, \tau_{R_2})$ and $y = (\tau_{R_1}, 1_{R_2}^\bullet)$. Their product is the specified zero of P_I . The stipulated images are $(1, 0)^\bullet$ and $(0, 1)^\bullet$, whose product is $e_{R_1 \times R_2}$, distinct from $q(0_{P_I}) = \tau_{R_1 \times R_2}$. This contradicts multiplicativity and zero preservation. The statement concerns exactly the map in (MFC.10); it leaves the proven maps j, p, s intact.

MFC.4. The original quadratic convolution carrier. Fix a nonzero ring A , set $S = G(A)$, $u = (-1_A)^\bullet$, and put

$$D_A = S \oplus S, \quad (a, b) \star (c, d) = (ac + ubd, ad + bc), \quad \mathbf{0} = (\tau_A, \tau_A), \quad X_1 = (1_A^\bullet, \tau_A). \quad (\text{MFC.11})$$

Addition remains coordinatewise. In this formula a, b, c, d lie in S , so every sum and product on the right is the original split operation. Set

$$B = A[t]/(t^2 + 1), \quad X_a = (a^\bullet, \tau_A), \quad Y_b = (\tau_A, b^\bullet), \quad Z_{a+tb} = (a^\bullet, b^\bullet). \quad (\text{MFC.12})$$

Division by the monic polynomial $t^2 + 1$ gives every element of B a unique expression $a + tb$. For completeness, repeated subtraction of the leading monomial times $t^2 + 1$ reduces a polynomial to degree at most one. A nonzero multiple of this monic polynomial has degree at least two, since its leading coefficient equals the nonzero leading coefficient of the multiplier. Therefore two reduced expressions cannot differ by a nonzero multiple. In particular $A \hookrightarrow B$, $B \neq 0$, and t is a unit with inverse $-t$. No assumption on the characteristic or on the invertibility of 2 is used.

The multiplication in (MFC.11) is associative. For $(a, b), (c, d), (h, k) \in S^2$, the first coordinate in either association is

$$ach + ubdh + uadk + ubck, \quad \text{and the second is} \quad ack + ubdk + adh + bch. \quad (\text{MFC.13})$$

This follows by distributing each of the two products; commutativity of S puts the resulting four terms in the displayed order. Commutativity follows directly from (MFC.11). Distributing its two coordinates proves distributivity over coordinatewise addition. Substitution gives the stated zero and unit, so D_A is a commutative semiring. Substitution also gives every nonempty-face product:

$$\begin{aligned} X_a X_c &= X_{ac}, & X_a Y_b &= Y_{ab}, & Y_b Y_d &= X_{-bd}, \\ X_a Z_z &= Z_{az}, & Y_b Z_z &= Z_{tbz}, & Z_z Z_w &= Z_{zw}. \end{aligned} \quad (\text{MFC.14})$$

For example, for $z = c + td$, $Y_b Z_z$ has coordinates $(-bd)^\bullet, (bc)^\bullet$, which are exactly those of tbz . Products of two full faces similarly have coordinates $(ac - bd)^\bullet, (ad + bc)^\bullet$. The four elements $\mathbf{0}, X_0, Y_0, Z_0$ are distinct. Unlike $P_{\{1,2\}}$, the carrier D_A uses convolution multiplication; (MFC.14) specifies the difference without identifying the two semiring structures.

MFC.5. Four support fibres and the scalar character. Write $\mathbb{B}[C_2]$ for the semiring of pairs of bits with coordinatewise join and

$$(p, q)(r, s) = (pr \vee qs, ps \vee qr). \quad X : D_A \longrightarrow \mathbb{B}[C_2], \quad X(a, b) = (\chi_A(a), \chi_A(b)). \quad (\text{MFC.15})$$

Here pr means Boolean meet. Applying χ_A to (MFC.11), and using $\chi_A(u) = 1$, proves the multiplication formula; addition, zero, and unit are also preserved. The support semiring laws can alternatively be verified by distributing Boolean products as in (MFC.13). The fibres over $(0, 0), (1, 0), (0, 1), (1, 1)$ are respectively $\{\mathbf{0}\}, \{X_a : a \in A\}, \{Y_b : b \in A\}, \{Z_z : z \in B\}$. Every one retains its zero-amplitude entry. The amplitude map $\pi : D_A \rightarrow B$, obtained by replacing absent coordinates by zero, preserves all operations by (MFC.11). The map (π, X) is injective: support determines which coordinates are absent, and the unique coordinates of $\pi(x)$ determine all active entries.

There is exactly one unital semiring homomorphism $f : D_A \rightarrow \mathbb{B}$: it sends $\mathbf{0}$ to 0 and every nonempty face to 1. To prove uniqueness, $f(X_1) = 1$ and $X_1 + X_{-1} = X_0$ imply $f(X_0) = 1$. The equality $X_0 X_a = X_0$ then forces $f(X_a) = 1$ for every a . Next $Y_1^2 = X_{-1}$ forces $f(Y_1) = 1$, and $Y_a = X_a Y_1$ forces $f(Y_a) = 1$. Finally $Z_{a+tb} = X_a + Y_b$ forces $f(Z_{a+tb}) = 1$. Existence follows because a sum or product of two nonempty faces is nonempty, as follows respectively from coordinate addition and (MFC.14); the cases with $\mathbf{0}$ are the zero laws. Thus scalar support is an exact further observation of the four fibres, and does not replace (MFC.15).

MFC.6. The quadratic synchronization quotient and all fibres. Define

$$q_D : D_A \longrightarrow G(B), \quad \mathbf{0} \longmapsto \tau_B, \quad X_a \longmapsto a^\bullet, \quad Y_b \longmapsto (tb)^\bullet, \quad Z_z \longmapsto z^\bullet. \quad (\text{MFC.16})$$

This is a surjective unital semiring homomorphism. Surjectivity follows from the Z -face and $\mathbf{0}$. A sum of two nonempty faces is nonempty and has amplitude equal to the sum in B . The same assertion for multiplication follows from the six products in (MFC.14). Thus both operations are preserved, even when the resulting amplitude is zero. Operations with $\mathbf{0}$ obey the zero laws, and $q_D(X_1) = 1_B^\bullet$. Its complete fibre list, in the unique coordinates $z = a + tb$, is

target	fibre	
τ_B	$\{\mathbf{0}\}$	
e_B	$\{X_0, Y_0, Z_0\}$	
$(a + tb)^\bullet, a \neq 0, b \neq 0$	$\{Z_{a+tb}\}$	(MFC.17)
$a^\bullet, a \neq 0$	$\{X_a, Z_a\}$	
$(tb)^\bullet, b \neq 0$	$\{Y_b, Z_{tb}\}$	

Indeed an X -preimage requires second coordinate zero, a Y -preimage requires first coordinate zero, and the Z -preimage always exists uniquely. These alternatives exhaust the four faces.

The kernel congruence of q_D is generated by $X_0 \sim Y_0$. Adding X_0 and then Y_0 to this relation shows $X_0 \sim Z_0 \sim Y_0$. Adding X_a to $X_0 \sim Y_0$ gives $X_a \sim Z_a$; adding Y_b gives $Z_{tb} \sim Y_b$. Hence each fibre in (MFC.17) is identified. Conversely the kernel of the proved homomorphism q_D is a congruence containing the generator, so no generated identification can connect distinct fibres. This proves the equality of congruences.

MFC.7. The full section, its unit, and the localization. There is a zero-preserving additive and multiplicative section

$$\iota : G(B) \longrightarrow D_A, \quad \iota(\tau_B) = \mathbf{0}, \quad \iota(z^\bullet) = Z_z, \quad q_D \iota = \text{id}_{G(B)}. \quad (\text{MFC.18})$$

Addition within the Z -face is $Z_z + Z_w = Z_{z+w}$; multiplication is (MFC.14), and $\mathbf{0}$ obeys the required zero laws. These prove every asserted property. This section is not unital as a map to D_A , since $\iota(1_B^\bullet) = Z_1 = (1_A^\bullet, 0_A^\bullet) \neq X_1$.

In fact no unital semiring section σ of q_D exists. The equality $1_B^\bullet + e_B = 1_B^\bullet$ forces $X_1 + \sigma(e_B) = X_1$. Among the three possibilities in the e_B -fibre, only X_0 satisfies this equality: adding Y_0 or Z_0 gives Z_1 . Thus $\sigma(e_B) = X_0$. The $t^\bullet$ -fibre is $\{Y_1, Z_t\}$, using $1_A \neq 0_A$. But $e_B t^\bullet = e_B$, while $X_0 Y_1 = Y_0 \neq X_0$ and $X_0 Z_t = Z_0 \neq X_0$. Both possibilities contradict multiplicativity.

The element Z_1 is idempotent, and its corner is

$$Z_1 D_A = \{\mathbf{0}\} \sqcup \{Z_z : z \in B\}, \quad D_A[Z_1^{-1}] \cong Z_1 D_A \cong G(B). \quad (\text{MFC.19})$$

The corner has unit Z_1 . The map $d \mapsto Z_1 d$ is a unital homomorphism to that corner: idempotence gives $(Z_1 d)(Z_1 d') = Z_1 dd'$, and distributivity gives additivity. It equals ιq_D with this codomain, by (MFC.14). To prove the localization universal property, let $f : D_A \rightarrow T$ be a unital homomorphism for which $f(Z_1)$ is invertible. An invertible idempotent is 1_T , since multiplying $f(Z_1)^2 = f(Z_1)$ by its inverse gives that equality. Therefore $f(d) = f(Z_1 d)$. Restricting f to the corner gives the unique unital homomorphism through which f factors; it is unital because $f(Z_1) = 1_T$, and uniqueness follows from surjectivity of $d \mapsto Z_1 d$. This proves (MFC.19), retaining both the full fibres of q_D and the exact category of its section.

MFC.8. All ordinary semiring ideals of D_A . For ring ideals $H \triangleleft B, J \triangleleft A$, define

$$\begin{aligned} M_H &= \{\mathbf{0}\} \cup \{Z_z : z \in H\}, & M &= M_B, \\ I_{J,H} &= M_H \cup \{X_a : a \in J\} \cup \{Y_a : a \in J\}, & JB &\subseteq H. \end{aligned} \quad (\text{MFC.20})$$

Here JB is the ideal of B generated by the image of J . Every ideal of D_A is exactly one of

$$\{\mathbf{0}\}, \quad M_H, \quad I_{J,H} \quad (H \triangleleft B, J \triangleleft A, JB \subseteq H). \quad (\text{MFC.21})$$

We prove the statement for the ordinary ideal convention in MFC.1. Let $\mathcal{I}$ be such an ideal. If it has no X - or Y -entry and is not $\{\mathbf{0}\}$, it contains some Z_z . The set $H = \{z : Z_z \in \mathcal{I}\}$ is nonempty. Multiplication by Z_0 shows $0 \in H$, multiplication by Z_{-1} gives additive inverses, addition gives closure under sums, and multiplication by Z_w for arbitrary $w \in B$ gives absorption. Hence H is a ring ideal and $\mathcal{I} = M_H$.

If $\mathcal{I}$ has an X - or Y -entry, put $J_X = \{a : X_a \in \mathcal{I}\}$ and $J_Y = \{a : Y_a \in \mathcal{I}\}$. The identities $X_a Y_1 = Y_a$ and $Y_a Y_{-1} = X_a$ give $J_X = J_Y =: J$, and this common set is nonempty. Multiplication of an X -entry by X_0 puts 0 in J ; addition, multiplication by X_{-1} , and multiplication by arbitrary X_r prove respectively closure under sums, additive inverses, and absorption by A . Thus $J \triangleleft A$. Multiplying an X -entry by Z_0 puts Z_0 in $\mathcal{I}$, and the preceding Z -face argument proves that $H = \{z : Z_z \in \mathcal{I}\}$ is a ring ideal of B . For $a \in J, w \in B$, $X_a Z_w = Z_{aw}$ puts aw in H ; closure under finite sums proves $JB \subseteq H$. The definitions now give $\mathcal{I} = I_{J,H}$.

Conversely M_H is closed under addition, and every nonempty face multiplied by $Z_h, h \in H$, remains a Z -entry with amplitude in H , by (MFC.14). The absent face multiplies it to $\mathbf{0}$, which is also in M_H . Thus M_H is an ideal. For $I_{J,H}$, same-face sums stay in J or H . Cross-face sums have the precise forms

$$X_a + Y_b = Z_{a+tb}, \quad X_a + Z_h = Z_{a+h}, \quad Y_b + Z_h = Z_{tb+h}. \quad (\text{MFC.22})$$

When $a, b \in J$ and $h \in H$, these amplitudes lie in H because $JB \subseteq H$. Multiplication of an X - or Y -entry of $I_{J,H}$ by an X - or Y -entry of D_A has coefficient in J , and its product with a Z -entry has amplitude in JB . A Z -entry of $I_{J,H}$ multiplied by any face remains in M_H . Products with $\mathbf{0}$ are $\mathbf{0}$. This verifies absorption in every case. Each listed family is therefore an ideal. Their descriptions are unique by reading the amplitudes in each face. The three families are disjoint: M_H contains Z_0 but no X - or Y -entry, while $I_{J,H}$ contains X_0, Y_0, Z_0 .

Their complete inclusion rules, aside from the least ideal $\{\mathbf{0}\}$, are

$$\begin{aligned} M_H \subseteq M_{H'} &\iff H \subseteq H', \\ M_H \subseteq I_{J',H'} &\iff H \subseteq H', \\ I_{J,H} \subseteq I_{J',H'} &\iff J \subseteq J' \text{ and } H \subseteq H'. \end{aligned} \quad (\text{MFC.23})$$

No $I_{J,H}$ is contained in an $M_{H'}$, since it contains X_0 . Each equivalence follows by inspecting the relevant faces in (MFC.20), which are disjoint.

MFC.9. All prime branches and their exact inclusions. For $\mathfrak{q} \in \text{Spec } B$ and $\mathfrak{p} \in \text{Spec } A$, put

$$P_\tau = \{\mathbf{0}\}, \quad Q_\mathfrak{q} = I_{\mathfrak{q} \cap A, \mathfrak{q}}, \quad T_\mathfrak{p} = I_{\mathfrak{p}, B}. \quad \text{Spec } D_A = \{P_\tau, M\} \sqcup \{Q_\mathfrak{q}\} \sqcup \{T_\mathfrak{p}\}. \quad (\text{MFC.24})$$

We prove exhaustion and primality, rather than imposing a subtractive prime convention. The complement of P_τ is closed under multiplication by (MFC.14). The complement of M consists of all X - and Y -entries, and is also closed under multiplication. Both ideals are proper, so both are prime. If $H \subsetneq B$, choose $z \notin H$. Then $X_0, Z_z \notin M_H$ but $X_0 Z_z = Z_0 \in M_H$; thus M_H is not prime.

Suppose $I_{J,H}$ is prime and $H \subsetneq B$. The rule $Z_z Z_w = Z_{zw}$ shows that H is prime in B . The condition $JB \subseteq H$ gives $J \subseteq H \cap A$. If $a \in H \cap A$, then $X_a Z_1 = Z_a \in I_{J,H}$ while $Z_1 \notin I_{J,H}$, so primality gives $a \in J$. Thus $I_{J,H} = Q_H$. Conversely take a prime $\mathfrak{q}$ in B , and let $\mathfrak{p} = \mathfrak{q} \cap A$. This contraction is proper and prime: $1 \notin \mathfrak{q}$, and $ab \in \mathfrak{q}$ forces $a \in \mathfrak{q}$ or $b \in \mathfrak{q}$. Two X - or Y -entries outside $Q_\mathfrak{q}$ have coefficients outside $\mathfrak{p}$, so their product coefficient, with either sign, remains outside $\mathfrak{p}$. An X_a outside this ideal and a Z_z outside it have $a, z \notin \mathfrak{q}$, so $az \notin \mathfrak{q}$. For $Y_a Z_z$, the same holds for taz , since t is a unit and cannot lie in a proper prime. Two Z -entries outside the ideal have product outside by primality of $\mathfrak{q}$. These are all products in its complement, proving primality.

If $H = B$, the ideal $I_{J,B}$ is proper precisely when $J \subsetneq A$. Its complement consists of X_a, Y_a with $a \notin J$. It is multiplicatively closed when J is prime, by the first row of (MFC.14). Conversely, if it is multiplicatively closed and $ab \in J$, the product $X_a X_b$ belongs to the ideal, so at least one factor does, proving that J is prime. This gives exactly the T_p -family. Together with (MFC.21), it proves (MFC.24).

The complete prime inclusion rules are

$$\begin{aligned} P_\tau \subsetneq M, \quad P_\tau \subsetneq Q_q, \quad P_\tau \subsetneq T_p, \quad M \subsetneq T_p, \\ Q_q \subseteq Q_{q'} \iff q \subseteq q', \quad T_p \subseteq T_{p'} \iff p \subseteq p', \\ Q_q \subseteq T_p \iff q \cap A \subseteq p. \end{aligned} \tag{MFC.25}$$

Every inclusion of a Q -prime in a T -prime is strict, because Z_1 lies only in the latter. The prime M is incomparable with each Q_q : $Z_1 \in M \setminus Q_q$ and $X_0 \in Q_q \setminus M$. No T -prime is contained in a Q -prime, because it contains Z_1 ; no T -prime is contained in M , because it contains X_0 . These assertions and (MFC.25) follow directly from (MFC.23), and exhaust the possible pairs of families. The ordinary ideal convention matters here. Each M_H is non-subtractive: $Z_0 \in M_H$ and $Z_0 + X_0 = Z_0 \in M_H$, whereas $X_0 \notin M_H$. Each T_p is likewise non-subtractive: $Z_0, Z_0 + X_1 = Z_1 \in T_p$, whereas $X_1 \notin T_p$ because p is proper. Thus restricting to subtractive primes would remove original prime branches occurring in (MFC.24).

MFC.10. The dimension calculation, including incomparability. If $A \neq 0$ and its Krull dimension is $\dim A = d < \infty$, then

$$\dim D_A = d + 2. \tag{MFC.26}$$

Here dimension means the ideal-theoretic prime-chain dimension of MFC.1. We give the integral-extension argument needed for the upper bound in full. The ring $B = A[t]/(t^2 + 1)$ is integral over its embedded copy of A , since every $b = a + tc$ satisfies

$$b^2 - 2ab + (a^2 + c^2) = 0. \tag{MFC.27}$$

Suppose primes $q \subsetneq q'$ of B had the same contraction p in A . Then $R = A/p$ embeds in the domain $C = B/q$, and C is integral over R : reduce any monic equation over A modulo these ideals. The nonzero prime $\tau = q'/q$ of C has zero contraction in R . Let $S = R \setminus \{0\}$ and $K = S^{-1}R$. The localization $S^{-1}C$ is a domain, and every c/s in it is integral over the field K . Indeed, dividing a monic equation for c by the corresponding power of s produces a monic equation for c/s with coefficients in K . A domain integral over a field is a field: for a nonzero element v , choose a monic relation of least degree over that field. Its constant coefficient is nonzero, because otherwise division by v in the domain would give a monic relation of lower degree. Rearranging the relation expresses v^{-1} as a polynomial in v divided by that nonzero constant coefficient. Thus $S^{-1}C$ is a field. Since $\tau \cap S = \emptyset$, its localization is a proper prime ideal of this field: if $1 = c/s$ with $c \in \tau$, $s \in S$, clearing the equality gives $v(c - s) = 0$ for some $v \in S$, and the domain property implies $s = c \in \tau$, a contradiction. It follows that $S^{-1}\tau = 0$. But a nonzero $c \in \tau$ remains nonzero after localization, since $sc = 0$, $s \in S$, is impossible in the domain. This contradiction proves that strict prime inclusions in B have strict contractions in A .

The ring $A \neq 0$ has a maximal proper ideal: the union of a chain of proper ideals is proper, since otherwise it contains 1 at some stage, and Zorn's lemma applies. A maximal ideal is prime because its quotient is a field: if the class of a is nonzero, maximality of the ideal generated by that class supplies its multiplicative inverse. Thus $d \geq 0$, and a chain of length d exists. Indeed the supremum of a nonempty set of nonnegative integer lengths, when finite, is attained. Choose $p_0 \subsetneq \cdots \subsetneq p_d$. Then (MFC.25) gives the strict chain

$$P_\tau \subsetneq M \subsetneq T_{p_0} \subsetneq \cdots \subsetneq T_{p_d}, \tag{MFC.28}$$

of length $d + 2$.

For the upper bound, it suffices to bound every finite strict chain, since an infinite chain would contain finite chains of arbitrarily large length. Adjoin P_τ at its beginning if it is missing. By (MFC.25), a chain containing M contains no Q -prime, and after M contains only a T -chain. If that T -chain has ℓ entries, then $\ell - 1 \leq d$, and the full chain has length at most $\ell + 1 \leq d + 2$. A chain with no Q - or T -entries has length at most one. A chain with Q -entries and no M has a Q -chain of $k \geq 1$ entries followed by a T -chain of $\ell \geq 0$ entries. The contractions of the Q -entries are strictly increasing by the preceding proof. If $\ell \geq 1$, they are followed by the strictly increasing T -indices, with at most one equality, at the junction. Therefore this chain in $\text{Spec } A$ has at least $k + \ell - 1$ distinct entries, so $k + \ell - 2 \leq d$. The original chain, including P_τ , has length $k + \ell \leq d + 2$. If $\ell = 0$, then $k - 1 \leq d$ and its length is $k \leq d + 1$. A chain having T -entries but neither Q -entries nor M has length at most $d + 1$. These cases exhaust (MFC.24), proving the upper bound and therefore (MFC.26).

MFC.11. Higher distributive-lattice zero fibres. Let L be a bounded distributive lattice, with bottom 0_L and top 1_L , and let $R \neq 0$ be a ring. The original carrier is

$$\begin{aligned} G_L(R) &= \{(0_R, \lambda) : \lambda \in L\} \cup \{(r, 1_L) : r \in R\} \subseteq R \times L, \\ (r, \lambda) + (s, \mu) &= (r + s, \lambda \vee \mu), \\ (r, \lambda)(s, \mu) &= (rs, \lambda \wedge \mu), \\ 0_{G_L(R)} &= (0_R, 0_L), \quad 1_{G_L(R)} = (1_R, 1_L). \end{aligned} \tag{MFC.29}$$

This is a union inside a product; the two descriptions of $(0_R, 1_L)$ denote one element. A nonzero amplitude is permitted only at top support. The operations are closed. If $r + s \neq 0$, at least one summand has nonzero amplitude and hence top support, so the sum has top support. If $rs \neq 0$, both amplitudes are nonzero and both supports are top. Zero-amplitude results allow any support. Associativity and commutativity follow in each coordinate from the ring and lattice laws. Distributivity follows from ring distributivity and distributivity of meet over join in L . The displayed zero and unit satisfy their laws in each coordinate. Thus (MFC.29) is a semiring.

The projections

$$p_L : G_L(R) \rightarrow R, \quad (r, \lambda) \mapsto r, \quad \chi_L : G_L(R) \rightarrow L, \quad (r, \lambda) \mapsto \lambda, \quad p_L^{-1}(0_R) = \{(0_R, \lambda) : \lambda \in L\} \tag{MFC.30}$$

are unital semiring homomorphisms, where L has join and meet as its operations. The last fibre is exactly the entire original lattice. Moreover p_L is the universal unital homomorphism from $G_L(R)$ to a ring. To prove this, write $z_\lambda = (0_R, \lambda)$ and $e = (0_R, 1_L)$. For any homomorphism $f : G_L(R) \rightarrow T$ to a ring, $e + z_\lambda = e$ gives $f(z_\lambda) = 0_T$ by additive cancellation in T . The function $\bar{f} : R \rightarrow T, r \mapsto f(r, 1_L)$, therefore preserves zero, addition, multiplication, and unit, so is a ring homomorphism. Every element of $G_L(R)$ is a z_λ or a $(r, 1_L)$, proving $f = \bar{f}p_L$, and the surjectivity of p_L proves uniqueness. If L is the one-element lattice, the carrier is R itself; the distinct absent and supported-zero elements occur precisely when $0_L \neq 1_L$.

MFC.12. All lattice-localization fibres and the universal map. For every $\lambda \in L$, the element z_λ is idempotent and

$$z_\lambda G_L(R) = \{z_\nu : \nu \leq \lambda\}, \quad G_L(R)[z_\lambda^{-1}] \cong \downarrow \lambda, \quad \ell_\lambda : G_L(R) \rightarrow \downarrow \lambda, \quad (r, \mu) \mapsto \lambda \wedge \mu. \tag{MFC.31}$$

Here $\downarrow \lambda$ has join and meet, bottom 0_L , and unit λ . Multiplying in (MFC.29) gives $z_\lambda(r, \mu) = z_{\lambda \wedge \mu}$; every $\nu \leq \lambda$ occurs by taking $(0_R, \nu)$. This proves the corner equality and its identification with $\downarrow \lambda$, including its unit. Distributivity of L proves that ℓ_λ preserves addition, and associativity and idempotence of meet prove that it preserves multiplication. It sends the original zero to 0_L , the original unit to λ , and z_λ to that unit. For a unital map f making z_λ invertible, idempotence forces $f(z_\lambda) = 1$. Hence $f(x) = f(z_\lambda x)$, and restriction to the corner gives its unique factorization through

ℓ_λ . This is the required localization universal property. At $\lambda = 0_L$ the localization is the one-element semiring; the universal statement allows that zero semiring. Its exact fibres are

$$\ell_\lambda^{-1}(\nu) = \{(r, \mu) \in G_L(R) : \lambda \wedge \mu = \nu\}, \quad \nu \leq \lambda. \quad (\text{MFC.32})$$

Thus every top-supported amplitude, including every nonzero amplitude, maps to the unit λ of the localized interval. The formula specifies every erased amplitude and every identified support stratum.

MFC.13. The higher-zero carrier inside the full independent cube. Take $R = R_I$ and $L = \mathcal{P}(I)$. Define

$$J : G_{\mathcal{P}(I)}(R_I) \hookrightarrow P_I, \quad J(r, I) = (r^\bullet)_i, \quad J(0, A) = x(0, A). \quad (\text{MFC.33})$$

The two formulas agree at $(0, I)$. Two full-support entries add and multiply by the ring operations in every coordinate, so J preserves their sum and product. Two zero-amplitude entries have support union under addition and intersection under multiplication, by (MFC.5), again as in (MFC.29). A full entry plus a zero-amplitude entry stays full with the original amplitude; a full entry multiplied by a zero-amplitude entry gives the same zero-amplitude face, because supported multiplication by zero gives supported zero in exactly the active coordinates of that face. These cases exhaust all pairs and prove preservation of addition and multiplication. The bottom entry maps to the all-absent zero and $(1, I)$ to the unit. Recovering amplitude and support proves injectivity. Its exact image is all full-support tuples together with all zero-amplitude faces. Proper faces with nonzero amplitude are the additional elements of P_I . The synchronized inclusion factors as

$$G(R_I) \xrightarrow{k} G_{\mathcal{P}(I)}(R_I) \xrightarrow{J} P_I, \quad k(\tau_{R_I}) = (0, \emptyset), \quad k(r^\bullet) = (r, I), \quad Jk = j. \quad (\text{MFC.34})$$

The formulas prove that k is injective and unital, using (MFC.2) and (MFC.29). Both maps also commute with amplitude and support, since those coordinates are the coordinates used in their definitions.

MFC.14. Every original chain stratum and each threshold fibre. Let $n \geq 1$ and $C_n = \{0 < 1 < \dots < n\}$. In $G_{C_n}(R)$ put

$$\begin{aligned} e &= (0_R, n), & \tau_i &= (0_R, n - i) \quad (1 \leq i \leq n), \\ \tau_0 &= e & \text{when indexing formulas,} \\ \tau_i + \tau_j &= \tau_{\min(i, j)}, & \tau_i \tau_j &= \tau_{\max(i, j)}. \end{aligned} \quad (\text{MFC.35})$$

These equalities follow from join = max and meet = min in (MFC.29). For every $r \in R$, $(r, n) + \tau_i = (r, n)$ and $(r, n)\tau_i = \tau_i$. The carrier consists of the full ring copy $\{(r, n) : r \in R\}$, with its zero e , and the n further distinct entries $\tau_1, \dots, \tau_n$. In particular its amplitude-zero fibre has $n + 1$ entries.

For $1 \leq k \leq n$, the original threshold and induced map are

$$\begin{aligned} \alpha_k : C_n &\rightarrow \mathbb{B}, & \alpha_k(j) &= \begin{cases} 0 & j < k, \\ 1 & j \geq k, \end{cases} \\ T_k : G_{C_n}(R) &\rightarrow G(R), & T_k(r, n) &= r^\bullet, & T_k(0_R, j) &= \begin{cases} \tau_R & j < k, \\ e_R & j \geq k. \end{cases} \end{aligned} \quad (\text{MFC.36})$$

The formulas agree at $(0_R, n)$. The threshold sends bottom to zero and top to one. The maximum of two indices is at least k precisely when at least one is, and the minimum is at least k precisely when both are. Thus it preserves join and meet. For two zero-amplitude entries this proves both laws for T_k . Two full entries use the original ring operations and stay full, even upon amplitude cancellation. A full entry plus any zero-amplitude entry stays full; its image plus either τ_R or e_R is

the same supported image. A full entry times $(0_R, j)$ equals $(0_R, j)$; its supported image times the prescribed image of that entry is respectively τ_R or e_R . These are all cases, proving that T_k is a unital semiring homomorphism. Its entire fibres are

$$\begin{aligned} T_k^{-1}(\tau_R) &= \{(0_R, j) : 0 \leq j < k\}, \\ T_k^{-1}(e_R) &= \{(0_R, j) : k \leq j \leq n\}, \\ T_k^{-1}(r^\bullet) &= \{(r, n)\} \quad (r \neq 0_R). \end{aligned} \quad (\text{MFC.37})$$

They have respectively $k, n - k + 1, 1$ entries. These formulas retain the exact depth lost under every binary threshold.

MFC.15. The all-ideal chain for the original two arithmetic rings. Let p be a prime integer, let k now denote a field, and let $n \geq 1$. Define the two rings and their ideals by

$$R_{p,n} = \mathbb{Z}/p^n\mathbb{Z}, \quad I_a = p^a R_{p,n}, \quad R_{k,n} = k[\epsilon]/(\epsilon^n), \quad J_a = \epsilon^a R_{k,n}, \quad 0 \leq a \leq n. \quad (\text{MFC.38})$$

In particular $I_0 = R_{p,n}$, $I_n = (0)$, $J_0 = R_{k,n}$, and $J_n = (0)$. We prove that these are all ideals, not a selected subfamily.

For a nonzero element of $R_{p,n}$, take its representative between 1 and $p^n - 1$. Its exact power of p is p^a with $0 \leq a < n$; thus the element is $p^a u$ with u prime to p . The class of u is a unit: the Euclidean algorithm applied to u, p^n , whose greatest common divisor is 1, supplies integers v, w with $uv + p^n w = 1$. Let $\mathfrak{a}$ be a nonzero ideal, and choose among its nonzero elements one with least exponent a . Multiplying this element by u^{-1} puts p^a in $\mathfrak{a}$, so $I_a \subseteq \mathfrak{a}$. Every other nonzero element has exponent at least a and is therefore a multiple of p^a ; zero also lies in I_a . Hence $\mathfrak{a} = I_a$. The zero ideal is I_n . The ideals are distinct: for $a < n$, an equality $p^a = p^{a+1}b$ modulo p^n would imply that p^{n-a} divides $1 - pb$, impossible upon reduction modulo p .

Every element of $R_{k,n}$ has a unique polynomial representative of degree less than n , by division by the monic polynomial ϵ^n . A nonzero representative with least nonzero degree a is $\epsilon^a u$, where $u = u_0(1 + v)$, $u_0 \in k^\times$, and $v \in (\epsilon)$. Since $v^n = 0$,

$$u^{-1} = u_0^{-1} \sum_{j=0}^{n-1} (-v)^j \quad (\text{MFC.39})$$

is an inverse: multiplication by $1 + v$ gives $1 - (-v)^n = 1$. In a nonzero ideal choose an element with least such degree a . Multiplication by u^{-1} puts ϵ^a in the ideal, while every other element has degree at least a and is divisible by ϵ^a . Thus the ideal is J_a ; the zero ideal is J_n . Uniqueness of the degree-less-than- n representative shows that $\epsilon^a \notin J_{a+1}$ for $a < n$, proving that these $n + 1$ ideals are distinct.

In both rings the ideals are nested by reversed exponent. Consequently their sums and intersections are

$$I_a + I_b = I_{\min(a,b)}, \quad I_a \cap I_b = I_{\max(a,b)}, \quad J_a + J_b = J_{\min(a,b)}, \quad J_a \cap J_b = J_{\max(a,b)}. \quad (\text{MFC.40})$$

For instance, if $a \leq b$, then $I_b \subseteq I_a$, so the sum is I_a and the intersection is I_b ; the other cases are the same two inclusions with indices interchanged. It follows that the explicit bijections

$$C_n \xrightarrow{\theta_p} \text{Id}(R_{p,n}), \quad j \mapsto I_{n-j}, \quad C_n \xrightarrow{\theta_k} \text{Id}(R_{k,n}), \quad j \mapsto J_{n-j} \quad (\text{MFC.41})$$

preserve bottom, top, join, and meet, with ideal sum as join and ideal intersection as meet. Surjectivity here is the all-ideal statement just proved; injectivity is the strictness proved above. Thus these are isomorphisms of the bounded-lattice semirings, preserving every stratum.

MFC.16. The separate, complete ideal-product law. The very same ideal carriers also retain ordinary ideal multiplication, with its different operation:

$$\begin{aligned} I_a I_b &= I_{\min(n, a+b)}, & J_a J_b &= J_{\min(n, a+b)}, \\ V_n &= (\{0, \dots, n\}, \min, (a, b) \mapsto \min(n, a+b), 0_{V_n} = n, 1_{V_n} = 0). \end{aligned} \quad (\text{MFC.42})$$

Indeed the product of the principal ideals generated by x, y is generated by xy : every finite sum of products $xr \cdot ys$ is a multiple of xy , and xy itself is one of the generating products. Applying this fact to p^a, p^b , and to ϵ^a, ϵ^b , proves the displayed laws, including the vanishing for $a + b \geq n$. The maps $a \mapsto I_a$ and $a \mapsto J_a$ are therefore bijective semiring homomorphisms from V_n to the respective all-ideal carriers with sum and ordinary ideal product. For completeness, associativity of the operation on exponents follows from $\min(n, \min(n, a+b) + c) = \min(n, a+b+c)$; its unit and absorbing zero are 0 and n . The identity

$$\min(n, a + \min(b, c)) = \min(\min(n, a+b), \min(n, a+c)) \quad (\text{MFC.43})$$

proves distributivity over the addition $\min$. This also checks all semiring laws directly on V_n .

Under the order-preserving coordinates of (MFC.41), ordinary ideal multiplication is the operation

$$j \odot \ell = \max(0, j + \ell - n) \quad \text{on } C_n, \quad (\text{MFC.44})$$

because $n - \min(n, (n-j) + (n-\ell)) = \max(0, j + \ell - n)$. It is distinct from the meet $\min(j, \ell)$ when $n \geq 2$: for $j = \ell = n-1$, their values are $\max(0, n-2)$ and $n-1$. Equivalently, $I_1^2 = I_2$ whereas $I_1 \cap I_1 = I_1$, with the convention $I_2 = 0$ when $n = 2$, and the same distinction holds for J_1 . The identity map on either all-ideal carrier preserves the carrier, order, zero, unit, and addition between these two presentations, but does not in general preserve multiplication. Equations (MFC.40)–(MFC.44) give its exact transported operations. No identification of the two underlying arithmetic rings is asserted.

MFC.17. Coefficient transport, support preservation, and prime maps. The preceding constructions are accompanied by their original coefficient maps; they are not merely lists of properties. For a unital ring homomorphism $f : R \rightarrow R'$, define

$$G(f)(\tau_R) = \tau_{R'}, \quad G(f)(r^\bullet) = f(r)^\bullet. \quad (\text{MFC.45})$$

Equation (MFC.2) proves that this is a unital semiring homomorphism, including when a nonzero r has $f(r) = 0$: that entry is still supported. For a family $f_i : R_i \rightarrow R'_i$, the product map $\prod_i G(f_i)$ preserves each mask exactly, has amplitude $\prod_i f_i$, and commutes with j and J in (MFC.8) and (MFC.33). Each assertion follows by substituting into one coordinate of the displayed formulas; inactive coordinates stay absent and active ones stay supported. Thus the support square and every independent face remain part of the transported diagram.

For $f : A \rightarrow A'$, let $\bar{f} : A[t]/(t^2 + 1) \rightarrow A'[t]/(t^2 + 1)$ be $\bar{f}(a + tb) = f(a) + tf(b)$. This is well-defined and a unital ring homomorphism: applying f to the two coefficients of a product $(ac - bd) + t(ad + bc)$ gives exactly the corresponding product of the two images. Define

$$D(f)(a, b) = (G(f)(a), G(f)(b)), \quad q_{D_{A'}} D(f) = G(\bar{f}) q_{D_A}, \quad D(f) \iota_A = \iota_{A'} G(\bar{f}). \quad (\text{MFC.46})$$

The equality $G(f)(u) = (-1_{A'})^\bullet$ and (MFC.11) prove that $D(f)$ is a unital semiring homomorphism. It sends X_a, Y_b, Z_z respectively to $X_{f(a)}, Y_{f(b)}, Z_{\bar{f}(z)}$, so it preserves each of the four faces exactly and proves both commuting identities in (MFC.46). It sends Z_1 to Z_1 , hence also induces the corner and localization map already represented by $G(\bar{f})$.

For ideals in the primed rings its inverse-image formulas are

$$\begin{aligned} D(f)^{-1}(M_{H'}) &= M_{\bar{f}^{-1}(H')}, \\ D(f)^{-1}(I_{J', H'}) &= I_{f^{-1}(J'), \bar{f}^{-1}(H')}, \\ D(f)^{-1}(P_\tau) &= P_\tau, & D(f)^{-1}(M) &= M, \\ D(f)^{-1}(Q_{q'}) &= Q_{\bar{f}^{-1}(q')}, & D(f)^{-1}(T_{p'}) &= T_{f^{-1}(p')}. \end{aligned} \quad (\text{MFC.47})$$

The first two formulas follow by the exact face images, and the required condition on the second ideal pair holds: if $a \in f^{-1}(J')$ and $b \in B$, then $\bar{f}(ab) = f(a)\bar{f}(b) \in J'B' \subseteq H'$. Closure under sums gives $f^{-1}(J')B \subseteq \bar{f}^{-1}(H')$. The two constant-family formulas follow because nonempty faces and full faces remain in precisely those classes. For the Q -formula the contraction identity $\bar{f}^{-1}(q') \cap A = f^{-1}(q' \cap A')$ proves agreement of both indices. Inverse images of proper prime ideals under unital ring maps are proper primes, because they omit the unit and satisfy the prime product implication. This proves the typing and the final two formulas. These maps are continuous on ideal-theoretic spectra: for any ideal $\mathcal{I} \subseteq D_A$, the inverse image, under prime contraction, of the closed set of primes containing $\mathcal{I}$ is the set of primes of $D_{A'}$ containing the ideal generated by $D(f)(\mathcal{I})$. The two containment conditions are equivalent by the definition of inverse image.

Finally, for a bounded-lattice homomorphism $\beta : L \rightarrow L'$ preserving bottom, top, joins, and meets and a unital ring homomorphism $f : R \rightarrow R'$, the map

$$G_\beta(f) : G_L(R) \rightarrow G_{L'}(R'), \quad (r, \lambda) \mapsto (f(r), \beta(\lambda)) \quad (\text{MFC.48})$$

is well-defined: a nonzero target amplitude comes from a nonzero source amplitude, hence from $\lambda = 1_L$, whose image is $1_{L'}$. The two operations in (MFC.29) and the hypotheses on f, β prove preservation of sum, product, zero, and unit. It commutes with amplitude and support via f, β , and sends z_λ to $z_{\beta(\lambda)}$. Its localization transport is the map $\downarrow \lambda \rightarrow \downarrow \beta(\lambda), \nu \mapsto \beta(\nu)$, because

$$\beta(\ell_\lambda(r, \mu)) = \beta(\lambda \wedge \mu) = \beta(\lambda) \wedge \beta(\mu) = \ell_{\beta(\lambda)}(G_\beta(f)(r, \mu)). \quad (\text{MFC.49})$$

It preserves the interval unit and bottom. The threshold maps of MFC.14 are exactly this construction for $f = \text{id}_R$ and $\beta = \alpha_k$, after the isomorphism $G_{\mathbb{B}}(R) \cong G(R)$ sending $(0_R, 0)$ to τ_R and $(r, 1)$ to $r^\bullet$. Substitution in (MFC.29) and (MFC.2) proves that this last bijection is a unital semiring isomorphism. All maps in this attachment preserve their stated source indices and codomains. Their exact fibres identify the information forgotten by a specified observation while retaining the full carriers to which the observation is attached.

112 All independent coefficient faces attached to the original theta source

This construction attaches the independent coefficient masks of the original mixed-support algebra to the actual theta complexes. It retains the original outer source label and leg mask independently of the coefficient mask. A further slot-local leg diagram and its exact comparison with that outer diagram are constructed explicitly. The source-level maps, their cohomology, and the full arithmetic boundary of the finite section are computed below. Every tensor operation already present in the ambient programme keeps its original tensor variables; the finite direct sums in this section are explicitly coefficient-slot observations.

112.1 The original source and its full finite arithmetic sections

Retain

$$\begin{aligned} V &= \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \int_{\mathbb{R}} \phi(x) dx = 0\}, \\ \mathcal{B} &= \{F \in C^\infty(\mathbb{R}_+) : \sup_{x>0} x^b |D^j F(x)| < \infty \quad (b \in \mathbb{Z}, j \geq 0)\}, \\ D &= -x\partial_x, \quad \hat{\phi}(\nu) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \nu} dx, \\ \Theta\phi(x) &= 2 \sum_{n \geq 1} \phi(nx), \quad Q = \mathcal{B}/\Theta V, \quad q : \mathcal{B} \longrightarrow Q. \end{aligned} \quad (\text{MCF1})$$

The letter q in (MCF1) denotes the quotient map; a coefficient Frobenius prime power will be denoted q_0 below. Put

$$U = \{s : 0 < \Re s < 1, \Re s \neq \tfrac{1}{2}\}, \quad T_U Q = \bigcup_p \ker(p(D) : Q \rightarrow Q), \quad (MCF2)$$

$$\mathcal{B}_U = q^{-1}(T_U Q), \quad C_U = [V \xrightarrow{\Theta} \mathcal{B}_U],$$

where p ranges over all monic polynomials with roots in U , including 1. The original source calculation proves injectivity of Θ , $D\Theta = \Theta D$, and injectivity of every nonzero polynomial $p(D)$ on V and $\mathcal{B}$. We use its exact range identities

$$p(D)V = \ker(j_p H), \quad p(D)\mathcal{B} = \ker(j_p \mathcal{M}),$$

$$\mathcal{M}F(s) = \int_0^\infty F(x)x^s \frac{dx}{x}, \quad \mathcal{M}\Theta\phi = gH_\phi, \quad g = 2\xi, \quad (MCF3)$$

$$H_{P(D)\phi_*} = P, \quad \phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}.$$

These are the original arithmetic identities (AG1) and (CAU1), with their full-plane Euler inverses. The attachment below uses their stated domains; it does not introduce a different test-function completion. For example, the last identity follows from

$$M_+\phi_*(s) = \tfrac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2), \quad H_\phi = \frac{2\pi^{s/2}M_+\phi}{s(s-1)\Gamma(s/2)}.$$

The displayed Mellin formula is obtained by integrating the two Gaussian monomials and using $\Gamma(z+1) = z\Gamma(z)$; the apparent exceptional values are handled by the original entire continuation. The moments of ϕ_* are zero because $\phi_*(0) = 0$ and $4\pi^2 \int x^4 e^{-\pi x^2} dx - 6\pi \int x^2 e^{-\pi x^2} dx = 3 - 3 = 0$.

For a nonempty finite full-order packet in U , write

$$h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}, \quad m_\rho = \text{ord}_\rho g, \quad d_h = \deg h, \quad (MCF4)$$

$$E_h = \mathbb{C}[s]/h, \quad A_h = M_s, \quad v_h = g/h, \quad v_h = j_h v_h, \quad \varepsilon_h = v_h^{-1},$$

$$F_h = S_h^{\mathcal{B}} \Theta \phi_*, \quad P_h(u) = r_h(\varepsilon_h u), \quad s_h u = P_h(u)(D)F_h, \quad \sigma_h = q s_h.$$

Here r_h is the unique polynomial representative of degree less than d_h , and $S_h^{\mathcal{B}}$ is the inverse of $h(D)$ on the exact range in (MCF3). Every actual multiplicity is retained, so v_h is nonzero at each packet centre and v_h is a unit in the full local algebra. Every packet index and directed limit in this module also includes the empty packet $h = 1$, with $F_1 = \Theta\phi_*$, $E_1 = 0$, $s_1 = \sigma_1 = \ell_1 = 0$, and $\mathcal{B}_1 = \Theta V$. Its maps into other packet stages are zero on E_1 and the original inclusion on ΘV . No inverse unit at this zero-vector-space stage is used. The definition of F_1 is forced by $1(D)F_1 = \Theta\phi_*$ and gives $\mathcal{M}F_1 = g$. Thus the directed systems are defined even when there is no nonempty packet in U . The equalities

$$h(D)F_h = \Theta\phi_*, \quad \mathcal{M}F_h = v_h, \quad J_h s_h = 1, \quad J_h = j_h \mathcal{M}, \quad J_h \Theta = 0,$$

$$h(D)s_h u = \Theta(P_h(u)(D)\phi_*), \quad (MCF5)$$

$$Ds_h - s_h A_h = \Theta\phi_* \ell_h, \quad \ell_h(u) = [s^{d_h-1}]P_h(u)$$

have the original source types. To verify the last equality in full, $sP_h(u) - P_h(A_h u)$ has zero h -jet, degree at most d_h , and leading coefficient $\ell_h(u)$. Monicity gives $sP_h(u) - P_h(A_h u) = h\ell_h(u)$. Apply this polynomial in D to F_h and use the first equality. The other identities follow directly from (MCF3)–(MCF4) and retain the entire multiplier v_h .

For completeness the finite arithmetic image is exactly $\sigma_h E_h = Q[h(D)]$. If $h(D)F = \Theta\phi$, the assignment $[F] \mapsto j_h H_\phi$ is well-defined because replacing F by $F + \Theta\psi$ replaces ϕ by $\phi + h(D)\psi$. A zero jet makes $\phi = h(D)\psi$ by (MCF3), and injectivity of $h(D)$ gives $F = \Theta\psi$. Every jet represented by a polynomial P is obtained from $S_h^{\mathcal{B}} \Theta(P(D)\phi_*)$, since $j_h(gP) = 0$. Thus this assignment is an isomorphism. Applied to $s_h u$ it gives $\varepsilon_h u$ by (MCF5), an invertible change of full jet coordinates. In particular σ_h is injective and has the asserted image.

112.2 The independent coefficient face category and its exact quotient

Fix $n \geq 1$ and $I_n = \{0, \dots, n-1\}$. For every subset $A \subseteq I_n$, including the empty subset, put

$$C_U[A] = \bigoplus_{i \in A} C_U = [V^A \xrightarrow{(\phi_i) \mapsto (\Theta \phi_i)} \mathcal{B}_U^A], \quad E_h[A] = E_h^A. \quad (\text{MCF6})$$

Empty direct sums are zero vector spaces. If $A \subseteq B$, define z_{AB} by the identity in each old coordinate and by the typed zero in every coordinate of $B \setminus A$, in both degrees and in $E_h[A]$. Then $dz_{AB} = z_{AB}d$ coordinate by coordinate, and $z_{BC}z_{AB} = z_{AC}$. This is a functor from the inclusion category $\mathcal{P}(I_n)$ to complexes. The complete face diagram is retained; no colimit is taken that would identify its different masks.

For a complex vector space X , set $G(X) = \{\tau\} \sqcup \{x^\bullet : x \in X\}$, with the original supported addition and scalar action. The degree- j mixed carrier is

$$\mathcal{D}_n^j = \prod_{i \in I_n} G(C_U^j) \simeq \prod_{A \subseteq I_n} \{A\} \times (C_U^j)^A. \quad (\text{MCF7})$$

The empty term on the right is one point, corresponding to the all-absent tuple. The bijection sends each present coordinate to its original amplitude and records every present zero in A . Its inverse puts those amplitudes in the coordinates of A as supported values and puts τ in the other coordinates. Thus all 2^n masks, including the proper nonempty faces, are present. A face arrow z_{AB} changes the recorded mask from A to B and fills the new coordinates with supported zeros. It is an arrow between labelled faces, not an identification of them.

The differential preserves the original mask of its input and applies Θ independently in every present coordinate. A source vector annihilated by its amplitude differential reaches the supported zero at the same mask. In the internal split cycle and boundary construction, $\epsilon(A, x) = (A, 0)$ and $Z = \text{Eq}(d, \epsilon d)$; boundary relations are the coequalizer of b and ϵb within each labelled fibre. Consequently the exact cohomology and quotient are

$$\begin{aligned} H^0(C_U[A]) &= 0, & H^1(C_U[A]) &= (T_U Q)^A, \\ \mathcal{D}_n^1 &\longrightarrow \prod_i G(T_U Q), & F_i^\bullet &\longmapsto (qF_i)^\bullet, \quad \tau \longmapsto \tau. \end{aligned} \quad (\text{MCF8})$$

Indeed Θ is injective in every active coordinate, and the image in degree one is exactly $(\Theta V)^A$. Two amplitudes at mask A are identified precisely when their coordinate differences belong to $(\Theta V)^A$. The fibre over the supported zero at A is $\{A\} \times (\Theta V)^A$; it is not combined with any other mask. More generally, choosing any lift F of an amplitude in $(T_U Q)^A$ gives its entire fibre as $F + (\Theta V)^A$ at that same mask.

The full finite arithmetic attachment is

$$\begin{array}{ccccc} E_h[A] & \xrightarrow{s_h^A} & \mathcal{B}_U^A & \xrightarrow{q^A} & (T_U Q)^A \\ z_{AB} \downarrow & & z_{AB} \downarrow & & \downarrow z_{AB} \\ E_h[B] & \xrightarrow{s_h^B} & \mathcal{B}_U^B & \xrightarrow{q^B} & (T_U Q)^B. \end{array} \quad (\text{MCF9})$$

All squares commute because every displayed map is applied independently to the unchanged old coordinates and is linear on the inserted zeros. Every $\sigma_h^A = q^A s_h^A$ is injective by (MCF5). In every active coordinate its exact Euler boundary is

$$(D^A s_h^A - s_h^A A_h^A)(u_i)_{i \in A} = (\Theta \phi_* \ell_h(u_i))_{i \in A}. \quad (\text{MCF10})$$

This is an equality of actual functions, whose primitive is $(\phi_* \ell_h(u_i))_{i \in A} \in V^A$. After the original quotient it proves $D^A \sigma_h^A = \sigma_h^A A_h^A$. Thus every proper coefficient face carries the same full arithmetic boundary calculation, with its mask still specified.

112.3 Independent slot-local leg presentations

There is also a slot-local copy of the original two-leg presentation at every active coefficient. This auxiliary indexing does not replace the original outer leg label: its exact attachment, including empty coefficient support, is (MCF34)–(MCF40) below. Its objects are

$$\lambda = (A, (S_i)_{i \in A}), \quad A \subseteq I_n, \quad \emptyset \neq S_i \subseteq \{+, -\}. \quad (\text{MCF11})$$

For empty A the family is empty. Order these objects by $\lambda \leq \lambda'$ when $A \subseteq A'$ and $S_i \subseteq S'_i$ for every $i \in A$. Thus each coefficient slot has four states: absent, plus only, minus only, or both. There are exactly 4^n slot-local masks.

At λ put

$$\begin{aligned} C_\lambda^0 &= \bigoplus_{i \in A} \left(\bigoplus_{+ \in S_i} V_+ \oplus \bigoplus_{- \in S_i} V_- \right), \\ C_\lambda^1 &= \mathcal{B}_U^A, \quad d_\lambda(\phi_i, \psi_i)_i = (\Theta\phi_i - \Theta\widehat{\psi}_i)_i. \end{aligned} \quad (\text{MCF12})$$

A coordinate of a missing leg in the displayed formula is its typed zero; that convention evaluates the formula without adjoining that leg to the mask. The plus and target actions of $t \in \mathbb{C}[t]$ are D ; the minus action is $1 - D$. The Fourier identity $\widehat{D}\phi = (1 - D)\widehat{\phi}$ proves that this is a complex of $\mathbb{C}[t]$ -modules. For $\lambda \leq \lambda'$, retain every old source leg and coefficient, insert typed zeros in the new legs and slots, and use zero insertion in degree one. Both differentials then agree term by term, proving a strictly composing cochain map. The actual supported arrow changes the label from λ to λ' and retains every newly supported zero as such.

The natural comparison with (MCF6) is the cochain map

$$p_\lambda : C_\lambda \longrightarrow C_U[A], \quad p_\lambda^0(\phi_i, \psi_i)_i = (\phi_i - \widehat{\psi}_i)_i, \quad p_\lambda^1 = 1. \quad (\text{MCF13})$$

It commutes with every zero-insertion transition. In a plus-only slot its degree-zero map is the identity, in a minus-only slot it is $-\widehat{}$, and in a joint slot it has the exact inverse coordinates

$$u = \phi - \widehat{\psi}, \quad v = \frac{1}{2}(\phi + \widehat{\psi}), \quad \phi = v + \frac{1}{2}u, \quad \psi = \widehat{v} - \frac{1}{2}\widehat{u}. \quad (\text{MCF14})$$

Fourier squares to the identity on V , so every displayed map and inverse has its stated domain. Write $J(\lambda) = \{i \in A : S_i = \{+, -\}\}$. The exact kernel and cohomology are

$$\begin{aligned} 0 \longrightarrow V^{J(\lambda)}[0] &\xrightarrow{\delta_\lambda} C_\lambda \xrightarrow{p_\lambda} C_U[A] \longrightarrow 0, \\ \delta(v)_i &= (v_i, \widehat{v}_i) \quad (i \in J(\lambda)), \\ H^0(C_\lambda) &= V^{J(\lambda)}, \quad H^1(C_\lambda) = (T_U Q)^A. \end{aligned} \quad (\text{MCF15})$$

Surjectivity of p^0 follows from the single-leg formulas and (MCF14). Its kernel in a joint slot is exactly the displayed diagonal, and its degree-one kernel is zero. Its differential on (u, v) is Θu . Injectivity of Θ now proves the cohomology statement directly. Thus the two-leg diagonal remains present at every relevant independent coefficient; it is not removed when the arithmetic degree-one quotient is observed.

The slot-local cohomology carrier is the following. The separate outer label is retained in (MCF34).

$$\widetilde{H}_n^1 = \{\tau_n\} \sqcup \coprod_{\substack{\lambda=(A,S) \\ A \neq \emptyset}} \{\lambda\} \times (T_U Q)^A. \quad (\text{MCF16})$$

Forgetting only the leg masks gives a pointed map to $\prod_i G(T_U Q)$. Over a specified tuple of coefficient mask A it has exactly $3^{|A|}$ labelled preimages, one for every nonempty S_i ; the amplitudes are fixed.

Over the all-absent tuple its fibre is the single τ_n . A specified section takes the joint leg mask at every active coefficient. These formulas prove the exact relationship between the combined support diagram and the coefficient-mask observation; neither is silently used in place of the other. The maps s_h^A and σ_h^A of (MCF9) give their source and arithmetic amplitudes at every λ , with the same recorded coefficient and leg masks.

One can also lift each original one-leg complex into its selected leg presentation. At a single slot the degree-zero section of p_λ is

$$j_+(u) = u, \quad j_-(u) = -\widehat{u}, \quad j_{+-}(u) = (u/2, -\widehat{u}/2), \quad (\text{MCF17})$$

and degree one is the identity. They are $\mathbb{C}[t]$ -linear cochain maps by the Fourier identity. For the two inclusions into the joint slot their precise difference is

$$\text{inc}_+ j_+ - j_{+-} = \delta(u/2), \quad \text{inc}_- j_- - j_{+-} = -\delta(u/2) \quad \text{in degree zero,} \quad (\text{MCF18})$$

and zero in degree one. These retain the original diagonal; a claim of strict naturality for these three chosen sections would omit it. There is also an explicit complex-linear homotopy. The coherent original sections give $\mathcal{B}_U = \Theta V \oplus s_U E_U$, with $E_U = \varinjlim_h E_h$; define $t_U(\Theta\phi + s_U u) = \phi$. Then $t_U\Theta = 1$. The degree-minus-one maps $H_\pm(F) = \pm\delta(t_U F)/2$ obey $dH_\pm = 0$ and $H_\pm\Theta = \pm\delta/2$, so $dH_\pm + H_\pm d$ equals (MCF18). This is the exact homotopy of the chosen sections. No equivariance of t_U or $H_\pm$ is asserted. Existence of the coherent s_U and its original unit is checked in the divisor calculation below.

112.4 Arithmetic dilation on every face and its full source boundary

For $a > 0$ write $\mathcal{R}_a F(x) = F(x/a)$, with the same formula on V . Changing variables shows that it preserves the original spaces, preserves the value-zero condition, and multiplies the source integral by a . Direct substitution gives

$$\Theta\mathcal{R}_a = \mathcal{R}_a\Theta, \quad \widehat{\mathcal{R}_a\phi} = a\mathcal{R}_{1/a}\widehat{\phi}, \quad \mathcal{M}\mathcal{R}_a F = a^s \mathcal{M}F. \quad (\text{MCF19})$$

It commutes with D and hence preserves $T_U Q$ and its inverse image $\mathcal{B}_U$. On every combined face its action is

$$(\phi_i, \psi_i)_i \mapsto (\mathcal{R}_a\phi_i, a\mathcal{R}_{1/a}\psi_i)_i, \quad F_i \mapsto \mathcal{R}_a F_i. \quad (\text{MCF20})$$

The coefficient and leg masks are unchanged. The Fourier formula in (MCF19) makes the two differentials commute exactly. These actions also commute with every face inclusion and with p_λ , since

$$\mathcal{R}_a\phi - a\widehat{\mathcal{R}_{1/a}\psi} = \mathcal{R}_a(\phi - \widehat{\psi}).$$

On the diagonal the action is $v \mapsto \mathcal{R}_a v$, because its minus coordinate becomes $a\mathcal{R}_{1/a}\widehat{v} = \widehat{\mathcal{R}_a v}$. Thus (MCF15) is an equivariant exact sequence.

The finite arithmetic action is

$$A_{a,h} = M_{j_h(a^s)} : E_h \longrightarrow E_h, \quad A_{a,h}|_\rho = a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho = M_{s-\rho}. \quad (\text{MCF21})$$

The complete nilpotent Taylor polynomial is displayed. Mellin and (MCF19) give $J_h \mathcal{R}_a = A_{a,h} J_h$. Dilation preserves $Q[h(D)]$, and J_h is the inverse of σ_h there by (MCF5). Therefore $\widehat{\mathcal{R}_a\sigma_h} = \sigma_h A_{a,h}$, an exact equality on the original arithmetic quotient.

The source defect has a full original primitive, rather than an assumed equivariant lift. Define

$$\begin{aligned} \chi_{a,h}(u) &= \mathcal{R}_a(P_h(u)(D)\phi_*) - P_h(A_{a,h}u)(D)\phi_* \in V, \\ \Psi_{a,h}(u) &= S_h^V \chi_{a,h}(u), \end{aligned} \quad (\text{MCF22})$$

where S_h^V is the inverse of $h(D)$ on $\ker(j_h H)$ from (MCF3). This inverse is applied on its proved domain: the Mellin calculation gives

$$H_{\chi_{a,h}(u)} = a^s P_h(u) - P_h(A_{a,h}u), \quad j_h H_{\chi_{a,h}(u)} = j_h(a^s) \varepsilon_h u - \varepsilon_h A_{a,h}u = 0. \quad (\text{MCF23})$$

The complete $\varepsilon_h = j_h(g/h)^{-1}$ occurs in both terms. Applying $h(D)$ to the two sides and using (MCF5), (MCF19), and $h(D)\Psi = \chi$, gives

$$\mathcal{R}_a s_h u - s_h A_{a,h}u = \Theta \Psi_{a,h}(u). \quad (\text{MCF24})$$

Indeed the difference after application of $h(D)$ is zero, and its injectivity on $\mathcal{B}$ proves the displayed equality. In every coefficient face this equality is applied separately to each u_i . In a combined leg presentation an actual degree-zero primitive is $j_{S_i}(\Psi_{a,h}(u_i))$ from (MCF17). Its differential is precisely the corresponding coordinate of (MCF24). The alternative single-leg and joint-leg primitives differ by the diagonal terms of (MCF18), which remain recorded in (MCF15).

The primitives themselves have the exact composition law

$$\Psi_{ab,h}(u) = \mathcal{R}_a \Psi_{b,h}(u) + \Psi_{a,h}(A_{b,h}u). \quad (\text{MCF25})$$

Expand $\mathcal{R}_{ab}s_h - s_h A_{a,h}A_{b,h}$ as $\mathcal{R}_a(\mathcal{R}_b s_h - s_h A_{b,h}) + (\mathcal{R}_a s_h - s_h A_{a,h})A_{b,h}$, apply (MCF24), and cancel the injective Θ . This proves the law with the original dilation order, source action, and full arithmetic multiplier.

112.5 Packet enlargement with every coefficient face retained

For full-order packets $h \mid H$, put $b = H/h$. Their supports differ by whole local factors, so b and h are coprime. Let $\iota_{hH} : E_h \rightarrow E_H$ insert the old full jets and zero jets at every added centre. CRT gives this injective $\mathbb{C}[s]$ -linear map and the restriction left inverse. At old centres $v_H = b^{-1}v_h$ and $\varepsilon_H = b\varepsilon_h$. At added centres b vanishes to the full required order. Hence

$$r_H(\varepsilon_H \iota_{hH} u) = b r_h(\varepsilon_h u), \quad b(D)F_H = F_h, \quad s_H \iota_{hH} = s_h. \quad (\text{MCF26})$$

When $h = 1, b = H$ and the middle identity is exactly $H(D)F_H = \Theta \phi_* = F_1$; the first and third identities have zero domain and are zero-map identities. The highest-coefficient, action, and primitive identities below also have zero domain there. For a nonempty h , the first identity holds in every full local factor and both polynomials have degree less than $\deg H$; uniqueness of the remainder proves it. For the second identity, apply $h(D)$ and use the injectivity in (MCF3). Together they prove the third. Monicity of b preserves the highest coefficient of the remainders in the first identity, giving

$$\ell_H \iota_{hH} = \ell_h, \quad A_{a,H} \iota_{hH} = \iota_{hH} A_{a,h}, \quad \Psi_{a,H} \iota_{hH} = \Psi_{a,h}. \quad (\text{MCF27})$$

The action identity follows in the unchanged old jets and the zero added jets. The primitive identity follows from (MCF24), the section identity, and injectivity of Θ . All statements hold coordinatewise in $E_h[A]$ and commute with every coefficient and combined-leg face map. Thus the finite face attachments glue by literal source equalities. Their directed union supplies the coherent s_U used in (MCF18). The decomposition $\mathcal{B}_U = \Theta V \oplus s_U E_U$ follows from surjectivity onto $T_U Q$ and injectivity of each σ_h ; every vector and every finite relation occurs in a common full packet. The original all-polynomial calculation (CAU5)–(CAU13) proves that these packets exhaust $T_U Q$, retaining every local zero order.

112.6 The original negacyclic masks and coefficient Frobenius

At its finite arithmetic-algebra vertex, the complete independent carrier is the original

$$D_{E_h,n} = G(E_h)^n, \quad B_{h,n} = E_h[t]/(t^n + 1), \quad \pi_n(c) = \sum_{i=0}^{n-1} p(c_i)t^i. \quad (\text{MCF28})$$

The variable t here is the additional coefficient variable of this finite observation. The spectral variable in E_h is still s . The negacyclic product, its original unit, and its mask law are

$$(c \star d)_k = \bigoplus_{i+j=k} c_i d_j \oplus \bigoplus_{i+j=k+n} (-1)^{\bullet} c_i d_j, \quad 1_D = (1^{\bullet}, \tau, \dots, \tau), \quad (\text{MCF29})$$

$$\text{mask}(c + d) = \text{mask}(c) \cup \text{mask}(d), \quad \text{mask}(c \star d) = \text{mask}(c) + \text{mask}(d) \pmod{n}.$$

For the product, an output is supported exactly when at least one pair of supported input indices sums to it. Wrap signs are supported and a nonempty sum of supported summands remains supported even when its coefficient cancels. This proves the stated law with every mixed face. Monic remainder in t gives the unique coefficients of $\pi_n(c)$; the mask then distinguishes each coefficient zero from absence. Thus (mask, π_n) is injective. Its facewise source and cohomology attachment is exactly (MCF9), or (MCF16) when leg masks are also retained. The product in (MCF29) belongs to this finite algebra vertex. The source maps s_h^A have their stated linear types; no unproved ring multiplication on the original source is inserted.

Let q_0 be an odd prime power with $\gcd(q_0, n) = 1$, and put $\kappa(i) = q_0 i \bmod n$ and $\epsilon_i = (-1)^{\lfloor q_0 i/n \rfloor}$. The coefficient Frobenius lift on the entire independent object is

$$c_i \mapsto \epsilon_i^{\bullet} c_i \quad \text{in slot } \kappa(i), \quad A \mapsto \kappa(A). \quad (\text{MCF30})$$

An absent coordinate stays absent. On a combined label it sends S_i to $S'_{\kappa(i)} = S_i$ and multiplies every present source-leg and target amplitude in that coefficient by ϵ_i . It commutes with the differential because it uses the same coefficient sign in each term of that differential. It commutes with face inclusion, the maps p_λ , s_h^A , σ_h^A , and all arithmetic dilations by coordinate permutation and complex linearity.

On the integral coefficient ring $\mathbb{Z}[t]/(t^n + 1)$ this is the matrix of $t \mapsto t^{q_0}$. It is well-defined since $(t^{q_0})^n = -1$, and choosing r with $q_0^r \equiv 1 \pmod{2n}$ proves its r th power is the identity. Reduction to $\mathbb{F}_{q_0}$ is exactly coefficient Frobenius; extension to $\mathbb{C}$ retains the same integral signed-permutation matrix. On supported monomials, reducing the exponent before or after substitution gives the same wrap sign, since q_0 is odd. Distributivity and the absent cases therefore prove multiplicativity on (MCF29), before synchronization. In particular its support action is the exact permutation in (MCF30), rather than an observation of one global Boolean support bit.

The synchronization arrow is also retained explicitly:

$$E_n = (1^{\bullet}, e, \dots, e), \quad E_n D_{E_h, n} \simeq G(B_{h, n}), \quad D_{E_h, n} [E_n^{-1}] \simeq E_n D_{E_h, n}. \quad (\text{MCF31})$$

Its multiplication fills every missing coordinate of an active input with a supported zero while leaving all ordinary coefficients unchanged; every output has a supported summand using any chosen active input coordinate. Hence $E_n^2 = E_n$. A unital map making this idempotent invertible sends it to 1 and identifies c with $E_n c$, proving the localization universal property. If $f = \sum f_i t^i$ and $J(f) = \{i : f_i \neq 0\}$, its fibre over $f^{\bullet}$ consists of one original vector for each nonempty mask A with $J(f) \subseteq A \subseteq I_n$. The fibre over τ is the all-absent vector alone. In particular a supported zero has $2^n - 1$ distinct independent-mask preimages. These exact fibres remain attached; the synchronized observation does not replace (MCF28).

Finally the original arithmetic coefficients have an exact retract

$$\iota_n : E_h \longrightarrow B_{h, n}, \quad f \mapsto f, \quad r_n : B_{h, n} \longrightarrow E_h, \quad r_n(b) = \frac{1}{n} \text{Tr}_{B_{h, n}/E_h}(M_b), \quad r_n \iota_n = 1. \quad (\text{MCF32})$$

In the basis $1, t, \dots, t^{n-1}$, multiplication by t^i has no diagonal entries for $1 \leq i < n$, while multiplication by b_0 has n diagonal entries b_0 . Thus $r_n(\sum b_i t^i) = b_0$ and its kernel is exactly $\bigoplus_{i=1}^{n-1} E_h t^i$. Writing Ψ_{q_0} for (MCF30) on coefficients, it fixes ι_n and preserves r_n . The coefficientwise extension of $A_{a, h}$ commutes with it and intertwines both arrows in (MCF32). On a coefficient eigenspace of

eigenvalue ω , define the combined operator $T_{a,q_0} = A_{a,h}\Psi_{q_0} = \Psi_{q_0}A_{a,h}$ on $B_{h,n}$. Its actual full local action is

$$\omega a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j. \quad (\text{MCF33})$$

Every ω is a root of unity by the proved finite order, and the original arithmetic action is recovered on the constant-coefficient retract. This completes the attachment of independent mixed coefficient support to the original theta source, its combined leg diagram, and its actual arithmetic operators. All masks, source diagonals, full units, nilpotents, and comparison fibres have their displayed maps.

112.7 The independent outer source label, including empty coefficient support

The original outer source label is (W, S) , with $W \subseteq V$ a complex linear D -invariant subspace and $\emptyset \neq S \subseteq \{+, -\}$. It is independent of the coefficient mask $A \subseteq I_n$. Denote the set of those subspaces W by $\mathcal{W}_D$. Its exact coefficient diagram is

$$\begin{aligned} \mathcal{J}_n^{\text{out}} &= \{(W, S; A) : W \in \mathcal{W}_D, \emptyset \neq S \subseteq \{+, -\}, A \subseteq I_n\}, \\ C_{W,S;A}^0 &= \left(\bigoplus_{+ \in S} W \oplus \bigoplus_{- \in S} \widehat{W} \right)^A, \quad C_{W,S;A}^1 = \mathcal{B}_U^A, \\ d_{W,S;A}(\phi_i, \psi_i)_i &= (\Theta\phi_i - \Theta\psi_i)_i. \end{aligned} \quad (\text{MCF34})$$

The minus leg is exactly $\widehat{W}$; it is not replaced by W unless the two spaces are equal. Its action is $1 - D$, preserving that space by the Fourier identity. The target restriction $\mathcal{B}_U \subseteq \mathcal{B}$ is an injective cochain map to the original outer complex, since $\Theta W \subseteq \Theta V \subseteq \mathcal{B}_U$. For $W \subseteq W', S \subseteq S'$ and $A \subseteq A'$, the transition includes the old source subspaces and coordinates and inserts the typed zeros in new legs and coefficient slots. The degree-one transition is zero insertion. These are cochain maps, by substitution in the displayed differential, and compose literally.

At $A = \emptyset$ this is a zero complex *at its retained outer label* (W, S) . Its single coefficient value has empty coefficient support; the outer leg mask is still S . In the represented carrier one retains all triples $(W, S; A, x)$ and separately adjoins a global external point τ_{out} . In particular

$$(W, S; \emptyset, 0) \neq \tau_{\text{out}}, \quad (W, S; A, 0) \neq (W, S; A', 0) \quad \text{if } A \neq A'. \quad (\text{MCF35})$$

These are explicit distinct elements of the disjoint labelled carrier; they do not assert a nonzero amplitude in a zero complex. Taking a colimit over coefficient masks would identify these zero insertions with their images in the terminal full face. That colimit is not part of this construction.

Define $Q_{W,U} = \mathcal{B}_U / \Theta W$ and $\eta_W : V/W \rightarrow Q_{W,U}$ by $[v] \mapsto [\Theta v]_W$. The complete arithmetic quotient and kernel are

$$\begin{aligned} 0 \longrightarrow (V/W)^A &\xrightarrow{\eta_W^A} Q_{W,U}^A \xrightarrow{\pi_W^A} (T_U Q)^A \longrightarrow 0, \\ H^0(C_{W,S;A}) &= \begin{cases} W^A, & S = \{+, -\}, \\ 0, & |S| = 1, \end{cases} \quad H^1(C_{W,S;A}) = Q_{W,U}^A. \end{aligned} \quad (\text{MCF36})$$

For the kernel sequence, injectivity of Θ proves that $\Theta v \in \Theta W$ exactly when $v \in W$. A class of $\mathcal{B}_U / \Theta W$ maps to zero modulo ΘV exactly when it is represented by Θv for some $v \in V$. Surjectivity follows from the definition of $\mathcal{B}_U$. Applying this proof independently in the coordinates proves the exact sequence. For the cohomology calculation, a joint slot has the reversible coordinates (MCF14) with $u, v \in W$, since $\psi \in \widehat{W}$. Its differential is Θu and its diagonal is W . A single-leg differential is injective with image ΘW . This proves every case, including the zero coefficient vector spaces at empty A . For $W \subseteq W'$ the transition on degree one has kernel exactly $(W'/W)^A$ under the same original map $[v] \mapsto [\Theta v]_W$. The outer-label kernel is thus fully retained.

The exact relation to the slot-local diagram is an enlarged index

$$(W, S; A, (T_i)_{i \in A}), \quad \emptyset \neq T_i \subseteq S. \quad (\text{MCF37})$$

Its source uses W on the present plus legs and $\widehat{W}$ on the present minus legs, according to T_i , and its target is $\mathcal{B}_U^A$. Every differential is the original signed theta differential in that coordinate. The outer diagram (MCF34) embeds by $T_i = S$ for every $i \in A$, with the identity on its coefficient spaces. This embedding remains injective on the index when A is empty because W and S are retained separately. Forgetting W, S and including $W, \widehat{W}$ into V gives the explicit cochain comparison to (MCF12); its target map is the identity on $\mathcal{B}_U^A$. Its induced map on H^1 is precisely π_W^A in (MCF36), and its induced map on H^0 is the diagonal inclusion $W^{\{i:T_i=\{+,-\}\}} \subseteq V^{\{i:T_i=\{+,-\}\}}$. For fixed $W = V$, forgetting only the outer S has exactly three labelled preimages over the empty slot-local mask, two when the union of the nonempty T_i is a single leg, and one when that union contains both legs. Indeed these are exactly the nonempty subsets $S \subseteq \{+, -\}$ containing $\bigcup_i T_i$. This computes the lost outer information of that specified forgetting map; its empty coefficient value is not identified with global absence in (MCF35).

There is a useful original-outer-source retract, which also checks the empty coefficient endpoint without changing the label. At a fixed (W, S) , write $C_{W,S}^U$ for its one-coefficient original complex with central term $\mathcal{B}_U$, and take the constant coefficient map

$$c_0 : C_{W,S;A} \longrightarrow C_{W,S}^U, \quad c_0(x) = \begin{cases} x_0, & 0 \in A, \\ 0, & 0 \notin A, \end{cases} \quad i_0 : C_{W,S}^U \longrightarrow C_{W,S;\{0\}}, \quad x \longmapsto (x)_0. \quad (\text{MCF38})$$

Here i_0 includes the original outer complex as the coefficient-face vertex $A = \{0\}$ in the full represented diagram. This notation does not assert an inclusion into every other face. Each c_0 is a cochain map and commutes with all coefficient zero insertions, since a newly inserted coordinate has zero amplitude. On the represented carrier it sends $(W, S; \emptyset, 0)$ to the supported outer zero at (W, S) . On global τ_{out} the pointed extension has value τ_{out} . Its composite with the selected i_0 is the identity on the original outer coefficient amplitude and label. The coefficient Frobenius fixes index zero and its sign is one, so $c_0 \Psi_{q_0} = c_0$. This proves an actual outer-label-preserving comparison, rather than identifying the original outer label with a slot-local mask.

The finite arithmetic section at a proper outer source is $\sigma_{h,W}(u) = [s_h u]_W \in Q_{W,U}$. It is injective because $\pi_W \sigma_{h,W} = \sigma_h$ and σ_h is injective. Its exact retained defects are

$$\begin{aligned} D\sigma_{h,W} - \sigma_{h,W} A_h &= \eta_W([\phi_* \ell_h(\cdot)]_W), \\ \overline{\mathcal{R}}_a^{W \rightarrow \mathcal{R}_a W} \sigma_{h,W} - \sigma_{h,\mathcal{R}_a W} A_{a,h} &= \eta_{\mathcal{R}_a W}([\Psi_{a,h}(\cdot)]_{\mathcal{R}_a W}). \end{aligned} \quad (\text{MCF39})$$

The first is (MCF5) in the quotient by ΘW and the second is (MCF24) in the quotient by $\Theta \mathcal{R}_a W$. Dilation transports the outer label to $\mathcal{R}_a W$, as required by (MCF19); it need not fix an arbitrary D -invariant W . On the minus source it maps $\widehat{W}$ to $a\mathcal{R}_{1/a}\widehat{W} = \overline{\mathcal{R}_a W}$. This proves that every arrow in (MCF39) has the stated domain and codomain. The original primitives belong to V ; their possibly nonzero classes in V/W or $V/\mathcal{R}_a W$ are retained in (MCF36). No primitive in V has been declared to be a boundary in a smaller source W . For the full outer source $W = V$, both kernel classes are zero and (MCF39) recovers the proved full-source intertwining.

Apply (MCF39) coordinatewise on every A , keeping all outer and slot-local labels. Packet inclusion, zero insertion, and coefficient Frobenius commute with these defects by (MCF27), linearity and the permutation (MCF30). In particular the complete retained data form the commuting represented diagram

$$\{C_{W,S;A}\}_{W,S,A} \longrightarrow \{Q_{W,U}^A[-1]\}_{W,S,A} \xrightarrow{\{\pi_W^A\}} \{(T_U Q)^A[-1]\}_{W,S,A}, \quad \ker \pi_W^A = \eta_W^A((V/W)^A), \quad (\text{MCF40})$$

with the enriched slot-local faces and their inclusion and forgetting maps specified in (MCF37). The first arrow is the actual cochain map to $Q_{W,U}^A[-1]$ given by zero in degree zero and the original quotient in degree one. Its exact kernel complex is also retained:

$$K_{W,S;A} = [C_{W,S;A}^0 \xrightarrow{d} (\Theta W)^A], \quad 0 \longrightarrow K_{W,S;A} \longrightarrow C_{W,S;A} \longrightarrow Q_{W,U}^A[-1] \longrightarrow 0. \quad (\text{MCF40a})$$

Degree-wise kernel computation proves this short exact sequence. The single-leg differential onto ΘW is an isomorphism, and the joint differential in (MCF14) has kernel the full W diagonal. Thus $K_{W,S;A}$ retains exactly the degree-zero diagonal specified in (MCF36), including its zero-insertion and source-inclusion maps. The original outer source, every coefficient mask including the empty one, every present source leg, and the exact arithmetic comparison kernel are simultaneously specified by this diagram.

112.8 Exact enlargement from offcritical support to all nontrivial packets

The offcritical region U throughout the preceding construction remains unchanged. A packet containing critical-line zeros has a larger original source domain, which we now attach by its exact inclusions. Put

$$\begin{aligned} \Omega &= \{s \in \mathbb{C} : 0 < \Re s < 1\}, & L &= \Omega \setminus U = \{s : \Re s = \tfrac{1}{2}\}, \\ T_X Q &= \bigcup_{p \in \mathcal{P}_X} \ker(p(D) : Q \rightarrow Q), & \mathcal{B}_X &= q^{-1}(T_X Q), & C_X &= [V \xrightarrow{\Theta} \mathcal{B}_X] \quad (X = U, \Omega, L), \\ \mathcal{P}_X &= \{p \text{ monic} : \text{every root of } p \text{ belongs to } X\}, & C_+ &= [V \xrightarrow{\Theta} \mathcal{B}]. \end{aligned} \quad (\text{MCF41})$$

The polynomial 1 is in every $\mathcal{P}_X$. The notation C_L denotes an algebraic source complex; no openness of the line L or sheaf restriction to an open L is required. The same polynomial range identities (MCF3) hold for every root in the open strip Ω , including its critical line.

The exact source inclusions, with their original degree-zero maps, are

$$C_U[A] \xrightarrow{(1, \text{inc})} C_\Omega[A] \xrightarrow{(1, \text{inc})} C_+[A]. \quad (\text{MCF41a})$$

Indeed $\mathcal{P}_U \subseteq \mathcal{P}_\Omega$ gives $T_U Q \subseteq T_\Omega Q$ and then $\mathcal{B}_U \subseteq \mathcal{B}_\Omega \subseteq \mathcal{B}$. All differentials are the same original Θ and the degree-zero maps are the identity on V^A , proving both cochain identities. Injectivity holds in each degree. Cohomology in degree zero is zero by injectivity of Θ , and the induced degree-one sequence is the literal sequence of submodules $(T_U Q)^A \hookrightarrow (T_\Omega Q)^A \hookrightarrow Q^A$.

Its full quotient has the exact arithmetic meaning

$$T_\Omega Q = T_U Q \oplus T_L Q, \quad T_\Omega Q / T_U Q \xrightarrow{\sim} T_L Q. \quad (\text{MCF41b})$$

Here is a direct proof without presuming a list of existing zeros. For $u \in T_\Omega Q$, choose an annihilator p in $\mathcal{P}_\Omega$ and factor it as $p = p_U p_L$, retaining every multiplicity, with roots of p_U in U and roots of p_L in L . Either factor can be 1. The factors have disjoint roots, so there are polynomials a, b with $ap_U + bp_L = 1$. Then

$$u_U = b(D)p_L(D)u, \quad u_L = a(D)p_U(D)u, \quad u = u_U + u_L, \quad (\text{MCF41c})$$

and multiplication shows $p_U(D)u_U = p_L(D)u_L = 0$. If a vector is killed by a polynomial rooted in U and by a polynomial rooted in L , the same Bezout identity makes that vector zero. Thus the two submodules intersect in zero and the decomposition is unique, independent of the chosen annihilator and Bezout polynomials. This proves (MCF41b), including its inverse: include $T_L Q$ in $T_\Omega Q$ and take its class modulo $T_U Q$.

There is an exact original Mellin description of this quotient as well:

$$T_X Q \xrightarrow{\sim} \bigoplus_{\substack{\rho \in X \\ g(\rho)=0}} \mathcal{O}_\rho / (g), \quad [F] \mapsto ([\mathcal{M}F]_\rho)_\rho, \quad X = U, L, \Omega. \quad (\text{MCF41d})$$

To check the map, write $p(D)F = \Theta\phi$. Then $p(s)\mathcal{M}F(s) = g(s)H_\phi(s)$, so the Mellin class is zero at every zero of g outside the finite root set of p . Replacing F by a theta boundary changes its Mellin transform by gH and does not change a local class. For injectivity, suppose all local classes at roots of p vanish. At a root with g nonzero, g is a local unit; at a root of g , the vanishing class says that $\mathcal{M}F$ is a multiple of g . In either case write $\mathcal{M}F = gB$ locally. Cancellation in the local analytic domain gives $H_\phi = pB$, so $j_p H_\phi = 0$ at every required order. By (MCF3), $\phi = p(D)\psi$ with $\psi \in V$. Injectivity of $p(D)$ on $\mathcal{B}$ then yields $F = \Theta\psi$.

For surjectivity, take a finitely supported family of full local jets α_ρ at actual zeros in X . For its finite support Z put $h = \prod_{\rho \in Z} (s - \rho)^{m_\rho}$ with the complete actual orders and choose the unique polynomial P of degree less than $\deg h$ with $j_h P = j_h (g/h)^{-1} \alpha$. The complete unit exists at each specified centre and CRT supplies that polynomial. The original Euler range identity gives

$$F_\alpha = S_h^{\mathcal{B}} \Theta(P(D)\phi_*), \quad \mathcal{M}F_\alpha = (g/h)P, \quad h(D)F_\alpha \in \Theta V. \quad (\text{MCF41e})$$

These equations give the specified full jets and zero classes at all other zeros of g . The empty family uses the stage $h = 1$ and the zero class. Changing P by hR changes F_α by the original boundary $\Theta(R(D)\phi_*)$. This proves both inverse identities in (MCF41d), retaining the entire g/h , every coordinate $s - \rho$, and every multiplicity. Under this isomorphism the decomposition (MCF41b) is exactly zero insertion and restriction to the disjoint offcritical and critical-line sets of full local factors.

Degree-wise quotients of the actual complexes now give

$$\begin{aligned} 0 \longrightarrow C_U[A] \longrightarrow C_\Omega[A] \longrightarrow (T_\Omega Q / T_U Q)^A[-1] \longrightarrow 0, \\ 0 \longrightarrow C_\Omega[A] \longrightarrow C_+[A] \longrightarrow (Q / T_\Omega Q)^A[-1] \longrightarrow 0. \end{aligned} \quad (\text{MCF41f})$$

Their degree-zero quotients vanish because both inclusions are the identity on V^A . For the first degree-one quotient, the map $\mathcal{B}_\Omega / \mathcal{B}_U \rightarrow T_\Omega Q / T_U Q$ induced by q is onto, and has zero kernel because $qF \in T_U Q$ is exactly $F \in \mathcal{B}_U$. The second quotient is proved by the identical calculation with $\mathcal{B} / \mathcal{B}_\Omega$ and $Q / T_\Omega Q$. These prove the displayed short exact sequences on the original source domains. In particular a nonzero critical local factor survives in the first quotient; it has not been discarded by working with the original offcritical subcomplex.

For every actual nontrivial full packet h in Ω , including a critical pair or a mixture of critical and offcritical centres, the formulas (MCF4)–(MCF5) and (MCF22)–(MCF27) have their unchanged values and their source now lies in $\mathcal{B}_\Omega$ because $h(D)s_h u \in \Theta V$. Their proofs used (MCF3) in the open strip and the full local unit; they did not use $\Re \rho \neq 1/2$. Thus they apply to that precise larger domain. Their restriction to packets rooted in U agrees literally with the earlier formulas through (MCF41a). Every packet system includes $h = 1$ with $E_1 = 0$; no nonempty offcritical packet is assumed to make the enlarged construction or its embeddings.

Finally retain every coefficient and outer label in this enlargement. Replacing only the central term of (MCF34) by $\mathcal{B}_X^A$ defines $C_{W,S;A}^X$ and $Q_{W,X} = \mathcal{B}_X / \Theta W$. The maps from $X = U$ to $X = \Omega$ are the identity on the original source legs and the inclusion on the central term, and their degree-one quotient is again $(T_\Omega Q / T_U Q)^A$:

$$0 \longrightarrow Q_{W,U}^A \longrightarrow Q_{W,\Omega}^A \longrightarrow (T_\Omega Q / T_U Q)^A \longrightarrow 0. \quad (\text{MCF41g})$$

Indeed $\Theta W \subseteq \mathcal{B}_U$; quotienting the two nested central subspaces by that same subspace proves injectivity and the stated quotient. The proper-source kernel $(V/W)^A$ of (MCF36) remains attached

on each side. Empty coefficient support still retains (W, S) as in (MCF35). The enlarged maps commute with zero insertion, the specified slot-local comparisons, dilation and its proper-source transport, and coefficient Frobenius, since their source maps are identities and their central maps are the original coordinatewise inclusions. This attaches all actual nontrivial packets while preserving the original offcritical construction and its full comparison quotient.

112.9 Literal comparison with the earlier finite source and its cocycle

The earlier source (TC1) writes the spectral polynomial coordinate as t and the same residue representative as $R_Z(u)$; the coordinate isomorphism sends t to s , with $h_Z(t)$ sent to $h(s)$, every power $(t-\rho)^r$ sent to $(s-\rho)^r$, and the full unit unchanged. Consequently $R_Z(u)$ is $P_h(u)$ under this specified isomorphism. For the actual source functions, not only their quotient classes,

$$R_{\text{ref}} = s_h : E_h \longrightarrow \mathcal{B}_X, \quad X = U \text{ or } \Omega \text{ as the packet requires.} \quad (\text{MCF42})$$

Indeed applying $h(D)$ to either representative gives $\Theta(P_h(u)(D)\phi_*)$. The difference lies in $\mathcal{B}$ and is killed by the injective $h(D)$, hence vanishes. This proves the asserted equality with the original units and domains.

Put $t = \log a$, retaining its orientation when $a < 1$, and define

$$c_{t,h}(u) = \int_0^t \mathcal{R}_{e^{t-r}\phi_*} \ell_h(e^{rA_h}u) dr : E_h \longrightarrow V. \quad (\text{MCF43})$$

The integral converges in the original Schwartz topology. In fact on the compact interval joining 0 and t , every derivative of $\mathcal{R}_{e^{t-r}\phi_*}$ is a continuously varying rescaled derivative of the same Schwartz function, with the scaling parameter in a compact subset of $(0, \infty)$. For every pair N, k , its seminorm $\sup_x (1 + |x|)^N |\partial_x^k(\cdot)|$ is uniformly bounded there. The finite matrix e^{rA_h} is smooth and bounded there too. Riemann sums therefore converge in every seminorm in the complete Schwartz space; parity and the two zero moments pass to the limit by continuity, so the limit is in V .

Differentiate the actual $\mathcal{B}$ -valued function $\mathcal{R}_{e^{t-r}s_h} e^{rA_h}u$. Its derivative is $-\mathcal{R}_{e^{t-r}}(Ds_h - s_h A_h) e^{rA_h}u$. The same seminorm argument on $\mathcal{B}$, followed by (MCF5), allows the fundamental theorem of calculus. It gives

$$\Theta_{c_{\log a,h}} = \mathcal{R}_a s_h - s_h A_{a,h}, \quad \Psi_{a,h} = c_{\log a,h}. \quad (\text{MCF44})$$

The second equality follows by comparing with (MCF24) and canceling the injective map $\Theta : V \rightarrow \mathcal{B}$. Thus the previous oriented integral and the Euler-inverse primitive are the same map. Their packet and coefficient-face naturality are literal, by (MCF27) and coordinatewise integration. The joint primitive is $(c/2, -\widehat{c}/2)$; the difference between the two single-leg primitives $(c, 0)$ and $(0, -\widehat{c})$ is the full cycle $(c, \widehat{c})$. No diagonal is discarded by this comparison.

The earlier dual two-leg complex is obtained by applying algebraic $\text{Hom}_{\mathbb{C}}(-, \mathbb{C})$, so the map induced by $C_U \rightarrow C_+$ is restriction $\mathcal{B}^\vee \rightarrow \mathcal{B}_U^\vee$ in degree -1 and identity on both $V^\vee$ source coordinates in degree zero. Its differential, in the same order of legs, is

$$\ell \longmapsto (\ell\Theta, -\ell\Theta\mathcal{F}), \quad \mathcal{F}\phi = \widehat{\phi}. \quad (\text{MCF45})$$

Because $\Theta V \subseteq \mathcal{B}_U$, restriction followed by this differential equals the differential followed by the identity. Thus this is an actual cochain map. It induces restriction $Q^\vee \rightarrow (T_U Q)^\vee$ on degree -1 cohomology. At a joint source the two diagonal parameters $v \mapsto (v, \mathcal{F}v)$ and $w \mapsto (\mathcal{F}w, w)$ agree under $w = \mathcal{F}v$. Define $\mathcal{F}^\vee : V^\vee \rightarrow V^\vee$ by $\mathcal{F}^\vee(\ell) = \ell \circ \mathcal{F}$; the maps $\pi_v, \pi_w : V^\vee \oplus V^\vee \rightarrow V^\vee$ are

$$\pi_v(\alpha, \beta) = \alpha + \beta\mathcal{F}, \quad \pi_w(\alpha, \beta) = \alpha\mathcal{F} + \beta, \quad \pi_v = \mathcal{F}^\vee \circ \pi_w. \quad (\text{MCF46})$$

These identities follow by evaluation on the displayed diagonals and $\mathcal{F}^2 = 1$. The original actions intertwine because $\mathcal{F}\mathcal{R}_a = a\mathcal{R}_{1/a}\mathcal{F}$. For a proper source W , dualizing $W \hookrightarrow V$ gives restriction of diagonal functionals to W . For coefficient faces, dualizing zero insertion gives coordinate restriction. These are algebraic dual statements; no continuous splitting for arbitrary nonclosed W is asserted.

112.10 The shifted coefficient quotient on the original theta complexes

Fix one of the actual full packets h in Ω and a member ρ with $m = m_\rho \geq 2$. The calculation is indexed by precisely those members; it requires no assertion that the indexing set is nonempty. The coordinate isomorphism from the x presentation in (MW23) to this s presentation sends x to s and $e_\rho(x - \rho)^r$ to $e_\rho(s - \rho)^r$, with coefficient one and inverse $s \mapsto x$. It carries the full defining polynomial, its CRT idempotents, and every retained jet order. Use the original local subspace $E_\rho = e_\rho E_h$, $J_\rho = (s - \rho)^2 E_\rho$, and $C_\rho = E_\rho / J_\rho$ of (MW23). Write σ_ρ for the restriction of the original injective $\sigma_h : E_h \rightarrow Q$. Define actual subspaces of the original central source by

$$\mathcal{B}_\rho = q^{-1}(\sigma_\rho E_\rho), \quad \mathcal{B}_{J_\rho} = q^{-1}(\sigma_\rho J_\rho), \quad \Theta V \subseteq \mathcal{B}_{J_\rho} \subseteq \mathcal{B}_\rho \subseteq \mathcal{B}_\Omega. \quad (\text{MCF47})$$

The last inclusion follows because every displayed quotient class lies in the $h(D)$ -torsion, and h is rooted in Ω . The literal direct-sum equalities are

$$\mathcal{B}_\rho = \Theta V \oplus s_h E_\rho, \quad \mathcal{B}_{J_\rho} = \Theta V \oplus s_h J_\rho. \quad (\text{MCF48})$$

For the first, if $qF = \sigma_\rho x$, then $F - s_h x \in \Theta V$; injectivity of σ_ρ makes this x unique. If $\Theta v + s_h x = 0$, quotienting gives $x = 0$, then injectivity of Θ gives $v = 0$. The same argument with $x \in J_\rho$ proves the second equality. Every representative here is the original $s_h x = P_h(x)(D)F_h$ with the full unit $j_h(g/h)^{-1}$, including its components at all selected centres.

There is an actual short exact sequence of source complexes

$$0 \longrightarrow [V \xrightarrow{\Theta} \mathcal{B}_{J_\rho}] \xrightarrow{(1, \text{inc})} [V \xrightarrow{\Theta} \mathcal{B}_\rho] \longrightarrow C_\rho[-1] \longrightarrow 0. \quad (\text{MCF49})$$

The final map is zero in degree zero. In degree one it sends F to $[x]$, where the unique $x \in E_\rho$ satisfies $qF = \sigma_\rho x$. It is linear, vanishes on ΘV , is onto because $s_h x$ is a representative of every $[x]$, and has kernel exactly $\mathcal{B}_{J_\rho}$. These assertions prove both the cochain identity and degreewise exactness. Its inverse on the degree-one quotient sends $[x]$ to $[s_h x] \in \mathcal{B}_\rho / \mathcal{B}_{J_\rho}$; replacing x by $x + j$, $j \in J_\rho$, changes its representative by the actual element $s_h j \in \mathcal{B}_{J_\rho}$. Both inverse identities follow from (MCF48). Thus the length-two quotient used in (MW24)–(MW27) and (MRE34)–(MRE42) has this explicit original-source realization.

The arithmetic actions in this exact sequence also have their original types. Both E_ρ and J_ρ are invariant under $A_h, N_\rho = A_h - \rho I$ on E_ρ , and each $A_{a,h}$. The full-source intertwining (MCF5), (MCF21) makes $D, D - \rho$, and $\mathcal{R}_a$ preserve the corresponding spaces in (MCF47). Their maps on degree zero are respectively $D, D - \rho$, and $\mathcal{R}_a$ on V , and their maps on degree one use the same original operators on functions. Since each commutes with Θ , they are cochain maps. Under the final map in (MCF49) they give exactly the quotient $\bar{A}_h, \bar{N}_\rho$, and $\bar{A}_{a,h}$ of (MW25), with every surviving coefficient retained. The full higher powers remain in the original source operators and in the subcomplex on the left.

The induced filtration is realized before taking cohomology. For every integer j , set

$$\begin{aligned} \mathcal{B}_{\rho,j} &= q^{-1}(\sigma_\rho(M_j E_\rho)), & \mathcal{B}_{J_\rho,j} &= q^{-1}(\sigma_\rho(J_\rho \cap M_j E_\rho)) = \mathcal{B}_{J_\rho} \cap \mathcal{B}_{\rho,j}, \\ 0 \longrightarrow [V \xrightarrow{\Theta} \mathcal{B}_{J_\rho,j}] &\longrightarrow [V \xrightarrow{\Theta} \mathcal{B}_{\rho,j}] \longrightarrow \bar{M}_j C_\rho[-1] \longrightarrow 0. \end{aligned} \quad (\text{MCF50})$$

The intersection equality uses injectivity of σ_ρ . For the exact sequence, the last map of (MCF49) sends $\mathcal{B}_{\rho,j}$ onto $\pi_\rho(M_j E_\rho)$, because the representatives $s_h x$ exist for every $x \in M_j E_\rho$. Its kernel is precisely the displayed intersection. The degree-zero map remains identity and the last differential is zero, proving every case. Consequently the quotient filtration is exactly (MW24), with degrees $m - 1$ and $m - 3$, hence with its retained shift $m - 2$ relative to the displayed length-two centered filtration.

For all sufficiently negative j , the two central terms in (MCF50) equal ΘV . Their source complexes then remain $[V \xrightarrow{\Theta} \Theta V]$, with its actual invertible differential; no assertion that these source complexes are literally zero is made. They have zero cohomology because Θ is injective and onto its

displayed image. At every step the original D preserves $\mathcal{B}_{\rho,j}$, and $D - \rho$ sends it into $\mathcal{B}_{\rho,j-2}$ since its quotient action is precisely N_ρ . This proves the filtered source-map types as well as the induced filtered cohomology identities.

For each proper original $W \subseteq V$, replace the degree-zero term in (MCF49)–(MCF50) by the outer source $\bigoplus_{+ \in S} W \oplus \bigoplus_{- \in S} \widehat{W}$ with the original signed theta differential. Use that identical source in the left and middle complexes. The same proof of degreewise exactness applies, and in degree one their individual cohomology groups have the exact sequences

$$\begin{aligned} 0 \longrightarrow V/W &\longrightarrow \mathcal{B}_{\rho,j}/\Theta W \longrightarrow M_j E_\rho \longrightarrow 0, \\ 0 \longrightarrow V/W &\longrightarrow \mathcal{B}_{J_\rho,j}/\Theta W \longrightarrow J_\rho \cap M_j E_\rho \longrightarrow 0. \end{aligned} \tag{MCF51}$$

In both lines $[v] \mapsto [\Theta v]_W$ is the original kernel map, and the last map is $\sigma_\rho^{-1}q$ on its indicated image. Injectivity, surjectivity, and the kernel computation are the same as in (D11). Thus the low-filtration degree-one cohomology is V/W at a proper source, while the joint degree-zero diagonal is W ; both remain present. For D use $DW \subseteq W'$ and the specified source codomain W' as in (D14). For $D - \rho$ use $(D - \rho)W \subseteq W'$; its minus source operator is $1 - D - \rho$, because $\mathcal{F}(D - \rho) = (1 - D - \rho)\mathcal{F}$. The choice $W' = W + DW$ admits both maps. Dilation uses $\mathcal{R}_a W$. Apply the same proof independently at every coefficient mask, including its retained empty outer label. Zero insertion and coefficient Frobenius commute with the displayed quotient maps by linearity and their original signed coordinate permutation. This transports the strict shifted coefficient quotient to the original mixed source system without removing its actual comparison kernels.

113 The empty-packet endpoint of the exact source diagram

The original mixed coefficient attachment includes the empty packet $h = 1$, with $E_1 = 0$ and $\mathcal{B}_1 = \Theta V$. Its section, arithmetic-action and primitive maps on E_1 are the unique zero maps. To include this endpoint in the named source functions of (MCF4)–(MCF5) and (MCF26), define

$$F_1 = \Theta\phi_*, \quad 1(D)F_1 = \Theta\phi_*, \quad \mathcal{M}F_1 = g. \tag{EPE1}$$

These identities follow from the original theta seed equation; the first is forced by the second because $1(D)$ is the identity. For a nonempty full packet H , the defining equation $H(D)F_H = \Theta\phi_*$ consequently gives

$$(H/1)(D)F_H = F_1. \tag{EPE2}$$

For $H = 1$ this is the identity on the same source function. Every section, action and primitive compatibility with domain E_1 is the equality of the unique zero maps. Unit inverses and the nonempty local jet and polynomial-remainder formulas are used only at nonempty stages. Thus no unit inverse in the zero-vector-space stage is needed. The source inclusion at this stage is exactly $\Theta V \hookrightarrow \mathcal{B}_H$, not a new packet class. This makes the original empty endpoint explicit without assuming that the offcritical packet category has a nonempty member.

The historical MCF bytes are preserved in this reader. Equations (EPE1)–(EPE2) supply their explicit endpoint convention, also accepted by the author of the coordinating source.

114 The exact original cochain attachment on every independent coefficient face

This attachment supplies the cochain, source-section, balancing, and tensor arrows for the independent coefficient faces of the original mixed carrier. The coefficient mask and the original two-leg mask are separate indices. The finite mixed semiring multiplication remains the original algebra observation; the original source spaces acquire no additional multiplication. All tensor products below

are algebraic unless a topology is explicitly specified. We retain the original maps of (AG1)–(AG18), their analytic comparison in (CAU.9)–(CAU.20), and their two-leg source attachment in (CAU.34)–(CAU.37).

114.1 Original spaces, independent faces, and their exact cochain maps

Retain

$$\begin{aligned}
 V &= \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \quad \phi(0) = 0, \quad \int_{\mathbb{R}} \phi(x) dx = 0\}, \\
 \mathcal{B} &= \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^j F(x)| < \infty \quad (b \in \mathbb{Z}, j \geq 0)\}, \\
 D &= -x\partial_x, \\
 \Theta\phi(x) &= 2 \sum_{n \geq 1} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}, \\
 Q &= \mathcal{B}/\Theta V, \quad q : \mathcal{B} \rightarrow Q, \quad U = \{s : 0 < \Re s < 1, \Re s \neq \tfrac{1}{2}\}, \\
 T_U Q &= \{u \in Q : p(D)u = 0 \text{ for some } p \in \mathcal{P}_U\}, \\
 \mathcal{B}_U &= q^{-1}(T_U Q), \quad C_U = [V \xrightarrow{\Theta} \mathcal{B}_U].
 \end{aligned} \tag{CFA.1}$$

Here $\mathcal{P}_U$ is the set of monic polynomials all of whose roots lie in U , including 1. The last complex is in degrees zero and one. Products of annihilating polynomials prove that $T_U Q$ and $\mathcal{B}_U$ are vector spaces stable under D . The original theta map is injective. Its image lies in $\mathcal{B}_U$, and the definition of q proves the actual sequence

$$0 \longrightarrow V \xrightarrow{\Theta} \mathcal{B}_U \xrightarrow{q} T_U Q \longrightarrow 0. \tag{CFA.2}$$

We use $A_{\text{sp}} = \mathbb{C}[x]$ for spectral polynomials, with x acting by D . This is the original Euler polynomial algebra $\mathbb{C}[t]$ under its explicit isomorphism $t \mapsto x$. The cyclic coefficient variable t in the separate finite algebra $E_h[t]/(t^n + 1)$ is never substituted for the spectral variable x .

Fix $n \geq 1$, put $I_n = \{0, \dots, n-1\}$, and let $A \subseteq I_n$ be any coefficient mask, including the empty mask. For a vector space M put $M[A] = \bigoplus_{i \in A} M$. Its labelled carrier element $(A, (m_i))$ means the tuple with m_i in active slot i and external τ in each inactive slot. Thus the zero of this additive face group is e_A , supported exactly on A ; the empty face has the single wholly absent coefficient tuple. For $A \subseteq B \subseteq I_n$ define

$$z_A^B : M[A] \longrightarrow M[B], \quad (z_A^B m)_i = \begin{cases} m_i, & i \in A, \\ 0_M, & i \in B \setminus A. \end{cases} \tag{CFA.3}$$

This is linear. For $A \subseteq B \subseteq C$, each coordinate of $z_B^C z_A^B$ is its original value if it lies in A and is zero otherwise, proving $z_B^C z_A^B = z_A^C$. On labelled carriers (CFA.3) sends e_A to e_B . In particular, when A is empty and B is nonempty it sends the wholly absent coefficient tuple to a supported zero tuple. It is a support-changing map of face groups, not a globally τ -preserving pointed lift.

For any linear map $f : M \rightarrow N$, define $f[A]$ by applying f in each active coordinate. On coordinates in A , both composites below are $f(m_i)$; on coordinates in $B \setminus A$, both are zero because $f(0_M) = 0_N$. Thus

$$f[B] z_A^B = z_A^B f[A]. \tag{CFA.4}$$

This proves naturality on every face, including the empty one. The separate pointed coordinate map $\prod_{i \in I_n} G(f)$ preserves the mask exactly: it sends $m_i^\bullet$ to $f(m_i)^\bullet$, even when $f(m_i) = 0$, and sends an absent coordinate to an absent coordinate. Its inverse image of the supported zero on face A is exactly $(\ker f)[A]$. These statements apply in the actual scalar categories of q , the Mellin maps, the finite sections, the quotient inclusions, and the analytic comparison maps below.

The face diagram has a terminal vertex I_n . Its colimit as a diagram of vector spaces is $M[I_n] = M^n$: every compatible family of maps is uniquely its map from this terminal vertex. Such a colimit identifies each zero face with its full-face image. The independent mixed carrier is instead the labelled disjoint union of the faces. Its simultaneous amplitude and mask determine every coordinate, since they distinguish supported zero from absence. No colimit over the arrows (CFA.3) is taken in this attachment.

The coefficient mask is independent of the original source-leg mask $S \subseteq \{+, -\}$, with S nonempty. For a D -invariant original subspace $W \subseteq V$, give the plus leg W the action D and the minus leg $\widehat{W}$ the action $1 - D$, where the Fourier kernel is $e^{-2\pi i x \nu}$. The original complex $C_{W,S}$ has central term $\mathcal{B}$ in degree one, the indicated present legs in degree zero, and differential $d(\phi, \psi) = \Theta\phi - \Theta\widehat{\psi}$ with only present terms included. Define its coefficient face by

$$C_{W,S}[A] = \bigoplus_{i \in A} C_{W,S}, \quad C_U[A] = [V[A] \xrightarrow{\Theta[A]} \mathcal{B}_U[A]]. \quad (\text{CFA.5})$$

The differential acts independently on every active coordinate. Hence it commutes with (CFA.3); the same coordinate check proves that all source inclusions $W \subseteq W'$ and leg inclusions $S \subseteq S'$ commute with these face maps. The source inclusion is inclusion on each present degree-zero leg and the identity on the central term. Its cochain identity is the equality of the indicated signed theta terms before and after inclusion.

For the joint leg mask, set $u = \phi - \widehat{\psi}$ and $v = (\phi + \widehat{\psi})/2$. Then $\phi = v + u/2$ and $\psi = \widehat{v} - \widehat{u}/2$, and the differential is Θu . Injectivity of Θ gives a full diagonal copy of W in degree zero and $Q_W = \mathcal{B}/\Theta W$ in degree one. For a plus-only leg injectivity of Θ gives zero in degree zero; for a minus-only leg the Fourier isomorphism and the original minus sign give the same conclusion. In all cases the image is ΘW . Taking active coordinates proves

$$H^1(C_{W,S}[A]) = Q_W[A], \quad H^0(C_{W,S}[A]) = \begin{cases} W[A], & S = \{+, -\}, \\ 0, & |S| = 1. \end{cases} \quad (\text{CFA.6})$$

For (CFA.5)'s arithmetic complex, taking coordinates in (CFA.2) gives

$$0 \rightarrow V[A] \xrightarrow{\Theta[A]} \mathcal{B}_U[A] \xrightarrow{q[A]} (T_U Q)[A] \rightarrow 0. \quad (\text{CFA.7})$$

Every vector in the last kernel has unique original source coordinates under Θ ; this proves exactness directly. The boundary relation on face A is therefore exactly $(\Theta V)[A]$.

For the independent split carrier, the coordinatewise lift of the differential squares to e_A on an element of face A , because the ordinary differential squares to zero without changing the face. Even outside the nonzero ordinary degrees, the split carrier of the zero amplitude space is $G(0)^n = \{\tau, e\}^n$. The supported cycle condition is the equality of the differential with the supported-zero map on that face; it is precisely the ordinary linear cycle condition. The boundary coequalizer identifies exactly pairs whose difference is an ordinary boundary within that same face. Thus (CFA.6)–(CFA.7) compute the supported cohomology without replacing the independent face skeleton by one globally absent zero object.

114.2 The complete original section and its Euler boundary

Let $h(x) = \prod_{\rho \in Z} (x - \rho)^{m_\rho}$ be any nonempty actual finite full-order packet with $Z \subset U$, where $m_\rho = \text{ord}_\rho g$ and

$$g(s) = 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s), \quad E_h = A_{\text{sp}}/(h), \quad d_h = \deg h, \quad A_h = M_x : E_h \rightarrow E_h. \quad (\text{CFA.8})$$

Every original nilpotent coefficient through order $m_\rho - 1$ is retained. The statements on an empty packet use $E_1 = 0$ and zero maps, without asking for an inverse unit in a zero vector space. For a nonempty packet define the original maps of (AG6)–(AG8):

$$\begin{aligned} v_h(s) &= g(s)/h(s), & v_h &= j_h v_h \in E_h, & \varepsilon_h &= v_h^{-1}, \\ \phi_* &= (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, & H_{P(D)\phi_*} &= P, & F_h &= S_h^{\mathcal{B}} \Theta \phi_*, \\ h(D)F_h &= \Theta \phi_*, & \mathcal{M}F_h &= v_h, & P_h(u) &= r_h(\varepsilon_h u), & s_h u &= P_h(u)(D)F_h, \\ J_h &= j_h \mathcal{M}, & \sigma_h &= q s_h. \end{aligned} \quad (\text{CFA.9})$$

Here $r_h : E_h \rightarrow \mathbb{C}[x]_{<d_h}$ is the unique monic remainder representative and j_h retains all the specified Taylor jets. The original Euler range identity supplies $S_h^{\mathcal{B}}$ on this input because g has the required zeros. Injectivity of $h(D)$ on $\mathcal{B}$ makes the inverse unique. Full orders give $v_h(\rho) \neq 0$ at every retained centre, so ε_h is the inverse of the full unit jet, including its nilpotent coefficients.

Taking Mellin transforms gives $\mathcal{M}(s_h u) = v_h P_h(u)$, so its h -jet is $v_h \varepsilon_h u = u$. Therefore $J_h s_h = 1$ and s_h is injective. Since $h(D)s_h u = \Theta(P_h(u)(D)\phi_*)$, every image belongs to $\mathcal{B}_U$, with the specified original boundary. Define

$$\ell_h(u) = [x^{d_h-1}]P_h(u), \quad b_h(u) = \phi_* \ell_h(u). \quad Ds_h - s_h A_h = \Theta b_h. \quad (\text{CFA.10})$$

To prove the last identity, the polynomial $xP_h(u) - P_h(A_h u)$ has zero h -remainder and degree at most d_h . Its leading coefficient is $\ell_h(u)$, because the second polynomial has degree less than d_h . Since h is monic, this polynomial is exactly $h\ell_h(u)$. Apply it at D to F_h and use (CFA.9). This proves the entire coefficient, sign, and source boundary.

Applying these maps in every active coordinate gives

$$\begin{aligned} J_h[A]s_h[A] &= 1, & q[A]s_h[A] &= \sigma_h[A], \\ D[A]s_h[A] - s_h[A]A_h[A] &= \Theta[A]b_h[A], & b_h[A](u_i) &= (\phi_* \ell_h(u_i))_{i \in A}. \end{aligned} \quad (\text{CFA.11})$$

The proof is the coordinate identity (CFA.10), and (CFA.4) proves naturality of every map here under every face insertion. Regard $E_h[A]$ as a complex concentrated in degree one. Its map $s_h[A]$ to $C_U[A]$ is a cochain map, since the target differential out of degree one is zero. The map $b_h[A]$ has degree minus one, and (CFA.11) says exactly that the Euler composites differ by the cochain homotopy $db_h[A] + b_h[A]d = db_h[A]$. After $q[A]$ the difference vanishes, proving exact spectral equivariance of $\sigma_h[A]$. Before the quotient the section is a complex-linear observation and is not asserted to be a ring map or an A_{sp} -linear map.

114.3 Full-unit divisor transport on every face

For full packet divisors $h \mid H$, write $b = H/h$; their added and old zero sets are disjoint, so b and h are relatively prime. Retain the restriction and arithmetic zero-extension maps

$$\pi_{Hh} : E_H \rightarrow E_h, \quad \iota_{hH} : E_h \rightarrow E_H, \quad \pi \iota = 1, \quad \iota \pi = M_{e_{hH}}, \quad (\text{CFA.12})$$

where e_{hH} is one on old local factors and zero on the added ones. The polynomial Chinese remainder theorem gives these exact maps: Bezout for h, b constructs the complementary idempotents, and multiplication by them inserts the prescribed old or new jets. Thus π is unital, whereas ι preserves products and sends 1 to e_{hH} . Both are spectral-polynomial linear. The raw numerator map is a different map:

$$\mu_b : [P]_h \mapsto [bP]_H, \quad \mu_b = \iota M_{[b]_h}, \quad \iota = \mu_b M_{[b]_h}^{-1}. \quad (\text{CFA.13})$$

The value on each old factor is multiplication by its full unit $[b]_h$, and the value on each added factor is zero to the full order. These facts prove both equations and well-definedness.

The following are literal original function and polynomial identities:

$$\begin{aligned} v_h &= bv_H, & b(D)F_H &= F_h, & \pi\varepsilon_H &= [b]_h\varepsilon_h, \\ r_H(\varepsilon_H\iota u) &= bP_h(u), & s_H\iota &= s_h, & \sigma_H\iota &= \sigma_h, & \ell_H\iota &= \ell_h. \end{aligned} \quad (\text{CFA.14})$$

For the second function identity, applying $h(D)$ to both sides gives $\Theta\phi_*$, and injectivity of $h(D)$ proves equality. The inverse-unit equation follows by restricting $v_h = bv_H$ and taking the inverse in the old finite quotient. The polynomial $bP_h(u)$ has degree less than $\deg H$. On old factors, $v_H bP_h(u)$ has jet u ; on new factors it has zero jet because $v_H b = v_h$ vanishes to their full orders. Thus its full jet is ιu . Multiplication by the invertible v_H proves that this is the required unique remainder of $\varepsilon_H\iota u$. Applying that polynomial at D to F_H proves the section identity; applying q proves the quotient identity. Monicity of b identifies the top coefficient of $bP_h(u)$ with that of $P_h(u)$, proving the identity for ℓ .

On each coefficient face, (CFA.14) holds in every active coordinate. Equation (CFA.4) then proves all divisor/face squares commute. For a chain of full divisors, restriction and zero insertion compose because their values agree at every local factor; the raw numerator maps compose by multiplication of their literal polynomials. None of these equalities replaces μ_b by ι without its unit. The independent split lift $G(\iota)^n$ preserves every coefficient mask, and its finite mixed unit has image $(e_{hH}^\bullet, \tau, \dots, \tau)$, so it is not falsely declared to preserve the larger packet's unit.

114.4 The exact dilation homotopy on the original source

Let $R_a F(x) = F(x/a)$ for $a > 0$ on both original spaces. Positive dilation preserves evenness and the value at zero, and it multiplies the integral by a ; hence it preserves V . It preserves $\mathcal{B}$ by substituting in each Euler seminorm. Direct substitution in the theta sum gives $\Theta R_a = R_a \Theta$, and in the Mellin integral gives $\mathcal{M} R_a F = a^s \mathcal{M} F$. Write $L = \log a$ and $A_{h,t} = \exp(tA_h)$, so $A_{h,L}$ is the actual finite multiplication by $j_h(a^s)$. Define

$$B_{h,a}(u) = \int_0^L R_{e^{L-t}} \phi_* \ell_h(A_{h,t}u) dt \quad \text{in } V. \quad (\text{CFA.15})$$

This integral is taken with its indicated orientation also for $L < 0$. It is an original Schwartz-space integral. On the compact interval between 0 and L , the dilation parameters range in a compact subset of $(0, \infty)$. For a Schwartz seminorm $p_{r,j}(\phi) = \sup_x |x^r \phi^{(j)}(x)|$, substitution gives $p_{r,j}(R_c \phi) = c^{r-j} p_{r,j}(\phi)$. The same identity with the Euler derivatives of ϕ controls derivatives in t . The finite-dimensional function $\ell_h(A_{h,t}u)$ is smooth. Thus Riemann sums converge in every Schwartz seminorm, defining the integral in the complete Schwartz space. Each integrand has value zero at zero and integral zero; these are continuous functionals on that space, so the result belongs to V .

Differentiation in the same seminorms gives

$$\frac{d}{dt} (R_{e^{L-t}} s_h A_{h,t} u) = -R_{e^{L-t}} (Ds_h - s_h A_h) A_{h,t} u. \quad (\text{CFA.16})$$

Indeed the derivative of $R_{e^{L-t}}$ is $-DR_{e^{L-t}}$, and the derivative of $A_{h,t}$ is $A_h A_{h,t}$. The two terms give the displayed difference. Integrate from 0 to L and use (CFA.10) and $\Theta R_c = R_c \Theta$ to obtain exactly

$$R_a s_h - s_h A_{h,L} = \Theta B_{h,a}. \quad (\text{CFA.17})$$

The commutation with the integral follows from the original continuous theta map, or by its convergent original seminorm estimates on these compact families. This formula includes $a = 1$, when both sides are zero. It is a source-level cochain homotopy, not an assertion that s_h intertwines dilation on its nose. Coordinatewise application and (CFA.4) give this same homotopy naturally on every

face. Applying q gives the exact action relation $\overline{R}_a \sigma_h = \sigma_h A_{h,L}$. All multiplicities are retained: on the ρ factor this action is

$$a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho = M_{x-\rho}. \quad (\text{CFA.18})$$

It is the full Taylor expansion of a^s modulo the actual factor. The divisor identities (CFA.14), their commutation with A_h , and the coordinate formula for the integral also give $B_{H,a} \iota_{hH} = B_{h,a}$. Thus the full source homotopies, not only their quotients, have the exact divisor/face compatibility.

114.5 A strict cochain map that can actually be balanced

The section s_h is not A_{sp} -linear for any nonempty packet. For example take $u = v_h$, so $P_h(u) = 1$ and $h(D)s_h u = \Theta \phi_* \neq 0$, although $hu = 0$ in E_h . Here $\phi_* \neq 0$ and injectivity of Θ prove the nonvanishing. Thus $O \otimes_{A_{\text{sp}}} s_h$ is not a defined tensor arrow. There is a strict replacement with the same original cohomology map. Put

$$e_h = r_h(\varepsilon_h), \quad F'_h = e_h(D)F_h, \quad \phi'_h = e_h(D)\phi_*, \quad P_h^{\text{free}} = [A_{\text{sp}} \xrightarrow{h} A_{\text{sp}}] \quad (\text{CFA.19})$$

with degrees zero and one. Define

$$\kappa_h : P_h^{\text{free}} \longrightarrow C_U, \quad \kappa_h^0(P) = P(D)\phi'_h, \quad \kappa_h^1(P) = P(D)F'_h. \quad (\text{CFA.20})$$

Both maps are A_{sp} -linear because the polynomial actions commute. Moreover $h(D)F'_h = \Theta \phi'_h$, so $\kappa_h^1(hP) = \Theta \kappa_h^0(P)$, proving the cochain identity. For every polynomial P , retain the exact polynomial quotient

$$R_h(P) = \frac{Pe_h - r_h(\varepsilon_h[P]_h)}{h}, \quad \kappa_h^1(P) - s_h([P]_h) = \Theta(R_h(P)(D)\phi_*). \quad (\text{CFA.21})$$

The numerator has zero h -remainder, so the quotient is a polynomial. Applying the numerator at D to F_h and using (CFA.9) proves the displayed equality. The degree-one cohomology of the free source is E_h , and (CFA.21) proves that its induced map is exactly σ_h . Thus no new spectral injection or replacement unit has been substituted.

For every face, take the direct sum of (CFA.20). It commutes with zero insertion in both degrees by (CFA.4) and can be balanced at every analytic stalk $O = \mathcal{O}_{\mathbb{C},s_0}$ by the actual map $x \mapsto s$:

$$[O[A] \xrightarrow{h(s)} O[A]] \xrightarrow{O \otimes \kappa_h[A]} [(O \otimes_{A_{\text{sp}}} V)[A] \xrightarrow{\Theta[A]} (O \otimes_{A_{\text{sp}}} \mathcal{B}_U)[A]]. \quad (\text{CFA.22})$$

The formula is balanced because (CFA.20) is polynomial-linear. The stalk O is torsion-free over the PID A_{sp} and hence flat: it is the directed union of its finite generated torsion-free submodules, each free over the PID; tensoring by free modules and taking filtered colimits preserve exactness. Thus its degree-one map is the actual balanced version of $\sigma_h[A]$. The finite-dimensional section $s_h[A]$ remains a complex-linear observation with (CFA.11) and (CFA.17) as its full source homotopies. This keeps both descriptions connected by (CFA.21), rather than dropping the section when passing to the strict balanced map.

The divisor arrows between these strict free vertices must also be specified. For nonempty full divisors $h \mid H = bh$, put $a_{hH} = r_h([b]_h^{-1})$ and define

$$L_{hH} : P_h^{\text{free}} \longrightarrow P_H^{\text{free}}, \quad L_{hH}^0(P) = a_{hH}P, \quad L_{hH}^1(P) = ba_{hH}P. \quad (\text{CFA.22a})$$

Its cochain identity is $Ha_{hH} = ba_{hH}h$. On degree-one cohomology, the polynomial ba_{hH} equals one at the old factors and vanishes at the added factors, so this map induces exactly ι_{hH} . The original sections commute strictly by (CFA.14), whereas their free resolutions have the explicit homotopy

$$w_{hH} = \frac{a_{hH}e_H - e_h}{h} \in \mathbb{C}[x], \quad K_{hH}^1(P) = P(D)w_{hH}(D)\phi_*, \quad K_{hH}^0 = 0, \quad (\text{CFA.22b})$$

$$\kappa_H L_{hH} - \kappa_h = dK_{hH} + K_{hH}d.$$

The polynomial exists because $[e_H]_h = [b]_h \varepsilon_h$ and $[a_{hH}b]_h = 1$, so its numerator has zero h -remainder. In degree zero the difference is $P(D)(a_{hH}e_H - e_h)(D)\phi_* = K_{hH}^1(hP)$. In degree one, using $b(D)F_H = F_h$, the difference is $P(D)(a_{hH}e_H - e_h)(D)F_h = \Theta(P(D)w_{hH}(D)\phi_*)$. These are exactly the two components of (CFA.22b), proving its sign and degree.

For $h \mid H \mid J$, put $\eta = (a_{hH}a_{HJ} - a_{hJ})/h$. Its numerator vanishes modulo h : both factors give the inverse of J/h there. Thus η is a polynomial, and the degree-minus-one map $T^1 : P_h^{\text{free},1} \rightarrow P_J^{\text{free},0}$ given by multiplication by η satisfies

$$L_{HJ}L_{hH} - L_{hJ} = dT + Td. \quad (\text{CFA.22c})$$

In degree zero its right side is multiplication by $h\eta$, and in degree one it is multiplication by $J\eta$; these are precisely the differences of (CFA.22a)'s two multipliers. Consequently free-resolution divisor composition is retained with its exact homotopy, not asserted to be strict in these remainder coordinates. All multipliers here are polynomial-linear, and the homotopies in (CFA.22b)–(CFA.22c) are A_{sp} -linear. Their direct sums commute with every face insertion and can be balanced just as (CFA.20). The attachment homotopies have the exact further composition identity

$$K_{HJ}L_{hH} + K_{hH} = K_{hJ} + \kappa_J T. \quad (\text{CFA.22d})$$

On a degree-one input its left multiplier on ϕ_* is $ba_{hH}w_{HJ} + w_{hH}$, while the right multiplier is $w_{hJ} + \eta e_J$. Substituting their displayed polynomial definitions makes both equal to $(a_{hH}a_{HJ}e_J - e_h)/h$. All other components are zero by degree. This proves compatibility of the attachment with the composition homotopy itself, with its actual coefficients. The empty finite packet remains its specified zero amplitude observation; its independent split carrier still has every face of $G(0)^n$. The inverse-unit free vertices here are indexed by nonempty packets.

114.6 Every proper source retains its residual class

For any proper D -invariant $W \subseteq V$ the original exact sequence is

$$0 \rightarrow V/W \xrightarrow{[\phi] \mapsto [\Theta\phi]_W} Q_W \rightarrow Q \rightarrow 0, \quad Q_W = \mathcal{B}/\Theta W. \quad (\text{CFA.23})$$

The first map is well-defined. If $\Theta\phi \in \Theta W$, injectivity of Θ gives $\phi \in W$, proving injectivity. The quotient definitions identify its image with the last kernel and prove surjectivity of the last arrow. Taking active coordinates retains the kernel $(V/W)[A]$. For $W \subseteq W' \subseteq V$, the quotient $V/W \rightarrow V/W'$ has kernel W'/W , and the quotient $Q_W \rightarrow Q_{W'}$ has kernel identified with W'/W by $[\phi] \mapsto [\Theta\phi]_W$. The coordinate maps commute with all face arrows by their explicit zero-insertion formula.

Let $s_{h,W}(u) = [s_h u]_W$ as a complex-linear amplitude map to Q_W . Equation (CFA.10) has the exact residual form

$$Ds_{h,W} - s_{h,W}A_h = (u \mapsto [\Theta\phi_*\ell_h(u)]_W), \quad (\text{CFA.24})$$

which corresponds under the first map of (CFA.23) to $[\phi_*\ell_h(u)] \in V/W$. It is zero exactly when that source correction lies in W . Likewise (CFA.17) gives a precise residual class $[B_{h,a}(u)] \in V/W$ when its two target functions are compared in Q_W . Dilation as an action on source-labelled quotients actually goes from Q_W to $Q_{R_a W}$, since $R_a \Theta W = \Theta R_a W$; no invariance of W under all dilations is assumed. In that target the exact comparison is

$$\overline{R_a} s_{h,W}(u) - s_{h,R_a W}(A_{h,L}u) = [\Theta B_{h,a}(u)]_{R_a W}, \quad (\text{CFA.25})$$

whose residual source class lies in $V/R_a W$. Applying the transition to the full source kills these residual classes by (CFA.23). Their coefficientwise versions lie in $(V/W)[A]$ or $(V/R_a W)[A]$ with all labels retained. The strict cochain map (CFA.20) has degree-zero source in V ; it is not silently retyped as a map to a proper source not containing its source vectors. Thus the full-source equivariance statements do not erase any proper-label obstruction.

114.7 Naturality to the independent mixed observation vertices

Only the cochain transport of the original mixed observation is needed here. On the independent carrier $G(M)^n$ define the filling map syn_M to keep the wholly absent tuple absent and otherwise make every slot present with its original amplitude. For any linear $f : M \rightarrow N$, one has

$$G(f)^n \text{syn}_M = \text{syn}_N G(f)^n. \quad (\text{CFA.26})$$

If the input is wholly absent, both sides are wholly absent. Otherwise its mask remains nonempty after $G(f)^n$, even when all amplitudes vanish. Both sides then have all coordinates supported with coefficients $f(m_i)$, taking $m_i = 0$ at a formerly absent slot. This proves the equality with its exact empty and zero cases. It applies to the original section, quotient, divisor, and analytic comparison maps in their declared linear categories.

At the finite PS algebra $D_{E_h, n}$ this filling map is its proved synchronization by $E_{n, h} = (1^\bullet, e, \dots, e)$. Under the nonunital divisor map it has image $(e_{h, H}^\bullet, e, \dots, e)$, which need not equal $E_{n, H}$. Thus the synchronization square for this map is justified by (CFA.26), not by applying a unital localization universal property to a nonunital arrow. Its synchronized section has the actual image of the unit $E_{n, h}$, not the original mixed unit $(1^\bullet, \tau, \dots, \tau)$.

The PS arithmetic retraction is taken after synchronization. To verify its coordinate formula, in $B_n = E_h[t]/(t^n + 1)$ multiplication by t^j for $1 \leq j < n$ has no diagonal entry in the original basis $1, t, \dots, t^{n-1}$, because it shifts indices by the nonzero class j modulo n . Multiplication by the constant coefficient b_0 has n diagonal entries b_0 . Hence

$$r_n \left(\sum b_i t^i \right) = \frac{1}{n} \text{Tr}_{B_n/E_h} (M_{\sum b_i t^i}) = b_0. \quad (\text{CFA.27})$$

Its independent-carrier composite sends an empty mask to τ and every nonempty mask to $p(b_0)^\bullet$, including supported zero when coefficient slot zero was absent. Raw projection to slot zero instead returns τ on that latter face. These are distinct arrows. The PS constant section is carried to $(f^\bullet, e, \dots, e)$; (CFA.27) sends it back to $f^\bullet$. Consequently the section and retraction remain exactly the original arithmetic retract on all coefficient faces, with the factor $1/n$ and the changed masks retained.

For the original coefficient Frobenius, let q_0 be an odd prime power with $\gcd(q_0, n) = 1$. Its integral signed permutation has

$$t^i \mapsto (-1)^{\lfloor q_0 i / n \rfloor} t^{q_0 i \bmod n}. \quad (\text{CFA.28})$$

It takes coefficient mask A to $q_0 A$ modulo n . Applying any complex-linear map to a coordinate commutes with its specified sign, and permuting positions commutes with applying the same map in each position. This proves exact compatibility of (CFA.28) with the sections, source differentials, quotient maps, boundary homotopies, and face transitions. The original nilpotent arithmetic action (CFA.18) instead acts within each face.

For completeness its compatibility with the finite product has a different type from a semiring automorphism. Write $\star$ for the original PS negacyclic convolution, retaining every minus sign for a wrap and its relation $t^n + 1 = 0$. For $a, c > 0$ the coefficient elements satisfy $j_h(a^s)j_h(c^s) = j_h((ac)^s)$. Every convolution summand therefore gives

$$(A_{h, \log a} b) \star (A_{h, \log c} d) = A_{h, \log(ac)} (b \star d). \quad (\text{CFA.29})$$

The scalar elements commute with every coefficient and with the wrap sign, so summing proves the equality, including supported cancellations and absent slots. In particular the diagonal action with parameter a has target action with parameter a^2 , not a . The finite convolution is an algebra observation in degree zero. The packet source in C_U is in cohomological degree one; a degree-zero chain map $C_U \otimes C_U \rightarrow C_U$ induces zero on its degree-two cohomology because $H^2(C_U) = 0$. It therefore cannot realize the nonzero finite packet product on those degree-one source classes. The original DGA product of (AG14) is concatenation into tensor length two and degree two. The attachment keeps those two differently typed products as their actual arrows.

114.8 The full coherent and tensor comparison on all faces

The original Mellin isomorphism, with its original inverse, is

$$m : T_U Q \xrightarrow{\sim} E_U := \bigoplus_{\rho \in U: g(\rho)=0} \mathcal{O}_\rho / (g), \quad [F] \mapsto ([MF]_\rho)_\rho. \quad (\text{CFA.30})$$

Its complete original-function proof is (CAU.9)–(CAU.13). For clarity, its coordinate inverse on a full common packet h sends α to the class of

$$S_h^{\mathcal{B}} \Theta(r_h(\varepsilon_h \alpha)(D)\phi_*), \quad MF_\alpha = (g/h)r_h(\varepsilon_h \alpha). \quad (\text{CFA.31})$$

The Euler inverse exists because this theta input has all required moment-zero jets. Its Mellin identity gives exactly α at each retained centre, using the complete inverse unit. A different polynomial representative differs by hR and changes the source by $\Theta(R(D)\phi_*)$. If a torsion representative has zero full local Mellin class, its equation $pMF = gH_\phi$ forces every p -jet of H_ϕ to vanish. The original range identity gives $\phi = p(D)\psi$, and injectivity of $p(D)$ on $\mathcal{B}$ gives $F = \Theta\psi$. This proves both inverse identities used here and does not assume the existence of an offcritical zero.

On face A , apply these maps to each active coordinate. Its finitely many entries have altogether finite spectral support, so one common full packet contains all of them. Formula (CFA.14) proves that enlarging this common packet changes none of the original functions in the sections. Thus (CFA.30) gives the exact face isomorphism $(T_U Q)[A] \simeq E_U[A]$, naturally under all face maps by (CFA.4). An active zero entry remains active at its supported zero. At every analytic stalk with $s_0 \in U$, balancing and the canonical original maps j and β give

$$M[A] = N[A] \oplus K[A], \quad j[A] : N[A] \hookrightarrow M[A], \quad \beta[A]j[A] = 1, \quad N = O/(g). \quad (\text{CFA.32})$$

The coordinate formulas for j, β prove these identities; the full-source kernel K and the joint-leg diagonal of (CFA.6) remain separate attached factors. No field-vector property of K is asserted for a proper-source kernel from (CFA.23).

For a finite tensor word retain the tuple of coefficient masks $(A_1, \dots, A_k)$ and every original source-leg label. Tensor the already defined maps over $\mathbb{C}$, with the original differential

$$d(x_1 \otimes \dots \otimes x_k) = \sum_{i=1}^k (-1)^{\sum_{j<i} |x_j|} x_1 \otimes \dots \otimes dx_i \otimes \dots \otimes x_k. \quad (\text{CFA.33})$$

The two orders of differentiating distinct positions have opposite signs and cancel, while the same-position terms vanish because $d^2 x_i = 0$. Thus this is the original cochain tensor differential. An equality of the already defined maps holds on each factor of a pure tensor and therefore on their tensor product; pure tensors span, so every face, divisor, quotient, and section square remains an exact square. A tensor of injective complex-linear sections is injective: extend a basis of each image to a basis of its target, obtaining a linear retraction in each factor, and tensor those retractions.

Tensor source homotopies have the exact signs as well. If f_i, g_i are degree-zero cochain maps and H_i has degree minus one with $f_i - g_i = dH_i + H_i d$, then the tensor homotopy is

$$H = \sum_{i=1}^k g_1 \otimes \dots \otimes g_{i-1} \otimes H_i \otimes f_{i+1} \otimes \dots \otimes f_k. \quad (\text{CFA.34})$$

On a homogeneous input the i th summand includes the sign $(-1)^{\sum_{j<i} |x_j|}$ forced by the degree of H_i . Computing $dH + Hd$ cancels the different-position terms with the same signs as (CFA.33). The remaining terms are $\sum_i g_1 \otimes \dots \otimes g_{i-1} \otimes (f_i - g_i) \otimes f_{i+1} \otimes \dots \otimes f_k$; the middle products telescope to $\bigotimes_i f_i - \bigotimes_i g_i$. This proves the full tensor transport of the Euler and dilation homotopies, without asserting a strict section intertwining that the original source does not have.

The finite tensor packet on a word $h_1, \dots, h_k$ is exactly

$$\bigotimes_{i=1}^k E_{h_i} \simeq \frac{\mathbb{C}[x_1, \dots, x_k]}{(h_1(x_1), \dots, h_k(x_k))}. \quad (\text{CFA.35})$$

Successive monic division gives a basis with exponent of x_i strictly less than $\deg h_i$, and the tensor map takes the tensor of the one-variable remainder bases to precisely that basis. This proves the isomorphism and retains all local exponents $0 \leq j_i < m_{\rho_i}$. On each independent face of that word, (CFA.31) acts in each original coefficient coordinate, so its unit is the tensor of the literal full inverse unit jets. No nilpotent coordinate or coefficient mask is replaced by one common support bit.

114.9 Finite-stage continuity and the attachment category

Every fixed-packet section has a direct original seminorm bound. Choose a finite basis u_j of E_h , write $F_j = s_h u_j$, and let p be any original seminorm of $\mathcal{B}$. Linearity gives

$$p \left(s_h \sum_j c_j u_j \right) \leq \sum_j |c_j| p(F_j). \quad (\text{CFA.36})$$

Thus s_h is continuous in its actual finite-dimensional topology. Continuity of its Mellin inverse on the image can also be seen directly. For ρ of real part σ , choose an integer $N > |\sigma|$, put $p_+(F) = \sup_{x>0} x^N |F(x)|$ and $p_-(F) = \sup_{x>0} x^{-N} |F(x)|$. Splitting the integral at one gives

$$\left| \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} \right| \leq \frac{p_+(F)}{(N - \sigma)^{j+1}} + \frac{p_-(F)}{(N + \sigma)^{j+1}}. \quad (\text{CFA.37})$$

Indeed $\int_1^\infty x^{\sigma-N} (\log x)^j dx/x = j!/(N - \sigma)^{j+1}$ by $x = e^y$, and $\int_0^1 x^{\sigma+N} |\log x|^j dx/x = j!/(N + \sigma)^{j+1}$ by $x = e^{-y}$. The same integrable bounds justify differentiation at the fixed jet. Every fixed finite Mellin observation is therefore continuous. Together with $J_h s_h = 1$ this proves that the finite section is a topological embedding onto its image. The quotient map q is continuous in the original quotient topology, so the induced section σ_h is continuous; its inverse J_h descends continuously through q since $J_h \Theta = 0$.

Finite zero insertions and fixed-face maps are finite linear maps. For the labelled disjoint-union topology, addition has output mask $A \cup B$, and negacyclic multiplication has output mask $A + B$ in $\mathbb{Z}/n\mathbb{Z}$. A nonempty supported sum remains supported even when its amplitude cancels, so these output masks are fixed on a pair of input faces. On that pair the amplitude formulas are respectively linear and polynomial finite-dimensional maps, proving continuity there; the disjoint-union topology proves continuity on the whole finite mixed carrier. These are fixed-packet, fixed- n facts. Formula (CFA.36) does not give a uniform bound as the packet or n varies, and it does not identify the topology of an infinite section s_U with a direct-limit topology. No such additional continuity or estimate is asserted by this attachment.

Finally, the attachment is one specified extension of the represented object. Its generating indices are (W, S, h, n, A) with independent S and A , together with the actual full-source and empty-packet vertices. Its values are the face complexes, strict free complexes, finite observation modules, and the original mixed carriers above. For the cochain part use the graded complex-linear path category: degree-zero generators are the displayed cochain maps, and the specified homotopies are degree-minus-one linear generators. The target Hom complexes have their actual differential

$$\partial f = d_{\text{target}} f - (-1)^{|f|} f d_{\text{source}}. \quad (\text{CFA.38})$$

Direct expansion using $d^2 = 0$ gives $\partial^2 f = 0$, and expansion of both sides gives $\partial(fg) = (\partial f)g + (-1)^{|f|} f(\partial g)$. In particular a cochain map has $\partial f = 0$, while a homotopy has $\partial H = dH + H d$.

Impose the proved coordinate and linear composition relations, including $f - g = \partial H$ with the displayed generator H . This does not identify the two unmodified cochain paths f and g . Sending each generator to its actual graded map and each linear combination of paths to the same linear combination of composites is well-defined because precisely these identities were proved above. The differential formula proves compatibility with the graded structure.

Include all tensor words with (CFA.33) and their Koszul permutations. The finite mixed carriers, face-filling maps, and algebra observations are also retained with their independently specified types in the underlying-set representation of TO; no non-cochain observation is declared a degree-zero chain map. Thus this extends the same TO/CAU representation by the original coefficient faces and their exact graded cochain comparison. No colimit discards their labels and no supported zero is identified with global absence. The full ambient $\mathcal{B}$, original two legs, and proper-source residual kernels remain attached.

115 The nilpotent filtration on every independent arithmetic face

This construction applies Deligne's nilpotent-filtration linear algebra to the actual arithmetic packets and to every independent coefficient face. It does not assert an arithmetic purity estimate. Every formula below retains the original arithmetic dilation, its scalar eigenvalue, and all its nilpotent terms. The additional grading operator is recorded as an additional operator.

115.1 Original packets and the filtration

Let Z be a finite set of distinct zeros of the original function $g(s) = 2\xi(s)$, with their full orders $m_\rho \geq 1$. Put

$$h_Z(x) = \prod_{\rho \in Z} (x - \rho)^{m_\rho}, \quad E_Z = \mathbb{C}[x]/(h_Z), \quad E_\rho = e_\rho E_Z. \quad (\text{MW1})$$

Here e_ρ is the Chinese-remainder idempotent, and $u_\rho = e_\rho(x - \rho)$ is an element of this algebra, with local unit e_ρ . Write $v_{\rho,r} = e_\rho(x - \rho)^r$, for $0 \leq r < m_\rho$. These vectors are the original local jet basis. The nilpotent operator N_ρ is multiplication by u_ρ :

$$N_\rho v_{\rho,r} = v_{\rho,r+1} \quad (r < m_\rho - 1), \quad N_\rho v_{\rho,m_\rho-1} = 0. \quad (\text{MW2})$$

For an integer j , define the increasing filtration

$$M_j E_\rho = \text{span}_{\mathbb{C}}\{v_{\rho,r} : m_\rho - 1 - 2r \leq j\}, \quad M_j E_Z = \bigoplus_{\rho \in Z} M_j E_\rho. \quad (\text{MW3})$$

In particular a zero vector in $M_j E_\rho$ remains the zero of its specified coefficient face when this filtration is split-lifted.

Filtration calculation. Multiplication by u_ρ lowers the displayed index by exactly two. Thus $N_\rho M_j \subseteq M_{j-2}$. For $k \geq 0$, the only way $\text{Gr}_k^M E_\rho$ is nonzero is

$$k = m_\rho - 1 - 2r \geq 0, \quad 0 \leq r < m_\rho.$$

It is then one dimensional with basis the class of $v_{\rho,r}$. The map induced by N_ρ^k sends this basis vector to the class of $v_{\rho,r+k}$, whose index is $-k$ and whose exponent $r + k = m_\rho - 1 - r$ lies between zero and $m_\rho - 1$. Its coefficient is exactly one. Thus

$$N_\rho^k : \text{Gr}_k^M E_\rho \xrightarrow{\sim} \text{Gr}_{-k}^M E_\rho. \quad (\text{MW4})$$

When the source graded space is zero, the target is zero by the same index calculation. Direct sums prove the corresponding assertion for $N = \bigoplus_{\rho} N_{\rho}$ on E_Z . This is precisely the centered nilpotent filtration characterized in Weil II, Proposition 1.6.1.

There is an intrinsic formula which also proves functoriality without choosing a new jet basis:

$$M_j V = \sum_{i \geq 0} \left(\ker N^{i+1} \cap \operatorname{im} N^{\max(0, i-j)} \right), \quad V = E_Z. \quad (\text{MW5})$$

To verify it on a block of length m , both spaces in each intersection are terminal spans of the original basis. Their intersection starts at exponent $\max(0, m-1-i, i-j)$. The sum over i starts at the smallest such exponent, namely $\max(0, -j, \lceil (m-1-j)/2 \rceil)$; an exponent at least m denotes the zero space. When the extra term $-j$ exceeds the other terms, $j < 1-m$ and both spans are zero. Otherwise the starting exponents agree with MW3. Kernels and images commute with the finite direct-sum decomposition, proving MW5. A linear map commuting with the nilpotent operators carries each kernel and each image into the corresponding kernel and image. It therefore preserves MW5.

115.2 Independent masks and the arithmetic action

For $n \geq 1$, retain the independent carrier

$$D_{E_Z, n} = G(E_Z)^n, \quad G(E_Z) = \{\tau\} \sqcup \{b^{\bullet} : b \in E_Z\}. \quad (\text{MW6})$$

For each $A \subseteq I_n = \{0, \dots, n-1\}$, its face is $\{A\} \times E_Z^A$, with the empty face a single absent point. The filtration on the entire carrier is the collection

$$\widetilde{M}_j D_{E_Z, n} = \{\tau\} \sqcup \coprod_{\emptyset \neq A \subseteq I_n} \{A\} \times (M_j E_Z)^A. \quad (\text{MW7})$$

This notation specifies additive faces and their filtrations. No assertion that each $\widetilde{M}_j$ is a unital sub-semiring is made. Every present face has its own zero $(A, 0)$ in every filtration step; the filtration does not turn any of these zeros into absence. The zero-insertion maps for $A \subseteq B$ preserve MW7 because they insert the original zero of $M_j E_Z$.

The original arithmetic operator, for real $a > 0$, is multiplication by the full jet of $a^s = \exp(s \log a)$. On a local block it is

$$A_a|_{E_{\rho}} = a^{\rho} \sum_{r=0}^{m_{\rho}-1} \frac{(\log a)^r}{r!} N_{\rho}^r. \quad (\text{MW8})$$

It preserves MW3, and its induced action on every nonzero graded piece of that block is exactly a^{ρ} , since all terms with $r > 0$ lower the filtration index. Its inverse is $A_{a^{-1}}$. Thus the split lift preserves every independent mask, including the zero in each active slot.

For an odd prime power q with $\gcd(q, n) = 1$, retain the coefficient Frobenius from the original negacyclic algebra:

$$\Psi_q(v t^i) = (-1)^{\lfloor qi/n \rfloor} v t^{qi \bmod n}, \quad B_n = E_Z[t]/(t^n + 1). \quad (\text{MW9})$$

It sends A to qA and leaves the jet index unchanged. Consequently it preserves the full filtered face diagram, with its specified permutation of face labels and its original signs. It commutes with N and A_a . Define the combined operator, at its full linear coefficient-space type, by

$$\begin{aligned} B_{\rho, n} &= E_{\rho}[t]/(t^n + 1), & M_j B_{\rho, n} &= \bigoplus_{i=0}^{n-1} (M_j E_{\rho}) t^i, \\ T_{a, q} &= A_a \Psi_q = \Psi_q A_a : B_n \longrightarrow B_n, \\ T_{a, q}(v_{\rho, r} t^i) &= (-1)^{\lfloor qi/n \rfloor} a^{\rho} \sum_{\ell=0}^{m_{\rho}-1-r} \frac{(\log a)^{\ell}}{\ell!} v_{\rho, r+\ell} t^{qi \bmod n}. \end{aligned} \quad (\text{MW9a})$$

Here A_a and N act coefficientwise, and B_n is the direct sum of the $B_{\rho,n}$. Applying MW8 to MW9 gives every coefficient in MW9a; the two orders agree because the signed permutation acts only on the coefficient-slot index. The split lift of $T_{a,q}$ sends the face labelled A to the face labelled qA , with exactly the displayed signs. Eigenspaces below are taken in the full linear space $B_{\rho,n}$; an individual moving face need not be invariant.

Since q is a unit modulo $2n$, choose $h \geq 1$ with $q^h \equiv 1 \pmod{2n}$. Substitution sends t^i to $t^{q^h i} = t^i$, so $\Psi_q^h = I$. The polynomial $X^h - 1$ has distinct complex roots, hence Ψ_q is diagonalizable and its eigenvalues ω satisfy $\omega^h = 1$. On each nonzero graded part of its ω -eigenspace, the three separate operators therefore have eigenvalues

$$\mathrm{Gr}^M(A_a) : a^\rho, \quad \mathrm{Gr}^M(\Psi_q) : \omega, \quad \mathrm{Gr}^M(T_{a,q}) : \omega a^\rho, \quad |\omega| = 1. \quad (\text{MW10})$$

The eigenspace decomposition respects the filtration. Its projection onto the ω -eigenspace is

$$P_\omega = h^{-1} \sum_{d=0}^{h-1} \omega^{-d} \Psi_q^d.$$

On an eigenspace with eigenvalue ω' , this sum is one if $\omega' = \omega$ and zero otherwise, by the finite geometric-sum identity and $(\omega'/\omega)^h = 1$. Every summand preserves every filtration step, so the projection does too. Thus the asserted graded eigenspaces and the restrictions of A_a are defined. MW10 computes the combined operator's modulus as $a^{\mathrm{Re} \rho}$; no bound on $\mathrm{Re} \rho$ has been inserted.

115.3 Tensor products with every coefficient and sign retained

The following proof supplies the tensor compatibility on these blocks, including its constants. On a block of length m , define auxiliary operators

$$Hv_r = (m - 1 - 2r)v_r, \quad Lv_r = v_{r+1}, \quad Ev_r = r(m - r)v_{r-1}. \quad (\text{MW11})$$

The formulas at the endpoints use $v_{-1} = v_m = 0$; L is precisely the original nilpotent N_ρ . Direct subtraction on each basis vector gives

$$[H, L] = -2L, \quad [H, E] = 2E, \quad [E, L] = H. \quad (\text{MW12})$$

For example the coefficient in the last commutator is $(r+1)(m-r-1) - r(m-r) = m-1-2r$. For this algebraic proof alone equip this basis with the auxiliary positive Hermitian form having squared lengths

$$c_r = \frac{r!(m-1)!}{(m-1-r)!}, \quad c_0 = 1. \quad (\text{MW13})$$

This is an explicitly specified additional form, not a replacement for a source norm or an arithmetic positivity assertion. The identity $c_{r+1} = (r+1)(m-r-1)c_r$ proves $L^* = E$, and $H^* = H$.

On any finite tensor product of blocks, retain the original tensor basis and define $L_{\mathrm{tot}}, E_{\mathrm{tot}}, H_{\mathrm{tot}}$ as the sums of these operators acting in the individual factors. Operators on different factors commute, so MW12 still holds. With the product form from MW13, $L_{\mathrm{tot}}^* = E_{\mathrm{tot}}$ and $H_{\mathrm{tot}}^* = H_{\mathrm{tot}}$.

Here is a direct proof of the needed graded isomorphisms. Choose a nonzero vector v of maximal H_{tot} -eigenvalue d . Then $E_{\mathrm{tot}}v = 0$, because E_{tot} raises that eigenvalue by two. Induction using MW12 gives

$$E_{\mathrm{tot}}L_{\mathrm{tot}}^r v = r(d-r+1)L_{\mathrm{tot}}^{r-1}v. \quad (\text{MW14})$$

The operator L_{tot} is nilpotent. Let ℓ be the largest exponent for which $L_{\mathrm{tot}}^\ell v \neq 0$. Applying MW14 at $r = \ell + 1$ gives $(\ell+1)(d-\ell)L_{\mathrm{tot}}^\ell v = 0$, hence $d = \ell$. Thus d is a nonnegative integer and the chain has weights $d, d-2, \dots, -d$. Its span is invariant under $L_{\mathrm{tot}}, E_{\mathrm{tot}}, H_{\mathrm{tot}}$. Its orthogonal complement is invariant too, because the first two are adjoints and the third is self-adjoint. Induction on dimension

decomposes the entire tensor space into such chains. On each chain L_{tot}^k identifies weight k with weight $-k$ exactly as in MW4. Therefore the filtration by sums of H_{tot} -eigenspaces of index at most j is the centered nilpotent filtration. In the original tensor coordinates it is

$$M_j \left(\bigotimes_{\nu=1}^k E_{\rho_\nu} \right) = \sum_{j_1+\dots+j_k \leq j} M_{j_1} E_{\rho_1} \otimes \dots \otimes M_{j_k} E_{\rho_k}. \quad (\text{MW15})$$

This also proves the precise relation to Weil II 1.6.9 on these actual blocks. Tensoring labelled faces retains the ordered tuple of their masks; MW15 operates on their amplitude fibres.

The original arithmetic tensor operator is, without dropping any term,

$$\bigotimes_{\nu=1}^k A_a|_{E_{\rho_\nu}} = a^{\rho_1+\dots+\rho_k} \exp \left((\log a) \sum_{\nu=1}^k N_{\rho_\nu} \right). \quad (\text{MW16})$$

The exponential is finite and the equality follows by expanding the product of commuting finite exponentials. On the M -graded pieces its eigenvalue is $a^{\rho_1+\dots+\rho_k}$. For identical packets its modulus is $a^{k \operatorname{Re} \rho}$. In particular the original arithmetic weight survives this complete nilpotent-filtration construction.

For the coefficient spaces, take $n_\nu \geq 1$, a common odd prime power q coprime to every n_ν , and $B_\nu = E_{\rho_\nu}[t_\nu]/(t_\nu^{n_\nu} + 1)$. Write N_ν for the nilpotent in factor ν , extended by identities to the other factors. Define $A_a^\otimes = \bigotimes_\nu A_a|_{B_\nu}$, $\Psi_q^\otimes = \bigotimes_\nu \Psi_q|_{B_\nu}$, and $T_{a,q}^\otimes = \bigotimes_\nu T_{a,q}|_{B_\nu}$. Then

$$\begin{aligned} T_{a,q}^\otimes &= A_a^\otimes \Psi_q^\otimes = a^{\sum_\nu \rho_\nu} \exp \left((\log a) \sum_\nu N_\nu \right) \Psi_q^\otimes, \\ T_{a,q}^\otimes \left(\bigotimes_\nu v_{\rho_\nu, r_\nu} t_\nu^{i_\nu} \right) &= a^{\sum_\nu \rho_\nu} \left(\prod_\nu (-1)^{\lfloor q i_\nu / n_\nu \rfloor} \right) \\ &\quad \times \sum_{0 \leq \ell_\nu \leq m_{\rho_\nu} - 1 - r_\nu \text{ for all } \nu} \left(\prod_\nu \frac{(\log a)^{\ell_\nu}}{\ell_\nu!} \right) \bigotimes_\nu v_{\rho_\nu, r_\nu + \ell_\nu} t_\nu^{q i_\nu \bmod n_\nu}. \end{aligned} \quad (\text{MW16a})$$

Expanding the factor formulas MW9a proves the second line, including every sign and every factorial. The first line follows by grouping the commuting operators on different tensor factors, and then using MW16. On the tensor of coefficient eigenspaces with eigenvalues ω_ν , the three graded eigenvalues are respectively

$$A_a^\otimes : a^{\sum_\nu \rho_\nu}, \quad \Psi_q^\otimes : \prod_\nu \omega_\nu, \quad T_{a,q}^\otimes : \left(\prod_\nu \omega_\nu \right) a^{\sum_\nu \rho_\nu}. \quad (\text{MW16b})$$

The positive nilpotent powers in MW16a decrease total degree by at least two, which proves this graded formula from the complete operator formula. Its combined modulus is $a^{\sum_\nu \operatorname{Re} \rho_\nu}$. The coefficient permutation sends the ordered tuple $(A_\nu)_\nu$ to $(qA_\nu)_\nu$.

115.4 The exact Tate-scaling comparison

Deligne's local-monodromy operator has type $N : V(1) \rightarrow V$. For geometric Frobenius over $\mathbb{F}_q$, the Tate line has Frobenius eigenvalue q^{-1} . After recording a generator of that line, equivariance has the precise matrix form

$$FNF^{-1} = q^{-1}N. \quad (\text{MW17})$$

For the original arithmetic action MW8 one instead calculates $A_a N_\rho A_a^{-1} = N_\rho$. The exact relation between these operator presentations can be constructed on the same jet space. For real $q > 1$ define

$$\Gamma_{q,\rho} v_{\rho,r} = q^{(m_\rho-1)/2-r} v_{\rho,r}, \quad F_{q,\rho} = q^\rho \Gamma_{q,\rho}. \quad (\text{MW18})$$

Both are invertible and retain every original basis vector. The quotient of successive diagonal entries is q^{-1} , so

$$F_{q,\rho} N_\rho F_{q,\rho}^{-1} = q^{-1} N_\rho, \quad A_q = F_{q,\rho} \Gamma_{q,\rho}^{-1} \exp((\log q) N_\rho). \quad (\text{MW19})$$

The second equality is obtained by multiplying the first two diagonal operators, giving exactly $q^\rho I$, and then retaining the complete exponential MW8. It proves reconstruction of the original arithmetic action from the added operators. Moreover, if $U(z) = \exp(z N_\rho)$, then

$$F_{q,\rho} U(z) F_{q,\rho}^{-1} = U(q^{-1} z). \quad (\text{MW20})$$

Thus these explicit matrices define a complex representation of the group generated by the additive one-parameter operators $U(z)$ and an invertible element acting on the parameter by $z \mapsto q^{-1} z$. This statement is at the displayed complex-linear type; it does not assert that these matrices arise from an arithmetic lisse sheaf.

On the graded piece of index $j = m_\rho - 1 - 2r$, the eigenvalue of the added $F_{q,\rho}$ is $q^{\rho+j/2}$, with

$$2 \log_q |q^{\rho+j/2}| = 2 \operatorname{Re} \rho + j. \quad (\text{MW21})$$

This gives exactly the index shift $\beta + j$ in Weil II 1.8.4, with the explicitly computed $\beta = 2 \operatorname{Re} \rho$. It does not determine β . The two-sided boundary estimate in Deligne's theorem comes from the pure lisse source, the trace and Euler-product bound, and its tensor and dual arguments. MW18 constructs the matrix relation and MW21 computes every graded modulus; neither computation supplies that geometric input. All operators MW18 act coefficientwise on MW7, preserve its masks, and commute with the coefficient permutation MW9.

For admissible odd prime powers q as in MW9, retaining the separate coefficient operator also gives the exact reconstruction and its tensor version

$$\begin{aligned} T_{q,q}|_{B_{\rho,n}} &= F_{q,\rho} \Gamma_{q,\rho}^{-1} \exp((\log q) N_\rho) \Psi_q, \\ T_{q,q}^\otimes &= F_q^\otimes (\Gamma_q^\otimes)^{-1} \exp\left((\log q) \sum_\nu N_\nu\right) \Psi_q^\otimes, \\ F_q^\otimes &= \bigotimes_\nu F_{q,\rho_\nu}, \quad \Gamma_q^\otimes = \bigotimes_\nu \Gamma_{q,\rho_\nu}. \end{aligned} \quad (\text{MW21a})$$

The first two factors in the first line multiply to $q^\rho I$; in the tensor line they multiply to $q^{\sum_\nu \rho_\nu} I$. This proves both identities in their displayed order. On total degree j , the added $F_q^\otimes$ acts by $q^{\sum_\nu \rho_\nu + j/2}$. Its combination with $\Psi_q^\otimes$ acts by $(\prod_\nu \omega_\nu) q^{\sum_\nu \rho_\nu + j/2}$ on the indicated coefficient eigenspaces. These are added-operator eigenvalues; the unchanged arithmetic and combined eigenvalues remain MW16b.

For completeness, duality at the vector-space level also retains its signs. On $V^\vee$, use $N^\vee = -N^\top$ and $M_j V^\vee = (M_{-j-1} V)^\perp$. The dual of a basis vector of index d has index $-d$, and $N^\vee$ lowers that index by two with coefficient -1 . Its iterated graded isomorphisms have the nonzero coefficient $(-1)^k$. The original contragredient arithmetic action is

$$(A_a^{-1})^\top = a^{-\rho} \exp(-(\log a) N^\top), \quad (\text{MW22})$$

so its graded eigenvalue is exactly $a^{-\rho}$. On the full coefficient dual put $\Psi_q^\vee = (\Psi_q^{-1})^\top$ and $T_{a,q}^\vee = (T_{a,q}^{-1})^\top$. Commutativity in MW9a and transposition of the inverse product give

$$T_{a,q}^\vee = (A_a^{-1})^\top (\Psi_q^{-1})^\top. \quad (\text{MW22a})$$

The dual of the ω -coefficient eigenspace has $\Psi_q^\vee$ -eigenvalue ω^{-1} : evaluation gives $(\Psi_q^\vee f)(v) = f(\Psi_q^{-1} v) = \omega^{-1} f(v)$. Thus the three dual graded eigenvalues are $a^{-\rho}$, ω^{-1} , and $\omega^{-1} a^{-\rho}$, respectively. These formulas establish the tensor, dual and Tate-scaling comparisons on every arithmetic amplitude fibre while retaining the separate mixed-support labels.

115.5 The actual length-two quotient retains its induced degrees

Define $Z_{\geq 2} = \{\rho \in Z : m_\rho \geq 2\}$. For each member of this specified subset put $m = m_\rho$, $b = m - 2$, and

$$\begin{aligned} J_\rho &= u_\rho^2 E_\rho = \text{span}\{v_{\rho,r} : 2 \leq r < m\}, & C_\rho &= E_\rho / J_\rho, & \pi_\rho &: E_\rho \longrightarrow C_\rho, \\ w_0 &= \pi_\rho(v_{\rho,0}), & w_1 &= \pi_\rho(v_{\rho,1}), & \phi_\rho &: C_\rho \longrightarrow V_2 = \mathbb{C}[u]/(u^2), & \phi_\rho(c_0 w_0 + c_1 w_1) &= c_0 + c_1 u. \end{aligned} \quad (\text{MW23})$$

Here $u = x - \rho$ is the same local coordinate: the map sends the original local unit to 1 and the original first power to u . The basis multiplication satisfies $v_{\rho,r} v_{\rho,s} = v_{\rho,r+s}$ for $r + s < m$, and zero otherwise. Therefore J_ρ is an ideal, w_0 is the quotient unit, $w_1^2 = 0$, and ϕ_ρ is an algebra isomorphism with inverse $c_0 + c_1 u \mapsto c_0 w_0 + c_1 w_1$. For $m = 2$, the displayed span for J_ρ is zero. This construction is indexed by $Z_{\geq 2}$; it does not assert that this subset has a member. Raising an exponent preserves J_ρ , so N_ρ induces the operator $\bar{N}$ on C_ρ .

Give J_ρ the subspace filtration and C_ρ the quotient filtration of MW3. The latter is exactly

$$\begin{aligned} \bar{M}_j C_\rho = \pi_\rho(M_j E_\rho) &= \begin{cases} 0 & j < m - 3, \\ \mathbb{C}w_1 & m - 3 \leq j < m - 1, \\ C_\rho & j \geq m - 1, \end{cases} & (\text{MW24}) \\ \phi_\rho(\bar{M}_j C_\rho) &= M_{j-b} V_2. \end{aligned}$$

Indeed, all original powers of exponent at least two vanish under π_ρ ; the two surviving powers have their original degrees $m - 1$ and $m - 3$. Substituting $b = m - 2$ into the length-two degrees 1, -1 proves the second line. For every j the kernel of $M_j E_\rho \rightarrow \bar{M}_j C_\rho$ is $J_\rho \cap M_j E_\rho$, and its image is the whole indicated quotient step. Hence $0 \rightarrow J_\rho \cap M_j E_\rho \rightarrow M_j E_\rho \rightarrow \bar{M}_j C_\rho \rightarrow 0$ is exact, proving strictness of both maps. The quotient filtration is centered at b : its only nonidentity graded isomorphism is $\bar{N} : \text{Gr}_{b+1}^{\bar{M}} C_\rho \rightarrow \text{Gr}_{b-1}^{\bar{M}} C_\rho$, sending the class of w_0 to that of w_1 with coefficient one. For $k = 0$ the centered-at- b map is the identity, and for $k > 1$ both graded spaces are zero. If $m > 2$, this filtration is not centered at zero: Gr_{m-1} is nonzero whereas $\text{Gr}_{-(m-1)}$ is zero. MW24 retains the quotient's actual degrees in every case.

The ideal J_ρ is invariant under N_ρ , every A_a , and the added diagonal operators $\Gamma_{q,\rho}, F_{q,\rho}$. For N_ρ this follows by raising the exponent; for A_a it follows term by term in MW8; for the diagonals each basis line is invariant. Their induced quotient operators consequently satisfy

$$\begin{aligned} \bar{N}w_0 &= w_1, & \bar{N}w_1 &= 0, & \bar{A}_a w_0 &= a^\rho(w_0 + (\log a)w_1), & \bar{A}_a w_1 &= a^\rho w_1, \\ \bar{\Gamma}_q w_r &= q^{(m-1)/2-r} w_r, & \bar{F}_q w_r &= q^{\rho+(m-1)/2-r} w_r & (r = 0, 1), & & & (\text{MW25}) \\ \phi_\rho \bar{N} &= N_2 \phi_\rho, & \phi_\rho \bar{A}_a &= A_{a,2} \phi_\rho, & \phi_\rho \bar{\Gamma}_q &= q^{b/2} \Gamma_{q,2} \phi_\rho, & \phi_\rho \bar{F}_q &= q^{b/2} F_{q,2} \phi_\rho. \end{aligned}$$

The subscript 2 specifies the fixed length-two operators $N_2(1) = u$, $N_2(u) = 0$, $A_{a,2} = a^\rho(I + (\log a)N_2)$, $\Gamma_{q,2}(1) = q^{1/2}$, $\Gamma_{q,2}(u) = q^{-1/2}u$, and $F_{q,2} = q^\rho \Gamma_{q,2}$. Every line of MW25 follows by applying both sides to w_0, w_1 . In particular, the higher terms of MW8 are killed by this specified quotient map; they have not been discarded from the original packet.

An exact filtered operator isomorphism records both the degree and diagonal scalar shifts. Let $D_b = \mathbb{C}d_b$ have filtration $(D_b)_j = 0$ for $j < b$ and $(D_b)_j = D_b$ for $j \geq b$, with $N_{D_b} = 0$, $A_{a,D_b} = I$, and $\Gamma_{q,D_b} = F_{q,D_b} = q^{b/2}I$. Use sum filtrations, tensor-sum nilpotents, and tensor-product invertible operators. Then

$$\begin{aligned} \theta_\rho : C_\rho &\xrightarrow{\sim} V_2 \otimes D_b, & w_r &\longmapsto u^r \otimes d_b & (r = 0, 1), & & & (\text{MW26}) \\ \theta_\rho(\bar{M}_j C_\rho) &= M_{j-b} V_2 \otimes D_b, & \bar{A}_q &= \bar{F}_q \bar{\Gamma}_q^{-1} (I + (\log q) \bar{N}). \end{aligned}$$

The inverse sends $u^r \otimes d_b$ to w_r , so the displayed filtration equality proves strictness in both directions. MW25 proves intertwining for A, Γ, F , and its coefficient-one nilpotent relation proves

intertwining for N . In the reconstruction, $\overline{F}_q \overline{\Gamma}_q^{-1} = q^\rho I$, so the degree shift has changed no arithmetic scalar or logarithmic coefficient. The original auxiliary H in MW11 descends to $H_2 + bI$ under ϕ_ρ , where $H_2(1) = 1$ and $H_2(u) = -u$, by its two diagonal entries. For $m > 2$, the original auxiliary E does not descend: $E(v_{\rho,2}) = 2(m-2)v_{\rho,1} \notin J_\rho$. Thus MW26 is the explicitly proved filtered isomorphism for N, A, Γ, F , with the exact additional relation for H .

The kernel also has a specified shifted comparison. For $m > 2$, let $V_{m-2} = \mathbb{C}[u]/(u^{m-2})$ use the original powers, the centered filtration of a length- $m-2$ block, and the operators MW8 and MW18 with the same ρ . The linear map $\alpha_\rho : V_{m-2} \rightarrow J_\rho$, $\alpha_\rho(u^r) = v_{\rho,r+2}$, is bijective, with inverse given by removing these specified two powers. It is a module comparison for the displayed nilpotent and arithmetic operators. Its complete filtration and diagonal relations are

$$\begin{aligned} \alpha_\rho(M_{j+2}V_{m-2}) &= J_\rho \cap M_j E_\rho, & N_\rho \alpha_\rho &= \alpha_\rho N_{m-2}, & A_a \alpha_\rho &= \alpha_\rho A_{a,m-2}, \\ \Gamma_{q,\rho} \alpha_\rho &= q^{-1} \alpha_\rho \Gamma_{q,m-2}, & F_{q,\rho} \alpha_\rho &= q^{-1} \alpha_\rho F_{q,m-2}. \end{aligned} \quad (\text{MW26a})$$

The source degree of u^r is $m-3-2r$; the image's degree is $m-1-2(r+2) = (m-3-2r)-2$, proving the first relation at every step. Raising the exponent proves the nilpotent relation including the last zero vector; expanding MW8 proves the arithmetic relation with all its coefficients. The diagonal exponent on the image is $(m-1)/2 - (r+2) = ((m-3)/2 - r) - 1$, which proves both remaining relations. Consequently the kernel, quotient, and their exact sequence all retain their actual induced shifts. For $m = 2$ the kernel is zero as already specified.

The same quotient is available coefficientwise. Its map on each face is

$$(A, (x_i)_{i \in A}) \mapsto (A, (\pi_\rho x_i)_{i \in A}).$$

Even a coefficient in J_ρ becomes a present zero in the same slot. Surjectivity on each filtered face follows by choosing, independently in each slot, a preimage in $M_j E_\rho$ from MW24. Zero insertion commutes with this map because $\pi_\rho(0) = 0$. On the full coefficient space it intertwines Ψ_q since the map is linear and sends $(-1)^{\lfloor qi/n \rfloor} x$ to that same sign times $\pi_\rho(x)$; MW25 then proves intertwining for $T_{a,q}$. For a tensor of such quotient blocks the exact comparison is

$$\begin{aligned} \bigotimes_{\nu} C_{\rho_{\nu}} &\xrightarrow{\bigotimes_{\nu} \theta_{\rho_{\nu}}} \left(\bigotimes_{\nu} V_{2,\rho_{\nu}} \right) \otimes \left(\bigotimes_{\nu} D_{m_{\rho_{\nu}}-2} \right), \\ \text{total degree shift } \sum_{\nu} (m_{\rho_{\nu}} - 2), &\quad \text{added } F \text{ and } \Gamma \text{ factor } q^{\frac{1}{2} \sum_{\nu} (m_{\rho_{\nu}} - 2)}. \end{aligned} \quad (\text{MW27})$$

The tensor factors are rearranged by the explicit ordinary vector-space map $\bigotimes_{\nu} (u^{r_{\nu}} \otimes d_{b_{\nu}}) \mapsto (\bigotimes_{\nu} u^{r_{\nu}}) \otimes (\bigotimes_{\nu} d_{b_{\nu}})$, with coefficient one. Degrees add and diagonal eigenvalues multiply, which proves both formulas and their inverse on every tensor basis vector. The tensor quotient is strict: a source tensor basis vector survives exactly when each exponent is zero or one, and the degree of every surviving vector is unchanged. Thus each filtered target step is the image of the same source step. Its kernel is spanned by tensors with at least one exponent at least two, giving the complete filtered kernel as their intersection with that step. The unchanged arithmetic eigenvalues and the signed coefficient products are precisely MW16a–MW16b, with the nilpotent powers transported through these actual quotient maps. The strict length-two subobject and quotient maps are developed with these induced degrees in MRE34–MRE42 below.

Status of the geometric control. The construction proves MW1–MW27, including the lettered formulas, on the original finite packets and the specified quotients. It explicitly supplies the nilpotent filtration and its tensor and dual compatibility, and it reconstructs the unchanged arithmetic operator from a Tate-scaling operator. No theorem here identifies the resulting complex representation with a pure lisse sheaf over the absolute τ -base. In particular it proves no numerical restriction on $2 \operatorname{Re} \rho$. The relevant further comparison is with the actual hypotheses and proof of Weil II 1.8.4–1.8.5 and the compact-support pushforward estimate 3.3.1; the finite-poset section functor by itself has not supplied those estimates.

116 Strict filtered control of the original length-two jet extension

This calculation constructs the induced filtrations and exact operator maps on a specified arithmetic jet extension. It includes the uniqueness proof for the centered nilpotent filtration, the translation to a specified constituent degree, and the relative filtration on this extension. The original arithmetic action and the added Tate-scaling action are both retained as separate, explicitly related operators.

116.1 Uniqueness of the centered nilpotent filtration

Let V be a finite-dimensional complex vector space and N a nilpotent endomorphism. A finite increasing filtration in this paragraph means subspaces $M_j V$, indexed by $j \in \mathbb{Z}$, which are zero for all sufficiently negative j and equal to V for all sufficiently positive j . Suppose it has the centered nilpotent properties

$$NM_j V \subseteq M_{j-2} V, \quad N^k : \mathrm{Gr}_k^M V \xrightarrow{\sim} \mathrm{Gr}_{-k}^M V \quad (k \geq 0). \quad (\text{MRE1})$$

Here and below an isomorphism from the zero vector space to itself is included in the assertion.

We prove that these properties determine M uniquely. Choose $d \geq 0$ with $N^{d+1} = 0$. For $k > d$, the isomorphism in MRE1 is the zero map; its source and target therefore vanish. Exhaustiveness and finiteness give $M_d V = V$ and $M_{-d-1} V = 0$. The isomorphism for $k = d$ is induced by N^d from $V/M_{d-1} V$ to $M_{-d} V$. Consequently

$$M_{d-1} V = \ker N^d, \quad M_{-d} V = \mathrm{im} N^d. \quad (\text{MRE2})$$

For $d = 0$, this says that the only possibly nonzero graded piece is degree zero, and determines the filtration completely.

For $d \geq 1$, the subspace $\mathrm{im} N^d$ lies in $\ker N^d$, because $N^{2d} = 0$. The induced operator on

$$K_d = \ker N^d / \mathrm{im} N^d \quad (\text{MRE3})$$

satisfies $N^d = 0$. The filtration induced on K_d has the same graded pieces as V for $-d < j < d$, and zero graded pieces outside this range. Thus MRE1 descends to this quotient: for $0 \leq k < d$ its maps are the original graded maps, and for $k \geq d$ both sides vanish. Induction on d determines the filtration on K_d . Every intermediate step on V is its inverse image under the quotient $\ker N^d \rightarrow K_d$; MRE2 fixes the endpoints. This proves uniqueness.

For the original length- m jet basis v_r , $0 \leq r < m$, with $Nv_r = v_{r+1}$ and $Nv_{m-1} = 0$, existence is explicit:

$$M_j V = \mathrm{span}\{v_r : m - 1 - 2r \leq j\}. \quad (\text{MRE4})$$

The operator lowers the displayed index by two. When index $k \geq 0$ occurs, its basis vector has exponent $r = (m - 1 - k)/2$; applying N^k gives the index- $-k$ vector v_{r+k} , with coefficient one and $r + k = m - 1 - r$. If index k is absent, index $-k$ is absent as well. This proves MRE1. Taking direct sums proves existence on any finite packet of these original blocks. The preceding uniqueness proof identifies this explicit filtration with the centered nilpotent filtration.

116.2 Translation to a specified constituent degree

For an integer b , put a given original block in the one-step filtration

$$W_i^{[b]} V = \begin{cases} 0 & i < b, \\ V & i \geq b, \end{cases} \quad M_j^{[b]} V = M_{j-b} V. \quad (\text{MRE5})$$

The relative nilpotent-filtration identities for this specified $W^{[b]}$ are

$$NM_j^{[b]} \subseteq M_{j-2}^{[b]}, \quad N^k : \mathrm{Gr}_{i+k}^{M^{[b]}} \mathrm{Gr}_i^{W^{[b]}} V \xrightarrow{\sim} \mathrm{Gr}_{i-k}^{M^{[b]}} \mathrm{Gr}_i^{W^{[b]}} V. \quad (\text{MRE6})$$

For $i \neq b$, both sides of the second map vanish. For $i = b$, that map is exactly the already proved $N^k : \text{Gr}_k^M V \rightarrow \text{Gr}_{-k}^M V$. The first inclusion follows directly by shifting both indices in MRE1. This proves the relative-filtration translation for every integer b . The construction of these filtrations assigns the displayed degree; it does not change or determine any arithmetic eigenvalue.

116.3 The original extension and its arithmetic action

Fix $\rho \in \mathbb{C}$, retain the local coordinate $u = x - \rho$, and define the length-two jet algebra and its nilpotent operator by

$$V_2 = \mathbb{C}[u]/(u^2), \quad v_0 = 1, \quad v_1 = u, \quad Nv_0 = v_1, \quad Nv_1 = 0. \quad (\text{MRE7})$$

In this entire calculation these are the fixed original basis vectors and the coefficient of Nv_0 remains exactly one. For arbitrary ρ , MRE7 specifies this displayed local algebra; it asserts no zero or repeated zero of $g(s) = 2\xi(s)$. The exact comparison with any actual packet member of multiplicity at least two is proved in MRE34–MRE42. That comparison retains the quotient filtration induced from the full block, together with its degree translation and both added diagonal factors. Let $K = \mathbb{C}u \subset V_2$, let $Q = V_2/K$, and write $\bar{1}$ for the class of 1 in Q . The maps

$$i : K \longrightarrow V_2, \quad i(cu) = cu, \quad p : V_2 \longrightarrow Q, \quad p(a + bu) = a\bar{1} \quad (\text{MRE8})$$

give the exact sequence

$$0 \longrightarrow K \xrightarrow{i} V_2 \xrightarrow{p} Q \longrightarrow 0. \quad (\text{MRE9})$$

Indeed, i is injective, p is surjective, and $\ker p = \mathbb{C}u = \text{im } i$. The restricted operator on K and the induced operator on Q are both zero.

For real $a > 0$, retain the original arithmetic action

$$A_{a,2} = a^\rho (I + (\log a)N), \quad A_{a,K} = a^\rho I_K, \quad A_{a,Q} = a^\rho I_Q, \quad a^\rho = \exp(\rho \log a). \quad (\text{MRE10})$$

Since $N^2 = 0$, this is exactly the complete original finite exponential. It gives

$$A_{a,2}(c + du) = a^\rho (c + (d + c \log a)u). \quad (\text{MRE11})$$

The restriction to K and the induced quotient action are therefore the displayed scalars. In particular

$$A_{a,2}i = iA_{a,K}, \quad pA_{a,2} = A_{a,Q}p. \quad (\text{MRE12})$$

All maps in MRE9 preserve these original arithmetic actions.

116.4 Induced subobject and quotient filtrations

The centered filtration MRE4 on V_2 is

$$M_j V_2 = \begin{cases} 0 & j < -1, \\ K & -1 \leq j < 1, \\ V_2 & j \geq 1. \end{cases} \quad (\text{MRE13})$$

Give the subobject and quotient their actual induced filtrations:

$$M_j^K = K \cap M_j V_2 = \begin{cases} 0 & j < -1, \\ K & j \geq -1, \end{cases} \quad M_j^Q = p(M_j V_2) = \begin{cases} 0 & j < 1, \\ Q & j \geq 1. \end{cases} \quad (\text{MRE14})$$

Let $C_j K$ and $C_j Q$ denote the centered filtrations of the zero nilpotent on these one-dimensional spaces: each is zero for $j < 0$ and the whole space for $j \geq 0$. Then the precise shifts are

$$M_j^K = C_{j+1}K, \quad M_j^Q = C_{j-1}Q. \quad (\text{MRE15})$$

Thus the subobject retains degree -1 , the quotient retains degree $+1$, and the middle object's filtration remains MRE13.

For every integer j , the sequence

$$0 \longrightarrow M_j^K \xrightarrow{i} M_j V_2 \xrightarrow{p} M_j^Q \longrightarrow 0 \quad (\text{MRE16})$$

is exact. For $j < -1$, all three spaces are zero. For $-1 \leq j < 1$, it is $0 \rightarrow K \xrightarrow{1} K \rightarrow 0 \rightarrow 0$. For $j \geq 1$, it is MRE9. This exhaustive calculation also proves strictness: the image of the filtered inclusion is exactly $\text{im } i \cap M_j V_2$, and $p(M_j V_2) = M_j^Q$. On associated graded, the inclusion identifies the two degree- -1 spaces, the quotient identifies the two degree- $+1$ spaces, and all other graded spaces vanish.

The relation to the separately centered one-dimensional filtrations is also explicit. Their step -1 is zero, whereas $K \cap M_{-1} V_2 = K$. Therefore the original inclusion with the separately centered filtration is filtration preserving but is not strict. Formula MRE15 supplies the exact shifted subobject and quotient filtrations which restore the strict filtered exact sequence MRE16.

116.5 Added Frobenius and the exact shifted intertwiners

For real $q > 1$, use the additional diagonal operators

$$\Gamma_{q,2} v_0 = q^{1/2} v_0, \quad \Gamma_{q,2} v_1 = q^{-1/2} v_1, \quad F_{q,2} = q^\rho \Gamma_{q,2}. \quad (\text{MRE17})$$

Their induced operators on MRE9 are

$$\begin{aligned} \Gamma_{q,K} &= q^{-1/2} I_K, & F_{q,K} &= q^{\rho-1/2} I_K, \\ \Gamma_{q,Q} &= q^{1/2} I_Q, & F_{q,Q} &= q^{\rho+1/2} I_Q. \end{aligned} \quad (\text{MRE18})$$

Every displayed operator preserves the indicated filtration. Directly on u and $\bar{1}$, the inclusion and quotient satisfy

$$F_{q,2} i = i F_{q,K}, \quad p F_{q,2} = F_{q,Q} p, \quad \Gamma_{q,2} i = i \Gamma_{q,K}, \quad p \Gamma_{q,2} = \Gamma_{q,Q} p. \quad (\text{MRE19})$$

This proves exact filtered intertwining with the unchanged extension maps. If $F_{q,K}^{\text{cen}} = q^\rho I_K$ and $F_{q,Q}^{\text{cen}} = q^\rho I_Q$ are the operators obtained by assigning the one-dimensional spaces their separate centered degree zero, the same equations read

$$F_{q,2} i = q^{-1/2} i F_{q,K}^{\text{cen}}, \quad p F_{q,2} = q^{1/2} F_{q,Q}^{\text{cen}} p. \quad (\text{MRE20})$$

The degree shifts and the scalar factors are therefore exactly the same correction, in filtration and operator form respectively.

The original arithmetic operators are reconstructed without replacing their eigenvalues:

$$\begin{aligned} A_{q,2} &= F_{q,2} \Gamma_{q,2}^{-1} (I + (\log q) N), \\ A_{q,K} &= F_{q,K} \Gamma_{q,K}^{-1} = q^\rho I_K, \\ A_{q,Q} &= F_{q,Q} \Gamma_{q,Q}^{-1} = q^\rho I_Q. \end{aligned} \quad (\text{MRE21})$$

The first line has the displayed multiplication order. In all three lines $F \Gamma^{-1}$ is exactly q^ρ times the identity. Thus the shifted added eigenvalues retain, through these exact formulas, the original arithmetic scalar and its complete nilpotent term.

The added graded moduli are fully determined:

$$2 \log_q |F_{q,K}| = 2 \operatorname{Re} \rho - 1, \quad 2 \log_q |F_{q,Q}| = 2 \operatorname{Re} \rho + 1. \quad (\text{MRE22})$$

Here $|F|$ means the modulus of the displayed one-dimensional eigenvalue. Equation MRE22 records the exact shift; it imposes no restriction on $\operatorname{Re} \rho$.

116.6 The nilpotent link and its Tate-typed isomorphism

Since N vanishes on K and maps V_2 into K , it factors uniquely through the quotient as

$$N = i \bar{N} p, \quad \bar{N} : Q \xrightarrow{\sim} K, \quad \bar{N}(\bar{1}) = u. \quad (\text{MRE23})$$

The factorization follows by applying both sides to $a + bu$, where both sides give au . The factor map is bijective because it sends the specified basis vector to the specified basis vector with coefficient one. It lowers the induced filtration degree by exactly two. It commutes with the original arithmetic scalars and satisfies the exact added-operator relation

$$A_{a,K} \bar{N} = \bar{N} A_{a,Q}, \quad F_{q,K} \bar{N} = q^{-1} \bar{N} F_{q,Q}. \quad (\text{MRE24})$$

The second equality follows from $q^{\rho-1/2} = q^{-1} q^{\rho+1/2}$.

Define the explicit one-dimensional complex character $T_q = \mathbb{C}t$ with its chosen generator t , filtration concentrated in degree -2 , and operators

$$F_{q,T} t = q^{-1} t, \quad \Gamma_{q,T} t = q^{-1} t, \quad A_{a,T} t = t \quad (a > 0). \quad (\text{MRE25})$$

The added eigenvalue is the geometric-Frobenius Tate character. At this stage T_q is the displayed complex filtered line; no arithmetic sheaf realization is required for the following proved matrix map. Give tensor products the sum filtration and tensor product operators. Then $Q \otimes T_q$ is concentrated in degree $1 - 2 = -1$, with added eigenvalue $q^{\rho+1/2} q^{-1} = q^{\rho-1/2}$ and original arithmetic eigenvalue a^ρ . Therefore

$$\nu : Q \otimes T_q \xrightarrow{\sim} K, \quad \nu(\bar{1} \otimes t) = u \quad (\text{MRE26})$$

is a strict filtered isomorphism intertwining F_q , Γ_q , and every A_a . Its inverse sends u to $\bar{1} \otimes t$, so these claims include both inverse maps. Formula MRE26 is the exact Tate-typed form of the original nilpotent link MRE23.

The map N itself has the same strict filtered type. On $V_2 \otimes T_q$, define $\mathcal{N}(v \otimes t) = Nv$. The domain filtration is $M_j(V_2 \otimes T_q) = M_{j+2} V_2 \otimes T_q$. For every j ,

$$N(M_{j+2} V_2) = \text{im } N \cap M_j V_2. \quad (\text{MRE27})$$

For $j < -1$, both sides vanish: the domain step is at most K , which N kills. For $j \geq -1$, the domain step is V_2 , its image is K , and the right side is also K . This proves strictness. The relation $F_{q,2} N F_{q,2}^{-1} = q^{-1} N$, checked on v_0, v_1 , proves F_q -equivariance of $\mathcal{N}$. The corresponding relation for Γ_q proves its equivariance, and $A_{a,2} N = N A_{a,2}$ proves equivariance for every original arithmetic action.

116.7 The explicit relative filtration on this extension

Retain the extension filtration with its two induced constituent degrees:

$$W_j V_2 = \begin{cases} 0 & j < -1, \\ K & -1 \leq j < 1, \\ V_2 & j \geq 1. \end{cases} \quad (\text{MRE28})$$

This is a specified filtered extension, with degree- -1 constituent K and degree- $+1$ constituent Q . Set $R_j V_2 = M_j V_2$, with M as in MRE13. Then $R = W$ as displayed filtrations, and R is the relative nilpotent filtration for this specified W .

Here is the complete verification. Multiplication by u gives $N R_j \subseteq R_{j-2}$. The only nonzero W -graded pieces are $\text{Gr}_{-1}^W V_2 = K$ and $\text{Gr}_1^W V_2 = Q$. The operator induced by N on each of these pieces

is zero. The filtration induced by R on the first piece is concentrated in degree -1 , and on the second in degree $+1$, as proved in MRE14. Consequently, for every integer i and every $k \geq 0$,

$$N^k : \mathrm{Gr}_{i+k}^R \mathrm{Gr}_i^W V_2 \xrightarrow{\sim} \mathrm{Gr}_{i-k}^R \mathrm{Gr}_i^W V_2. \quad (\text{MRE29})$$

For $k = 0$, this is the identity. For $k > 0$, both source and target are zero, including when $i = -1$ or $i = 1$. For other i , the W -graded piece is itself zero. This proves every case of the relative-filtration identities.

In this two-dimensional extension uniqueness can also be proved directly. Any relative filtration R' induces the degree- -1 one-step filtration on K , and the degree- $+1$ one-step filtration on Q , because the induced nilpotent on each is zero and the relative graded isomorphisms force all other degrees to vanish. If $j < -1$, then $R'_j \cap K = 0$ and its image in Q is zero, so $R'_j = 0$. If $-1 \leq j < 1$, it contains K and its image in Q is zero, so $R'_j = K$. If $j \geq 1$, it contains K and surjects onto Q , so it equals V_2 . Thus $R' = R$, with every step determined.

This proves a relative filtration on the displayed original extension. Its additional eigenvalue shifts are MRE18 and MRE22. The proof assigns no independent geometric purity assertion to these constituents.

116.8 The original extension class is retained

Every linear section $s : Q \rightarrow V_2$ of p has the form

$$s(\bar{1}) = 1 + cu \quad (c \in \mathbb{C}). \quad (\text{MRE30})$$

For each such section,

$$Ns(\bar{1}) = u, \quad sN_Q(\bar{1}) = 0. \quad (\text{MRE31})$$

Hence no section intertwines the nilpotent operators: MRE9 is a non-split extension of nilpotent representations. The fixed nonzero map $\bar{N}$ of MRE23 records its extension coupling, and the Tate-typed isomorphism MRE26 retains that same coefficient-one coupling.

The arithmetic non-splitting is equally explicit. For every $a > 0$,

$$(A_{a,2}s - sA_{a,Q})(\bar{1}) = a^\rho(\log a)u. \quad (\text{MRE32})$$

The scalar is nonzero when $a \neq 1$, because $a^\rho \neq 0$ and $\log a \neq 0$. Thus no section intertwines even one fixed original arithmetic operator with $a \neq 1$, and no section intertwines the whole arithmetic family. The strict filtered exact sequence has therefore preserved the complete original arithmetic extension.

For the added diagonal operator alone, $s_0(\bar{1}) = 1$ is a filtered F_q -equivariant section. It is the only such section: equivariance for MRE30 forces $cq^{\rho-1/2} = cq^{\rho+1/2}$, and $q > 1$ forces $c = 0$. Equations MRE31–MRE32 calculate precisely how this additional diagonal splitting fails to split the original nilpotent and arithmetic actions. All three operator structures, their maps, and their difference are explicit on the original basis.

Their interaction also has an exact formula. Conjugating MRE10 gives

$$F_{q,2}A_{a,2}F_{q,2}^{-1} = a^\rho(I + q^{-1}(\log a)N), \quad F_{q,2}A_{a,2}F_{q,2}^{-1} - A_{a,2} = a^\rho(q^{-1} - 1)(\log a)N. \quad (\text{MRE33})$$

Every coefficient follows from $F_{q,2}NF_{q,2}^{-1} = q^{-1}N$. For $a \neq 1$, the last operator is nonzero, so the two retained actions do not commute. Equation MRE33 records their full interaction; no commuting-action assumption has been used in the filtered exact sequence or its twisted nilpotent maps.

116.9 Transport from the full original packet to its actual quotient

We give the exact downstream comparison, including the subobject, quotient, and all operators. In the original packet MW1 let $Z_{\geq 2} = \{\rho \in Z : m_\rho \geq 2\}$. The following construction is indexed by this subset and makes no assertion that it is nonempty. For each $\rho \in Z_{\geq 2}$ write $m = m_\rho$, $b = m - 2$, and retain the original $v_{\rho,r} = e_\rho(x - \rho)^r$. Define

$$\begin{aligned} J_\rho &= \text{span}\{v_{\rho,r} : 2 \leq r < m\}, \quad C_\rho = E_\rho/J_\rho, \quad \pi_\rho \left(\sum_{r=0}^{m-1} c_r v_{\rho,r} \right) = c_0 w_0 + c_1 w_1, \\ K_\rho &= \mathbb{C}w_1, \quad Q_\rho = C_\rho/K_\rho, \quad i_\rho(cw_1) = cw_1, \quad p_\rho(c_0 w_0 + c_1 w_1) = c_0[w_0], \\ \phi_\rho &: C_\rho \longrightarrow V_2, \quad \phi_\rho(c_0 w_0 + c_1 w_1) = c_0 + c_1 u. \end{aligned} \tag{MRE34}$$

Here $w_r = \pi_\rho(v_{\rho,r})$, $r = 0, 1$, and the coordinate $u = x - \rho$ is fixed as in MRE7. Multiplication of original powers shows that $J_\rho = u_\rho^2 E_\rho$ is an ideal and that w_0 is the quotient unit with $w_1^2 = 0$. The map ϕ_ρ is an algebra isomorphism: its inverse sends $c_0 + c_1 u$ to $c_0 w_0 + c_1 w_1$, and the multiplication rules on the two indicated bases agree. The maps i_ρ, p_ρ give an exact sequence, since i_ρ is injective, p_ρ is surjective, and $\ker p_\rho = \text{im } i_\rho = K_\rho$.

The filtration on C_ρ is the quotient of the full original MW3 filtration. Its two degrees are retained explicitly:

$$\begin{aligned} \overline{M}_j C_\rho &= \pi_\rho(M_j E_\rho) = \begin{cases} 0 & j < b - 1, \\ K_\rho & b - 1 \leq j < b + 1, \\ C_\rho & j \geq b + 1, \end{cases} \quad \phi_\rho(\overline{M}_j C_\rho) = M_{j-b} V_2, \\ \overline{M}_j K_\rho &= K_\rho \cap \overline{M}_j C_\rho = \begin{cases} 0 & j < b - 1, \\ K_\rho & j \geq b - 1, \end{cases} \quad \overline{M}_j Q_\rho = p_\rho(\overline{M}_j C_\rho) = \begin{cases} 0 & j < b + 1, \\ Q_\rho & j \geq b + 1, \end{cases} \\ 0 &\longrightarrow \overline{M}_j K_\rho \xrightarrow{i_\rho} \overline{M}_j C_\rho \xrightarrow{p_\rho} \overline{M}_j Q_\rho \longrightarrow 0. \end{aligned} \tag{MRE35}$$

Only the exponents zero and one survive π_ρ ; MW3 places them in degrees $m - 1 = b + 1$ and $m - 3 = b - 1$. This proves the first line and, by intersection and image, the second. The last line is zero in every position for $j < b - 1$; for $b - 1 \leq j < b + 1$, its only nonzero map is the identity on K_ρ ; for $j \geq b + 1$, it is the full exact sequence just proved. These three cases prove exactness and strictness. In terms of the separately centered degree-zero line filtrations C_j , the actual shifts are $\overline{M}_j K_\rho = C_{j-b+1} K_\rho$ and $\overline{M}_j Q_\rho = C_{j-b-1} Q_\rho$. The same coordinate calculation proves that $0 \rightarrow J_\rho \cap M_j E_\rho \rightarrow M_j E_\rho \xrightarrow{\pi_\rho} \overline{M}_j C_\rho \rightarrow 0$ is exact: its kernel is the displayed intersection and its image is the defined quotient step. Thus the map from the actual packet is strict before the subobject/quotient extension is formed.

All retained operators preserve J_ρ : the nilpotent raises exponents, each term of the original finite exponential raises exponents, and the added diagonals preserve every original basis line. Denote their induced operators on C_ρ by bars. Their entire formulas and their restriction and quotient values are

$$\begin{aligned} \overline{N}w_0 &= w_1, \quad \overline{N}w_1 = 0, \quad \overline{A}_a(c_0 w_0 + c_1 w_1) = a^\rho(c_0 w_0 + (c_1 + c_0 \log a)w_1), \\ \overline{\Gamma}_q w_r &= q^{(b+1)/2-r} w_r, \quad \overline{F}_q w_r = q^{\rho+(b+1)/2-r} w_r \quad (r = 0, 1), \\ \begin{array}{c|ccc} & A_a & \Gamma_q & F_q \\ \hline K_\rho & a^\rho I & q^{(b-1)/2} I & q^{\rho+(b-1)/2} I \\ Q_\rho & a^\rho I & q^{(b+1)/2} I & q^{\rho+(b+1)/2} I \end{array} \\ \overline{A}_q &= \overline{F}_q \overline{\Gamma}_q^{-1} (I + (\log q) \overline{N}), \\ 2 \log_q |F_{q,K_\rho}| &= 2 \text{Re } \rho + b - 1, \quad 2 \log_q |F_{q,Q_\rho}| = 2 \text{Re } \rho + b + 1. \end{aligned} \tag{MRE36}$$

In the full source exponential, terms with nilpotent power at least two have image in J_ρ ; applying π_ρ to each term therefore proves the first line with exactly its coefficient $a^\rho \log a$. The source diagonal

exponents are $(m-1)/2 - r = (b+1)/2 - r$, proving the second line. Restriction to w_1 and passage to $[w_0]$ prove the table. For each $O = A_a, \Gamma_q, F_q$, applying to w_1 proves $\overline{O}i_\rho = i_\rho O_{K_\rho}$, and applying to both w_0, w_1 proves $p_\rho \overline{O} = O_{Q_\rho} p_\rho$. For the nilpotent these maps intertwine its zero restriction and quotient. The product $\overline{F}_q \overline{\Gamma}_q^{-1}$ is $q^\rho I$, proving reconstruction in the displayed order. The two real logarithms follow from $|q^{\rho+c}| = q^{\operatorname{Re} \rho + c}$ for real c .

For a precise filtered comparison of entire exact sequences, take the line $D_b = \mathbb{C}d_b$ concentrated in degree b , with $N_{D_b} = 0$, $A_{a,D_b} = I$, and $\Gamma_{q,D_b} = F_{q,D_b} = q^{b/2}I$. This is a specified complex filtered line for every integer $b = m-2$; its definition does not assert a geometric realization. Give tensors sum filtrations, tensor-sum nilpotents, and tensor-product invertible operators. The comparison maps are

$$\begin{aligned} \theta_C : C_\rho &\xrightarrow{\sim} V_2 \otimes D_b, & w_0 &\mapsto 1 \otimes d_b, & w_1 &\mapsto u \otimes d_b, \\ \theta_K : K_\rho &\xrightarrow{\sim} K \otimes D_b, & w_1 &\mapsto u \otimes d_b, & \theta_Q : Q_\rho &\xrightarrow{\sim} Q \otimes D_b, & [w_0] &\mapsto \overline{1} \otimes d_b, \\ \theta_C i_\rho &= (i \otimes I) \theta_K, & (p \otimes I) \theta_C &= \theta_Q p_\rho, \\ \phi_\rho \overline{A}_a &= A_{a,2} \phi_\rho, & \phi_\rho \overline{\Gamma}_q &= q^{b/2} \Gamma_{q,2} \phi_\rho, & \phi_\rho \overline{F}_q &= q^{b/2} F_{q,2} \phi_\rho. \end{aligned} \quad (\text{MRE37})$$

The inverse maps send the displayed target basis vectors to their displayed sources. The filtration step on each tensor is the original MRE13–MRE14 step at $j-b$, tensored with D_b . Equation MRE35 therefore proves strictness in both directions for each comparison map. The two diagram equations hold on w_1 and on w_0, w_1 , respectively, proving commutativity of the whole exact-sequence comparison. The last three equations follow by applying both sides to w_0, w_1 , using MRE17 and MRE36. The same calculation intertwines the nilpotents with coefficient one. Thus all maps in the sequence are intertwined by the specified θ 's for N, A, Γ, F . For $m=2, b=0$ and these are exactly the fixed length-two maps. For $m>2$, ϕ_ρ with separately centered target filtration is filtration preserving because $j-b \leq j$, but non-strict: at $j=1$ its image of $\overline{M}_1 C_\rho$ omits 1, whereas $M_1 V_2 = V_2$. The scalar $q^{b/2}$ in both added operators and the degree shift b are retained in MRE37.

The actual nilpotent link is

$$\begin{aligned} \overline{N} &= i_\rho \eta_\rho p_\rho, & \eta_\rho : Q_\rho &\xrightarrow{\sim} K_\rho, & \eta_\rho([w_0]) &= w_1, \\ \nu_\rho : Q_\rho \otimes T_q &\xrightarrow{\sim} K_\rho, & \nu_\rho([w_0] \otimes t) &= w_1, \\ F_{q,K_\rho} \eta_\rho &= q^{-1} \eta_\rho F_{q,Q_\rho}, & \Gamma_{q,K_\rho} \eta_\rho &= q^{-1} \eta_\rho \Gamma_{q,Q_\rho}, & A_{a,K_\rho} \eta_\rho &= \eta_\rho A_{a,Q_\rho}. \end{aligned} \quad (\text{MRE38})$$

Here T_q is exactly MRE25, with degree -2 , both added scalars q^{-1} , and arithmetic scalar one. Applying the factorization to $c_0 w_0 + c_1 w_1$ gives $c_0 w_1$ on both sides. In ν_ρ , the domain and target both have degree $(b+1)-2 = b-1$, added F -eigenvalue $q^{\rho+(b+1)/2} q^{-1} = q^{\rho+(b-1)/2}$, and the analogous Γ -eigenvalue with ρ omitted. Their original arithmetic eigenvalues are both a^ρ . Its inverse is $w_1 \mapsto [w_0] \otimes t$. These computations prove strict filtered equivariance, its inverse, and all three identities in the last line. The comparison with MRE26 sends $(\overline{1} \otimes d_b) \otimes t$ to $(\overline{1} \otimes t) \otimes d_b$ and then to $u \otimes d_b$; the specified tensor rearrangement has coefficient one, so this is exactly $\theta_K \nu_\rho$.

The whole quotient has the corresponding strict map

$$\begin{aligned} \mathcal{N}_\rho : C_\rho \otimes T_q &\longrightarrow C_\rho, & z \otimes t &\longmapsto \overline{N} z, \\ \overline{N}(\overline{M}_{j+2} C_\rho) &= K_\rho \cap \overline{M}_j C_\rho, & \pi_\rho \mathcal{N}_{E_\rho} &= \mathcal{N}_\rho(\pi_\rho \otimes I), & \mathcal{N}_{E_\rho}(v \otimes t) &= N_\rho v. \end{aligned} \quad (\text{MRE39})$$

For $j < b-1$, the domain step in the middle equality is at most K_ρ , which $\overline{N}$ kills, and the right side is zero. For $j \geq b-1$, that domain step is C_ρ , its image is K_ρ , and the right side is K_ρ . This proves strictness at every integer. The quotient diagonal entries give $\overline{F}_q \overline{N} \overline{F}_q^{-1} = q^{-1} \overline{N}$ and the identical relation for $\overline{\Gamma}_q$; the full arithmetic formula gives $\overline{A}_a \overline{N} = \overline{N} \overline{A}_a$. These prove equivariance with the three operators on the Tate line. The last equality follows on $v \otimes t$ from the already proved identity $\pi_\rho N_\rho = \overline{N} \pi_\rho$.

The relative-filtration comparison shifts both filtrations of MRE28–MRE29. Define

$$\begin{aligned} W_i^{(\rho)} C_\rho &= \phi_\rho^{-1}(W_{i-b} V_2), & R_j^{(\rho)} C_\rho &= \phi_\rho^{-1}(R_{j-b} V_2), & W^{(\rho)} &= R^{(\rho)} = \overline{M}, \\ \overline{N}^k : \mathrm{Gr}_{i+k}^{R^{(\rho)}} \mathrm{Gr}_i^{W^{(\rho)}} C_\rho &\xrightarrow{\sim} \mathrm{Gr}_{i-k}^{R^{(\rho)}} \mathrm{Gr}_i^{W^{(\rho)}} C_\rho \quad (i \in \mathbb{Z}, k \geq 0). \end{aligned} \quad (\text{MRE40})$$

Multiplication by the local coordinate lowers the displayed degree by two. The only nonzero $W^{(\rho)}$ -graded spaces are K_ρ in degree $b-1$ and Q_ρ in degree $b+1$. The induced nilpotents on them are zero, and the induced $R^{(\rho)}$ -filtrations are concentrated in their respective degrees by MRE35. Thus for $k=0$ the displayed map is the identity, and for $k>0$ both spaces are zero. The comparison ϕ_ρ identifies each iterated graded space with $\mathrm{Gr}_{i-b\pm k}^R \mathrm{Gr}_{i-b}^W V_2$; hence these are exactly the MRE29 maps with i replaced by $i-b$. Any other relative filtration must induce degree $b-1$ on K_ρ and degree $b+1$ on Q_ρ , because for a zero nilpotent the relative isomorphisms force all other graded pieces to vanish. Below $b-1$ its intersection with K_ρ and image in Q_ρ are zero, so the step is zero. Between $b-1$ and $b+1$ it contains K_ρ with zero quotient image, so it equals K_ρ . From $b+1$ onward it contains K_ρ and surjects onto Q_ρ , so it equals C_ρ . This proves uniqueness with all induced degrees intact. The displayed $W^{(\rho)}$ is also the quotient of the specified full-block filtration $W_j^{\text{full}} E_\rho = M_j E_\rho$, since its quotient steps are MRE35. This is the specified filtration on the original coefficient packet, with its exact quotient map. For the separately specified one-step filtration on C_ρ concentrated in degree b , MRE5–MRE6 likewise identify $\overline{M}$ as its relative filtration: the only distance-one map sends $[w_0]$ to $[w_1]$ with coefficient one, distance zero gives the identity, and every distance at least two has both graded spaces zero.

The extension discrepancies also survive without any factor change. Every linear section $s_c : Q_\rho \rightarrow C_\rho$ of p_ρ sends $[w_0]$ to $w_0 + cw_1$. Direct substitution gives

$$\begin{aligned} (\overline{N} s_c - s_c N_{Q_\rho})([w_0]) &= w_1, & (\overline{A}_a s_c - s_c A_{a, Q_\rho})([w_0]) &= a^\rho (\log a) w_1, \\ (\overline{F}_q s_c - s_c F_{q, Q_\rho})([w_0]) &= c(q^{\rho+(b-1)/2} - q^{\rho+(b+1)/2}) w_1, \\ \overline{F}_q \overline{A}_a \overline{F}_q^{-1} - \overline{A}_a &= a^\rho (q^{-1} - 1) (\log a) \overline{N}. \end{aligned} \quad (\text{MRE41})$$

The first two differences are independent of c ; the second is nonzero for $a \neq 1$. Thus no section splits either the nilpotent or an original arithmetic operator with $a \neq 1$. The third difference vanishes only for $c=0$, since its parenthesized factor is $q^{\rho+(b-1)/2}(1-q) \neq 0$. The section s_0 preserves the filtration because its only source degree is $b+1$, when the target is already the full space. It therefore gives exactly the added diagonal splitting. Conjugating the full arithmetic formula in MRE36 by $\overline{F}_q$ and using its q^{-1} nilpotent relation proves the last line with its unchanged scalar. These are the transported MRE30–MRE33 calculations on the actual quotient.

Finally the transport is compatible with every independent slot and with the combined operator of MW9a. For an admissible odd prime power q coprime to n , extend π_ρ linearly to the coefficient algebra and put $\overline{T}_{a,q} = \overline{A}_a \Psi_q$. On the fixed bases,

$$\begin{aligned} \overline{T}_{a,q}(w_r t^i) &= (-1)^{\lfloor qi/n \rfloor} a^\rho \sum_{\ell=0}^{1-r} \frac{(\log a)^\ell}{\ell!} w_{r+\ell} t^{qi \bmod n}, \quad r=0,1, \\ \pi_\rho T_{a,q} &= \overline{T}_{a,q} \pi_\rho, & \bigotimes_{\nu} \theta_{C, \rho_\nu} : \bigotimes_{\nu} C_{\rho_\nu} &\xrightarrow{\sim} \left(\bigotimes_{\nu} V_{2, \rho_\nu} \right) \otimes \left(\bigotimes_{\nu} D_{b_\nu} \right), \\ b_\nu &= m_{\rho_\nu} - 2, & \text{degree translation } \sum_{\nu} b_\nu, & \text{added } F, \Gamma \text{ factor } q^{\frac{1}{2} \sum_{\nu} b_\nu}. \end{aligned} \quad (\text{MRE42})$$

Linearity of π_ρ preserves the displayed sign, and applying it to the full source finite Taylor sum keeps exactly the terms shown. This proves both the first line and the intertwining identity. On a face the map retains the mask and sends each coefficient to its quotient; a vanished coefficient remains the zero of that same present slot. Zero insertion commutes with π_ρ , since it is linear. For the tensor

comparison, send each displayed original tensor basis vector to $(\bigotimes_{\nu} u^{r_{\nu}}) \otimes (\bigotimes_{\nu} d_{b_{\nu}})$, with the inverse prescribed by the same basis pairs. Every filtration degree is translated by the sum $\sum_{\nu} b_{\nu}$, and both added diagonal factors multiply to $q^{\frac{1}{2} \sum_{\nu} b_{\nu}}$. This proves strictness and operator compatibility of this full tensor isomorphism. On coefficient eigenspaces with eigenvalues ω_{ν} , the original arithmetic graded eigenvalue is $a^{\sum_{\nu} \rho_{\nu}}$, the coefficient eigenvalue is $\prod_{\nu} \omega_{\nu}$, and their combined eigenvalue is $(\prod_{\nu} \omega_{\nu}) a^{\sum_{\nu} \rho_{\nu}}$, exactly as in MW16b. Positive nilpotent powers lower total degree by two per power, so none changes these graded eigenvalues; every such power is still retained in the exact tensor formula MW16a.

Proved control and continuing scope. The calculation constructs the strict filtered exact sequence on the length-two arithmetic extension, its exact shifted added eigenvalues, the Tate-typed nilpotent isomorphism, and its relative filtration. Every original arithmetic scalar and nilpotent coefficient survives. These results supply this local extension control within the program. MRE34–MRE42 supply its strict comparison with every specified actual length-two packet quotient, including the original induced degree translation, both added diagonal factors, and the full arithmetic and coefficient operators. The arbitrary parameter calculation MRE7–MRE33 makes no zero-multiplicity assertion. They do not determine $2 \operatorname{Re} \rho$, establish a pure lisse source, or supply the analytic upper estimate used in Weil II 1.8.1. Those numerical and geometric controls remain separate constructions to be carried out on the original arithmetic sources.

117 The same arithmetic discrepancy in the mixed filtration and the source boundary

The following calculation connects the independent mixed faces, the nilpotent filtration and the original phase observation on the same arithmetic class. All maps used here are constructed in the preceding attachments; this section computes their composite on the full packet.

Fix an actual zero $\rho = 1/2 + \delta + i\gamma$ in the open strip, with $0 < \delta < 1/2$ and $\gamma > 0$, its full order m , and a full packet h containing it. The other offcritical quadrants map to this quadrant by the original reflection and conjugation arrows of (CAU.30)–(CAU.32), retaining their full local jets. Retain the original CRT idempotent and terminal jet

$$v_{\rho} = e_{\rho}(s - \rho)^{m-1} \in E_h, \quad u_{\rho} = \sigma_h v_{\rho} \in T_U Q, \quad 0 < \delta < 1/2, \quad \gamma > 0. \quad (\text{MAI1})$$

The coefficient of $(s - \rho)^{m-1}$ in this local jet is one; therefore $v_{\rho} \neq 0$. The full-unit section satisfies $J_h s_h = 1$, so σ_h is injective and $u_{\rho} \neq 0$. The nilpotent kills v_{ρ} , and the full original exponential therefore gives

$$A_a v_{\rho} = a^{\rho} v_{\rho}, \quad \overline{\mathcal{R}}_a u_{\rho} = a^{\rho} u_{\rho} \quad (a > 0). \quad (\text{MAI2})$$

The second identity uses the actual theta-boundary homotopy, not an equivariance assertion for the section before quotienting.

For $n \geq 1$, in the coefficient algebra $B_{h,n} = E_h[t]/(t^n + 1)$, the original insertion and trace retraction satisfy

$$E_h \xrightarrow{\iota_n} B_{h,n} \xrightarrow{r_n} E_h, \quad r_n \iota_n = 1, \quad \Psi_{q_0} \iota_n = \iota_n, \quad r_n \Psi_{q_0} = r_n. \quad (\text{MAI3})$$

Here q_0 is an odd prime power coprime to n , and r_n is $1/n$ times the trace of multiplication. The complete coefficient computation is $r_n(\sum b_i t^i) = b_0$. Thus $\iota_n v_{\rho}$ is nonzero, fixed by coefficient Frobenius, and has arithmetic eigenvalue a^{ρ} . It is represented on the unsynchronized face $\{0\}$ by its supported constant coefficient and absent remaining slots. Synchronization also observes it on the full face. Both vertices and their connecting arrow are retained; (MAI3) identifies their unchanged arithmetic amplitude.

Tensor each of these maps over $\mathbb{C}$ on its amplitude spaces. To prove nonvanishing explicitly, choose a linear functional ℓ with $\ell(v_\rho) = 1$. Then $\ell^{\otimes k}(v_\rho^{\otimes k}) = 1$; similarly the tensor retraction $r_n^{\otimes k}$ carries $(\iota_n v_\rho)^{\otimes k}$ to $v_\rho^{\otimes k}$. The injective original cohomology map carries the latter to $u_\rho^{\otimes k} \neq 0$. These tensor arrows retain the ordered tuple of coefficient-face labels. Their arithmetic eigenvalue is $a^{k\rho}$, and hence

$$\log\left(\frac{|a^{k\rho}|^2}{a^k}\right) = 2k\delta \log a. \quad (\text{MAI4})$$

Now retain the entire tensor of the original length- m local blocks, not only this terminal line. In the original jet basis write $N_{\text{tot}} = \sum_{\nu=1}^k N_\nu$ and use the filtration proved in (MW15). On every nonzero graded piece Gr_j^M the added Tate-scaling operator $F_q^{\otimes k}$, for real $q > 1$, acts by $q^{k\rho+j/2}$. Indeed on a basis tensor of indices $j_1, \dots, j_k$ its scalar is the product $\prod_\nu q^{\rho+j_\nu/2}$, and their sum is j . The coefficient operator on a retained eigenspace contributes a root of unity ω . Every eigenvalue on that graded eigenspace is therefore

$$\lambda_{k,j,\omega} = \omega q^{k\rho+j/2}, \quad 2\log_q |\lambda_{k,j,\omega}| - (k+j) = 2k\delta. \quad (\text{MAI5})$$

The equality uses $|\omega| = 1$ and the original real logarithm of q . It holds for every chosen nonzero graded piece, including $j = 0$. For the tensor of the terminal lines in (MAI1), the index is exactly $j = -k(m-1)$ and $\omega = 1$. Thus this computation includes a specified nonzero line in the arithmetic retract.

The exact reconstruction from (MW19) also tensors without commuting operators in an unproved order:

$$A_q^{\otimes k} = F_q^{\otimes k} (\Gamma_q^{-1})^{\otimes k} \exp((\log q) N_{\text{tot}}). \quad (\text{MAI6})$$

Each tensor factor has that ordered identity. Operators in different factors commute, so multiplying their finite exponentials gives the displayed sum in the exponent. On the graded piece, the exponential induces the identity and $(\Gamma_q^{-1})^{\otimes k}$ contributes $q^{-j/2}$. The resulting arithmetic eigenvalue is exactly $q^{k\rho}$. This proves the map between the added Tate-scaling observation and the original arithmetic action, including every nilpotent term. Integer monodromy indices alone do not change its real exponent.

For its original source-norm observation, take the reflected quartet packet h_0 of (PAM.1), with $\delta > 0$, and the complete cyclic tensor factor of (PAM.2)–(PAM.5). Its nonzero terminal eigenvector v_k has eigenvalue $k\rho$. Its exact relation to the tensor in (MAI4) includes a nonzero scalar. Put $K = k(m-1)$. The extreme tensor centre $k\rho$ can arise only by choosing ρ in every factor of that quartet. On this block, the multinomial expansion gives $(N_1 + \dots + N_k)^K = K! / ((m-1)!)^k \prod_\nu N_\nu^{m-1}$. Every other term vanishes because some exponent is at least m . The complete unit of (PAM.3) acts on this terminal monomial by its nonzero scalar value. Consequently

$$\eta_k v_k = c_{h_0,k} v_\rho^{\otimes k}, \quad \mathcal{I}_k v_k = c_{h_0,k} u_\rho^{\otimes k}, \quad c_{h_0,k} = \frac{(k(m-1))!}{((m-1)!)^k} ((g/h_0)(\rho))^k \neq 0. \quad (\text{MAI6a})$$

Here v_ρ in the first equality is taken in E_{h_0} . If the initially chosen h differs from h_0 , use the common full packet $H = \text{lcm}(h, h_0)$. Both terminal jets have the same image in E_H , and the literal identities $\sigma_H \iota_h H = \sigma_h$ and $\sigma_H \iota_{h_0} H = \sigma_{h_0}$ identify their original arithmetic classes. This proves the second equality with the original u_ρ of (MAI1), retaining the entire coefficient. For this phase observation take $k \geq 2$, $L > 0$, $0 \leq \theta < 2\pi$, and an admitted polynomial cutoff $N \geq q_k - 1$, with $q_k = (1 + k(m-1))(k+1)^2$. Write $R_k = R_{N,\theta}$ for the canonical lift on this specified source of (PAM.9)–(PAM.13). The source lift $R_k v_k$ is nonzero because its original cohomology observation is injective. With the exact twisted phase domain and its generator $D_{L,\theta} = -\partial_r + k/2$, let

$$B_k = D_{L,\theta} R_k - R_k A_k. \quad (\text{MAI7})$$

Every term belongs to its proved domain. Put $f = R_k v_k$. The spectral expansion of the skew-adjoint derivative on that domain gives frequencies $u_n = (2\pi n + \theta)/L$ and

$$\frac{\|B_k v_k\|^2}{\|R_k v_k\|^2} = k^2 \delta^2 + \frac{\sum_n (u_n - k\gamma)^2 \|f_n\|^2}{\sum_n \|f_n\|^2} \geq k^2 \delta^2. \quad (\text{MAI8})$$

To verify the equality, apply $D_{L,\theta} - k\rho$ to each orthogonal frequency component. Its multiplier is $-k\delta + i(u_n - k\gamma)$, whose squared modulus is $k^2 \delta^2 + (u_n - k\gamma)^2$. Parseval and the domain condition justify both sums. The denominator is positive because $f \neq 0$.

Equations (MAI4), (MAI5) and (MAI8) are thus connected observations of the same original arithmetic displacement. The first follows through the coefficient-pure retract; the second computes it after the complete monodromy grading; the third measures its necessary original theta-boundary energy. In particular the fully evaluated phase calculation does not erase it: at the first cutoff the boundary is the nonzero residue map of (PSC.50)–(PSC.64), even when the two section gluing maps agree. The arithmetic four-window identities in (AAM.19)–(AAM.30) retain that same boundary scale and all its inverse Gram factors.

Deligne's final strict-weight exclusion in Weil II applies to geometric constituents whose integer weights and strict upper bound have both been proved: the complete calculation is recorded in the following dyadic-bootstrap chapter. In (MAI5) the integer j has been computed, whereas the central real weight is the unchanged $2\Re\rho$. Calling that central weight one would replace the explicitly computed scalar rather than deduce its value. The present calculation identifies its exact location in the assembled mixed object and in the original boundary operator; it proves no disappearance of the marked cohomology $T_U Q$.

Abstract

For the original monic packet polynomial, retaining all selected zero multiplicities, we calculate the missing u -connection of its polynomial exponential complex in the original monomial lattice. The connection has an explicit second-order coefficient, a first-order coefficient of trace $d/2$, and a degree-correct chain realization. We calculate its full tensor version and the exact period determinant, including its gamma factors and ordered contour phase. We also apply Deligne's lissity and local-monodromy theorems to the actual finite-field family on $u \neq 0$, obtaining a genuine mixed boundary extension there. The original theta source, its Taylor unit, and its metric enter through explicit maps. The exact single-primary branch now includes its full period matrix, boundary monodromy, finite cover, source-unit maps and finite-field character decomposition through every ordered tensor degree, together with the exact original coefficient lattice and its specialization maps. The general multi-primary sector transitions and original arithmetic uniform four-volume estimate remain continuing calculations on the retained objects.

118 Fixed objects and original source maps

Let Z be the original nonempty finite set of selected zeros of $g = 2\xi$, with the complete selected orders m_ρ , and put

$$h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho} = s^d + \sum_{b=0}^{d-1} h_b s^b, \quad d = \sum_{\rho \in Z} m_\rho \geq 1. \quad (1)$$

The primitive and its constant are fixed as

$$\Phi_h(s) = \frac{s^{d+1}}{d+1} + \sum_{b=0}^{d-1} \frac{h_b s^{b+1}}{b+1}, \quad \Phi_h(0) = 0, \quad f_t(s) = \Phi_h(s) - ts. \quad (2)$$

Retain the original source spaces, Fourier convention, and operators

$$\begin{aligned} V &= \{\phi \in \mathcal{S}(\mathbb{R})_{\text{ev}} : \phi(0) = 0, \int_{\mathbb{R}} \phi = 0\}, \\ \mathcal{B} &= \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^m F(x)| < \infty \text{ for all } b \in \mathbb{Z}, m \geq 0\}, \\ D &= -x\partial_x, \quad \Theta\phi(x) = 2 \sum_{n \geq 1} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}, \\ \widehat{\phi}(\xi) &= \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx. \end{aligned} \quad (3)$$

The seed is

$$\phi_* = (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2}, \quad \mathcal{M}\Theta\phi_* = g. \quad (4)$$

The inherited Euler inverses supply the original $F_h \in \mathcal{B}$ with $\mathcal{M}F_h = v_h = g/h$. Define

$$E_h = \mathbb{C}[s]/h, \quad A_h = M_s, \quad v_h = j_h v_h \in E_h^\times, \quad \alpha_h(P) = P(D)\phi_*, \quad \mathcal{T}_h(P) = P(D)F_h. \quad (5)$$

The original identities are

$$\Theta\alpha_h(P) = \mathcal{T}_h(hP), \quad J_h \mathcal{T}_h(P) = v_h[P]_h. \quad (6)$$

Thus $[\mathbb{C}[s] \xrightarrow{h} \mathbb{C}[s]ds]$ maps to $[V \xrightarrow{\Theta} \mathcal{B}]$ by $(\alpha_h, \mathcal{T}_h)$. Its degree-one map is exactly $\sigma_h M_{v_h}$ into $Q = \mathcal{B}/\Theta V$. The linear source section is not asserted to be a ring homomorphism. Tensoring these chain maps preserves the full factor $v_h^{\otimes k}$ and the original ordered exterior signs.

119 The full lattice and its marked fibre

For $R_k = \mathbb{C}[u, t_1, \dots, t_k]$ set

$$\mathcal{C}_k^j = R_k[s_1, \dots, s_k] \otimes \bigwedge^j (ds_1, \dots, ds_k), \quad \mathcal{D} = \sum_{i=1}^k L_i ds_i \wedge (-), \quad L_i = u\partial_{s_i} + h(s_i) - t_i. \quad (7)$$

The L_i commute, so the exterior signs give $\mathcal{D}^2 = 0$.

Proposition 119.1 (The original complete lattice). *The complex (7) has cohomology only in degree k , with*

$$\mathcal{H}_k := H^k(\mathcal{C}_k) = \bigoplus_{0 \leq a_i < d} R_k[s_1^{a_1} \cdots s_k^{a_k} ds_1 \wedge \cdots \wedge ds_k]. \quad (8)$$

Specialization at $u = t_1 = \cdots = t_k = 0$ identifies this displayed module with $E_h^{\otimes k}$, retaining every primary jet.

Proof. In one factor $L = u\partial_s + h - t$ increases the degree of a nonzero polynomial by exactly d and retains its leading coefficient. Consequently L is injective. Subtracting $L(as^j)$ at each highest degree gives a remainder of degree below d . A polynomial of degree below d in the image of L must be zero by the same degree identity. This proves the direct module decomposition

$$R[s] = L(R[s]) \oplus R[s]_{<d}, \quad R = \mathbb{C}[u, t].$$

The inverse of L on its image is R -linear and contracts the image two-term complex. Tensor the direct decompositions in the specified factor order. Every tensor summand with a contractible factor contracts by that factor's homotopy with the sign contributed by preceding degrees; the cross terms cancel by the tensor differential rule. Only the top remainder summand remains. The splitting is over R_k , so it remains a splitting after the stated coefficient specialization. $\square$

The family is a literal deformation of the original finite polynomial source images: with $V_* = \alpha_h(\mathbb{C}[s])$ and $\mathcal{B}_h = \mathcal{T}_h(\mathbb{C}[s])$, its one-factor differential is

$$d_{u,t}^\theta = \Theta|_{V_*} + u\mathcal{T}_h\partial_s\alpha_h^{-1} - t\mathcal{T}_h\alpha_h^{-1}. \quad (9)$$

The inverse maps here are defined on the displayed injective images. Equation (6) gives $d_{u,t}^\theta\alpha_h = \mathcal{T}_h L$. The derivative term is also the original function-space commutator

$$\mathcal{T}_h(P') = (\log x)P(D)F_h - P(D)((\log x)F_h),$$

because $[\log x, D] = 1$. In Mellin coordinates this subtraction retains and cancels the two equal $v_h'P$ terms, leaving $v_h P'$.

If χ is the minimal polynomial of $S = \sum_i s_i$ on $E_h^{\otimes k}$, the weighted cyclic injection is

$$\eta : \mathbb{C}[S]/\chi \hookrightarrow E_h^{\otimes k}, \quad \eta[P] = v_h^{\otimes k} P\left(\sum_i s_i\right)1. \quad (10)$$

For fixed-order monic division $\chi(S)P(S) = \sum_i h(s_i)Q_i(\mathbf{s})$, the ordered primitive $\sum_i (-1)^{i-1} Q_i ds_1 \wedge \cdots \widehat{ds_i} \cdots \wedge ds_k$ has image $\sum_i (h_i Q_i - t_i Q_i + u \partial_i Q_i)$. It follows that

$$[\chi(S)P(S)]_{\mathcal{H}_k} = \sum_i [t_i Q_i - u \partial_{s_i} Q_i]_{\mathcal{H}_k}. \quad (11)$$

The quotient by the cyclic image and this parameter defect remain in the full family.

120 A genuine finite-field mixed extension

Choose the same finitely generated coefficient ring $R_0 \subset \mathbb{C}$ containing the coefficients of h , the matrices of the complete v_h and its inverse, and $1/(d+1)!$. Fix a specified finite-field point $R_0 \rightarrow \kappa = \mathbb{F}_Q$ of characteristic $p > d+1$. For the rest of this section polynomial coefficients mean their images under this specified map. Let

$$\begin{aligned} S &= \mathbb{G}_{m_u} \times \mathbb{A}_{\mathbf{t}}^k, & \pi : \mathbb{A}_{\mathbf{s}}^k \times S &\longrightarrow S, \\ \mathcal{L} &= \mathcal{L}_\psi \left(\frac{\sum_i \Phi_h(s_i) - \sum_i t_i s_i}{u} \right), & \mathcal{F} &= R^k \pi_! \mathcal{L}. \end{aligned} \quad (12)$$

Here ψ is a fixed nontrivial additive character with values in the chosen ℓ -adic coefficient field, $\ell \neq p$.

Proposition 120.1 (The actual open family and boundary stalk). *The sheaf $\mathcal{F}$ in (12) is lisse, of rank d^k , and pointwise pure of weight k ; all $R^j \pi_! \mathcal{L}$ with $j \neq k$ vanish. Fix any finite-field parameter value $\mathbf{t} = \mathbf{t}_0$, after a residue-field extension when necessary, and write $\mathcal{F}_{\mathbf{t}_0}$ for its pullback to $\mathbb{G}_m$. For $j : \mathbb{G}_m \hookrightarrow \mathbb{A}_u^1$ and $i : \{0\} \hookrightarrow \mathbb{A}_u^1$ there is an exact sequence*

$$0 \longrightarrow j_! \mathcal{F}_{\mathbf{t}_0} \longrightarrow j_* \mathcal{F}_{\mathbf{t}_0} \longrightarrow i_*(V^I) \longrightarrow 0, \quad (13)$$

where V is the local geometric generic representation and I its inertia group. The boundary stalk V^I is mixed of weights at most k .

Proof. The highest homogeneous phase is $\sum_i s_i^{d+1}/((d+1)u)$. Its partial derivatives s_i^d/u cannot vanish simultaneously at a projective point. Therefore the explicit coefficient map from S to the universal degree- $(d+1)$ polynomial parameter space lands entirely in Deligne's good open. Weil II, Lemma 3.7.3, proves lissity of the universal proper-support cohomology sheaves there. Proper-support base change pulls these sheaves to (12). Statement 3.7.2.3, with polynomial degree $d+1$ and affine dimension k , proves the asserted concentration, rank, and weight. This check uses no simplicity assumption on finite critical roots.

The stalk of $j_*\mathcal{F}_{t_0}$ at zero is V^I ; the stalk of $j_!\mathcal{F}_{t_0}$ there is zero. On the open the map is the identity, proving (13) on every geometric stalk. The extension by zero is mixed of weight k .

On an open finite-index inertia subgroup with unipotent action, let N be the actual logarithmic monodromy operator and M its monodromy filtration. Weil II 1.8.4 applies to the lisse pointwise pure $\mathcal{F}_{t_0}$ and proves that $\mathrm{Gr}_r^M V$ is pure of weight $k + r$. By 1.8.8, V^I is obtained from $\ker N$ by finite-group invariants; the filtration it inherits has no graded pieces with $r > 0$. Its nonzero graded pieces therefore have weights at most k . No graded rank or numerical matrix for N is inserted in this argument. $\square$

This supplies an actual use of Deligne's mixed-boundary machinery on the finite-field branch. The coefficient specialization of (8), and the theta source map (6), are separately explicit. A comparison from their marked complex fibre to the local representation in (13) has not been proved by these constructions. The complex boundary data relevant to such a comparison are calculated next, with all original coefficients retained.

121 Exact division and the full boundary connection

For $0 \leq b < d$ perform monic division in the original variable s :

$$f_t(s)s^b = (h(s) - t)q_b(s, t) + r_b(s, t), \quad \deg_s r_b < d, \quad \deg_s q_b \leq b + 1 \leq d. \quad (14)$$

Let $C_h(t)$ and $B_h(t)$ be the matrices whose b th columns are the coefficients of r_b and $\partial_s q_b$, respectively, in the ascending monomial basis $1, s, \dots, s^{d-1}$.

Lemma 121.1 (Exact differential remainder). *In the one-factor top lattice,*

$$[f_t s^b] = [r_b - u \partial_s q_b]. \quad (15)$$

There is no further reduction of the displayed quotient derivative.

Proof. Subtract $Lq_b = (h - t)q_b + u \partial_s q_b$ from (14). The derivative has degree below d , so the right side is already in the retained remainder basis. $\square$

Theorem 121.2 (Degree-correct flat connection). *On the one-factor complex localized at u , the degree-one and degree-zero connections in the u direction are*

$$\nabla_u^1 = \partial_u - \frac{f_t}{u^2}, \quad \nabla_u^0 = \partial_u - \frac{f_t}{u^2} + \frac{1}{u}. \quad (16)$$

The induced top connection in the original monomial lattice is exactly

$$\boxed{\nabla_u = \partial_u - \frac{C_h(t)}{u^2} + \frac{B_h(t)}{u}}. \quad (17)$$

On the ordered k -factor complex the degree- j operator and its top cohomology operator are

$$\nabla_u^{(j)} = \partial_u - \frac{\sum_i f_{t_i}(s_i)}{u^2} + \frac{k - j}{u}, \quad (18)$$

$$\boxed{\nabla_u} = \left[\partial_u - \frac{\sum_i C_{h,i}(t_i)}{u^2} + \frac{\sum_i B_{h,i}(t_i)}{u} \right]. \quad (19)$$

These commute with the existing parameter connections $\nabla_{t_i} = \partial_{t_i} - s_i/u$ and are compatible with the original complex differential.

Proof. The commutators on polynomial coefficients are

$$[L, \partial_u] = -\partial_s, \quad [L, -f_t/u^2] = -(h-t)/u,$$

so $[L, \nabla_u^1] = -L/u$ and $\nabla_u^1 L = L(\nabla_u^1 + 1/u) = L\nabla_u^0$. This proves the chain identity, including the degree-zero correction. The differential remainder (15) proves (17).

For (18), the commutator with each L_i is $-L_i/u$, and the scalar difference between adjacent exterior degrees contributes $+L_i/u$. Their cancellation proves chain compatibility in the original order. Top cohomology and (15) give (19). Finally, differentiating $-s_i/u$ in u gives $+s_i/u^2$, whereas the commutator of $-\sum f_{t_i}/u^2$ with ∂_{t_i} is $-s_i/u^2$. All other terms commute. This proves the asserted flatness. $\square$

Proposition 121.3 (The exact first-order trace). *$B_h(t)$ is independent of t . In the unchanged ascending monomial basis it is upper triangular and satisfies*

$$(B_h)_{bb} = \frac{b+1}{d+1}, \quad \boxed{\text{Tr } B_h = \frac{d}{2}}. \quad (20)$$

Proof. In (14), compare coefficients of degrees greater than d . The perturbation $-ts^{b+1}$ and the product $-tq_b$ both have degree at most d . All coefficients of q_b except possibly its constant coefficient are therefore determined independently of t . Differentiation removes that constant. The leading term of q_b is $s^{b+1}/(d+1)$, so its derivative has degree b and leading coefficient $(b+1)/(d+1)$. Summing those diagonal entries proves (20). $\square$

The matrix B_h alone is not asserted to be the local monodromy residue: the order-two coefficient $C_h(t)$ is present and generally does not commute with B_h . Equations (17) and (19) retain their exact relationship.

122 The full primary jets at the boundary

Proposition 122.1 (Leading coefficient on every original primary block). *Retain the Chinese-remainder summands $E_\rho = \mathbb{C}[s]/(s-\rho)^{m_\rho}$ and their projectors. At $t=0$,*

$$C_h(0)|_{E_\rho} = \Phi_h(\rho)I_{E_\rho}, \quad A_h|_{E_\rho} = \rho I_{E_\rho} + N_\rho, \quad \dim E_\rho = m_\rho. \quad (21)$$

For the ordered tuple $(\rho_1, \dots, \rho_k)$ the leading matrix in (19) is scalar $\sum_i \Phi_h(\rho_i)$ on a block of dimension $\prod_i m_{\rho_i}$.

Proof. Write $h(s) = (s-\rho)^{m_\rho} a_\rho(s)$, where $a_\rho(\rho) \neq 0$. Integration of its Taylor polynomial, with the original constant retained, gives the exact identity

$$\Phi_h(s) - \Phi_h(\rho) = \sum_{j \geq 0} \frac{a_\rho^{(j)}(\rho)}{j!} \frac{(s-\rho)^{m_\rho+j+1}}{m_\rho+j+1}. \quad (22)$$

The sum is finite. Every term is divisible by $(s-\rho)^{m_\rho+1}$. The matrix $C_h(0)$ is multiplication by $[\Phi_h]_h$, by its definition in (14); hence its restriction is the first expression in (21). Multiplication by s remains $\rho + N_\rho$ on that same full module. The tensor statement follows by applying the sum of these matrices to the ordered tensor projectors. $\square$

Equal sums of critical values retain their separate original projectors and source labels. The scalar exponential factors for two tuples have the exact modulus ratio

$$\exp\left(\text{Re} \frac{\sum_i \Phi_h(\rho_i) - \sum_i \Phi_h(\rho'_i)}{u}\right). \quad (23)$$

For a nonzero difference, equal modulus occurs on $\arg u = \arg(\text{difference}) + \pi/2 \pmod{\pi}$. These are candidate Stokes directions of the displayed exponential factors. Equation (23) supplies no assertion that a particular Stokes entry is nonzero, and does not replace the calculation of the matrices for (19).

123 Exact ordered period determinant

Keep the original rays and contours

$$\vartheta_j = \frac{\arg u + \pi}{d+1} + \frac{2\pi j}{d+1}, \quad \Gamma_j = -\ell_0 + \ell_j \quad (1 \leq j \leq d), \quad (\Pi_h)_{jb} = \int_{\Gamma_j} e^{f_t(s)/u} s^b ds. \quad (24)$$

The leading radial exponent is $-r^{d+1}/((d+1)|u|)$; it proves absolute convergence and coefficient differentiation on compact parameter sets. Contours on nearby parameters deform within the same decaying sectors, with their original orientations. Every formula below uses a fixed retained branch for u and the ordered rays.

Theorem 123.1 (Full period determinant, including its constant). *Let $c_h(t) = \text{Tr } C_h(t)$, and put*

$$\begin{aligned} \zeta &= e^{2\pi i/(d+1)}, & \beta_b &= \frac{b+1}{d+1}, \\ W_{jb} &= \zeta^{j(b+1)} - 1 \quad (1 \leq j \leq d, 0 \leq b < d), \\ K_d &= (d+1)^{-d/2} e^{\pi i d/2} \left(\prod_{b=0}^{d-1} \Gamma(\beta_b) \right) \det W. \end{aligned} \quad (25)$$

Then $K_d \neq 0$ and

$$\boxed{\det \Pi_h(u, t) = K_d u^{d/2} e^{c_h(t)/u}.} \quad (26)$$

For the ordered external product $\Pi_k = \bigotimes_i \Pi_h(u, t_i)$,

$$\boxed{\det \Pi_k = K_d^{kd^{k-1}} u^{kd^k/2} \exp\left(\frac{d^{k-1} \sum_i c_h(t_i)}{u}\right).} \quad (27)$$

Both identities retain all lower coefficients of h and extend across critical-root collisions.

Proof. Differentiating (24) in u inserts $-f_t/u^2$. The exact reduction (15) gives

$$\partial_u \Pi_h = \Pi_h \left(-\frac{C_h(t)}{u^2} + \frac{B_h}{u} \right).$$

The determinant equation, valid as the exterior-power equation even before invertibility is known, is

$$\partial_u \det \Pi_h = \left(-\frac{c_h(t)}{u^2} + \frac{d}{2u} \right) \det \Pi_h. \quad (28)$$

Thus the remaining factor after division by $u^{d/2} e^{c_h(t)/u}$ is independent of u on a contour branch.

We prove its independence of t and all lower coefficients without deleting their effects. On the dense open of simple roots of $h - t$,

$$c_h(t) = \sum_{h(\rho)=t} f_t(\rho), \quad \partial_t c_h(t) = - \sum_{h(\rho)=t} \rho = -\text{Tr } A_h(t).$$

The terms containing derivatives of the roots vanish because $f_t'(\rho) = 0$. Both sides are polynomial expressions in the coefficients and t , so this identity holds across collisions too. The period equation $\partial_t \Pi_h = \Pi_h(-A_h(t)/u)$ cancels the derivative of $e^{c_h(t)/u}$, proving that the remaining factor is independent of t .

Differentiation in h_b inserts $s^{b+1}/((b+1)u)$. For a column s^j , its numerator has degree $j+b+1 \leq 2d-1$. In division by $h-t$ the quotient derivative has degree at most $j+b-d < j$. Consequently the differential-reduction correction has zero trace. The determinant logarithmic derivative in h_b is $\text{Tr } M_{s^{b+1}}/((b+1)u)$. On the simple-root open this equals $(\partial_{h_b} c_h(t))/u$, since again the root derivative is multiplied by $f'_t(\rho) = 0$. Polynomial continuation proves the identity for all coefficients. Therefore the remaining factor has zero derivative in every lower coefficient.

It remains to compute that factor at $h = s^d, t = 0$, with the original contours. Substitution $v = r^{d+1}/((d+1)|u|)$ on each ray gives

$$(\Pi_h)_{jb} = [(d+1)u]^{\beta_b} e^{\pi i \beta_b} \frac{\Gamma(\beta_b)}{d+1} (\zeta^{j(b+1)} - 1). \quad (29)$$

The sum of the β_b is $d/2$, so taking determinants gives exactly (25) and (26). For invertibility of W , suppose $\sum_{r=1}^d a_r(z^r - 1)$ vanishes at the d nontrivial roots of $z^{d+1} = 1$. It also vanishes at $z = 1$. Its degree is at most d , so it is identically zero and every $a_r = 0$. All gamma factors are nonzero, proving $K_d \neq 0$.

The periods and their parameter derivatives are entire in the lower coefficients on compact sets by the fixed leading radial decay. This justifies the coefficient continuation used above and proves the identities also at collisions. Finally, $\det(A \otimes B) = (\det A)^{\dim B} (\det B)^{\dim A}$ in the retained ordered product bases gives (27). $\square$

124 Exact comparison with the original source metric

The period Gram determinant following from (27) is

$$\det(\Pi_k^* \Pi_k) = |K_d|^{2kd^{k-1}} |u|^{kd^k} \exp\left(2d^{k-1} \text{Re} \frac{\sum_i c_h(t_i)}{u}\right). \quad (30)$$

Retain, independently, the actual one-factor source Gram

$$(G_\theta)_{ab} = \frac{1}{2\pi} \int_{\mathbb{R}} \overline{(1/2 + iy)^a} (1/2 + iy)^b |v_h(1/2 + iy)|^2 dy, \quad 0 \leq a, b < d. \quad (31)$$

This is the Gram of $\mathcal{T}_h(s^b) = D^b F_h$ in the original $L^2(dx)$ source norm by Mellin–Plancherel. Its complete multiplier is $v_h = g/h$. It is positive definite: a zero norm forces the continuous source function $\mathcal{T}_h(P)$ to vanish; its Mellin transform Pv_h is then zero, and the nonzero entire v_h forces $P = 0$. The original ordered tensor source Gram is $G_\theta^{\otimes k}$.

The exact comparison of the two finite forms is the endomorphism

$$T_{\text{per}} = (G_\theta^{\otimes k})^{-1} (\Pi_k^* \Pi_k). \quad (32)$$

It is self-adjoint and positive in the original source metric, since

$$\langle v, T_{\text{per}} w \rangle_{G_\theta^{\otimes k}} = v^* \Pi_k^* \Pi_k w, \quad \langle v, T_{\text{per}} v \rangle_{G_\theta^{\otimes k}} = \|\Pi_k v\|^2 > 0 \quad (v \neq 0).$$

Its determinant is exactly (30) divided by $(\det G_\theta)^{kd^{k-1}}$. This preserves both metrics rather than identifying them.

On the weighted cyclic image (10), the period form is $\eta^* \Pi_k^* \Pi_k \eta$. Its relation to the original cyclic source metric retains the rectangular map $\Pi_k \eta$, the complement of η , and the transverse map

$$E \xrightarrow{\eta} E_h^{\otimes k} \xrightarrow{\sum_i \mathcal{R}_{h,i}} E_h^{\otimes k} \longrightarrow E_h^{\otimes k} / \eta E.$$

The full determinant (30) does not determine the singular values of this rectangular restriction. The displayed maps are the exact relationship; no original relation norm has been set to zero.

125 Compatibility with independently retained mixed faces

For an original coefficient mask A , retain its A -indexed coefficient complex and the original outer theta-leg label. Let j_A^B be the specified constant zero-insertion linear map for $A \subseteq B$. It inserts represented zero in each added slot. The preceding complex differential and connection act with the same coefficients in each slot. Therefore

$$j_A^B \mathcal{D}_A = \mathcal{D}_B j_A^B, \quad j_A^B \nabla_A = \nabla_B j_A^B. \quad (33)$$

These equations hold componentwise on retained coordinates; on the inserted coordinates each derivative and matrix coefficient sends zero to zero. Since j_A^B is constant in all parameters, differentiation commutes with it as well.

On the carrier retaining its mask, a vector killed by an observation therefore remains the receiving represented zero with that mask. The empty coefficient face maps to the zero vector in the receiving face under zero insertion; this face-group map is not a τ -preserving pointed lift. A nonempty outer theta-leg label remains present when the coefficient mask is empty. No colimit over the entire mask poset is taken, since its terminal full face would discard the independent face labels.

The scalar structural specialization is still

$$\mathbb{F}_{1,\tau} \longrightarrow G(\mathbb{C}[u, \mathbf{t}]) \xrightarrow{G(\text{ev}_0)} G(\mathbb{C}).$$

It sends represented u, t_i to represented zero e , and τ to τ . The original absolute point, its source, and the coefficient specialization are retained. Equation (33) is an explicit compatibility with the mixed face maps; it supplies no claim that a Boolean mask itself is a Deligne weight.

126 Completed single-primary boundary calculation and the continuing mixed-support calculation

The full single-primary calculation SP.1–36 and SPF.1–29, included in this edition as *The actual single-primary marked family and its complete boundary monodromy* and its finite-field companion, sharpens the preceding connection and determinant calculations on their exact primary subcase. The formulas in this section are reused from that complete proof, with the original source, constant, unit and basis retained. They replace the earlier statement that this subcase's local inertia and periods still required calculation.

126.1 The exact primary specialization, connection and period matrix

Choose an actual nontrivial zero ρ of $g = 2\xi$, with its complete order $m \geq 1$. In this subsection fix $t = 0$ and put

$$\begin{aligned} n &= m + 1, & h(s) &= (s - \rho)^m, & y &= s - \rho, \\ \Phi_h(s) &= \frac{(s - \rho)^n - (-\rho)^n}{n} = \frac{y^n}{n} + c, & c &= -\frac{(-\rho)^n}{n}. \end{aligned}$$

Thus $\Phi_h(0) = 0$ and $\Phi'_h = h$; the constant c has its original value. In the ordered rows $e_s = (1, s, \dots, s^{m-1})$ and $e_y = (1, y, \dots, y^{m-1})$, the exact coefficient map is

$$e_s = e_y P, \quad P_{ab} = \binom{b}{a} \rho^{b-a} \quad (a \leq b), \quad (P^{-1})_{ab} = \binom{b}{a} (-\rho)^{b-a} \quad (a \leq b),$$

with entries zero when $a > b$. Substitution in the binomial theorem proves both maps and their inverse relation; $\det P = 1$.

The original complex has differential $L_u = u\partial_s + (s - \rho)^m$. Its leading-degree term gives the free degree-one remainder module $\bigoplus_{b=0}^{m-1} \mathbb{C}[u][s^b ds]$, whose marked fibre is $\mathbb{C}[s]/h ds$, with the full primary order. In these unchanged coefficient columns the exact division and its derivative are

$$\Phi_h(s)s^b = h(s)\frac{(s - \rho)s^b}{n} + cs^b, \quad \left(\frac{(s - \rho)s^b}{n}\right)' = \frac{(b + 1)s^b - b\rho s^{b-1}}{n}.$$

Subtracting $L_u((s - \rho)s^b/n)$ proves

$$C_s = cI_m, \quad (B_s)_{bb} = \frac{b + 1}{n}, \quad (B_s)_{b-1,b} = -\frac{b\rho}{n}, \quad \nabla_u = \partial_u - \frac{cI_m}{u^2} + \frac{B_s}{u}.$$

All other entries of B_s vanish. The degree-zero lift is still $\partial_u - \Phi_h/u^2 + 1/u$; it intertwines L_u with the degree-one lift $\partial_u - \Phi_h/u^2$. Writing $\beta_a = (a + 1)/n$ gives the exact conjugation

$$PB_sP^{-1} = \text{diag}(\beta_0, \dots, \beta_{m-1}), \quad \text{Tr } B_s = m/2.$$

These are SP.1–9, including the original coefficient and chain maps.

On a fixed branch of $\log u$, retain the ordered outward rays of angles $(\arg u + \pi)/n + 2\pi j/n$ and their differences $\Gamma_j = -\ell_0 + \ell_j$, $1 \leq j \leq m$. Set

$$\zeta = e^{2\pi i/n}, \quad W_{ja} = \zeta^{j(a+1)} - 1, \quad d_a = n^{\beta_a-1} e^{\pi i \beta_a} \Gamma(\beta_a), \quad D(u) = \text{diag}(d_a u^{\beta_a}).$$

The complete original period matrix, with original monomial columns, is

$$\Pi_s(u) = \left(\int_{\Gamma_j} e^{\Phi_h(s)/u} s^b ds \right)_{jb} = e^{c/u} W D(u) P.$$

SP.10–14 prove this equality on the original contours: translating their junction by ρ leaves connector integrals tending to zero by $\text{Re}(\Phi_h/u) = -R^n/(n|u|) + O(R^{n-1}) + O(1)$; the finite junction paths cancel with their original orientations. The radial substitution then gives exactly the d_a above. The matrix W is invertible by the degree- $(n - 1)$ polynomial root argument in SP.14. In particular,

$$\det \Pi_s = K_m u^{m/2} e^{mc/u}, \quad K_m = n^{-m/2} e^{\pi i m/2} \left(\prod_{a=0}^{m-1} \Gamma(\beta_a) \right) \det W \neq 0.$$

Thus the preceding determinant has its complete matrix refinement on this precise subcase, with all Gamma factors, contour phases, Pascal coefficients and the original scalar retained.

126.2 The computed boundary and its exact marked-source maps

The transported cycles satisfy $\Gamma_j \mapsto \Gamma_{j+1} - \Gamma_1$ for $j < m$ and $\Gamma_m \mapsto -\Gamma_1$. Consequently SP.16–21 give

$$M_{\text{cyc}} = W \text{diag}(\zeta, \zeta^2, \dots, \zeta^m) W^{-1}, \quad M_{\text{cyc}}^n = I, \quad \ker(M_{\text{cyc}} - I) = 0.$$

The horizontal coefficient convention is determined by the exact fundamental matrix

$$H_s(u) = P^{-1} e^{-c/u} \text{diag}(u^{-\beta_a}).$$

It has inverse eigencharacters, with the same zero invariant space. Under $u = v^n$, the displayed connection becomes

$$\partial_v - \frac{nc}{v^{n+1}} I_m + \frac{1}{v} \text{diag}(1, \dots, m).$$

The meromorphic change $x_y = \text{diag}(v^{-1}, \dots, v^{-m})z$ removes precisely these integer residues and retains the common irregular factor e^{-c/v^n} . This exact fundamental solution has identity monodromy after the cover; its unipotent logarithm is $N_{\text{boundary}} = 0$. Its sector restrictions agree on

overlaps with the same branch, so there are no additional Stokes factors in this one-critical-value calculation. Both ordinary invariant stalks and the derived local invariant and coinvariant groups vanish before the cover, since $M_{\text{cyc}} - I$ is invertible.

On the same marked fibre let J_m be multiplication by y , with $(J_m)_{a+1,a} = 1$. The original multiplication and its precise relation to the boundary connection are

$$A_s = P^{-1}(\rho I_m + J_m)P, \quad N_{\text{ar}} = P^{-1}J_mP, \quad [B_s, A_s] = \frac{1}{n}N_{\text{ar}}, \quad [\nabla_u, A_s] = \frac{N_{\text{ar}}}{nu}.$$

With $D_0 = \text{diag}(d_a)$ and $K_0 = WD_0J_mD_0^{-1}W^{-1}$, the complete period transport is

$$\Pi_s A_s \Pi_s^{-1} = \rho I_m + u^{1/n} K_0, \quad M_{\text{cyc}} K_0 M_{\text{cyc}}^{-1} = \zeta K_0.$$

The coefficient calculation on each monomial proves these commutators and conjugations, including the last nilpotent column. They retain the original arithmetic nilpotent through its exact nonhorizontal map; see SP.22–24.

For the entire quotient $v_h = g/h$, retain every coefficient

$$a_j = \frac{v_h^{(j)}(\rho)}{j!} = \frac{g^{(m+j)}(\rho)}{(m+j)!}, \quad 0 \leq j < m, \quad a_0 \neq 0.$$

Its marked multiplication and inverse are

$$U_s = P^{-1} \left(\sum_{j=0}^{m-1} a_j J_m^j \right) P, \quad U_s^{-1} = P^{-1} \left(\sum_{j=0}^{m-1} b_j J_m^j \right) P,$$

$$b_0 = a_0^{-1}, \quad b_r = -a_0^{-1} \sum_{j=1}^r a_j b_{r-j}.$$

Multiplication of these finite series proves their inverse relation, using $J_m^m = 0$. Its complete period and connection images are

$$\Pi_s U_s \Pi_s^{-1} = \sum_{j=0}^{m-1} a_j u^{j/n} K_0^j, \quad [\nabla_u, U_s] = \frac{1}{nu} P^{-1} \left(\sum_{j=1}^{m-1} j a_j J_m^j \right) P.$$

These retain the full Taylor unit, rather than only its leading coefficient.

The original Euler/theta square remains, with $D = -x\partial_x$ and $\mathcal{M}F_h = v_h$,

$$\alpha_h(P) = P(D)\phi_*, \quad \mathcal{T}_h(P) = P(D)F_h, \quad \Theta\alpha_h(P) = \mathcal{T}_h(hP), \quad J_h\mathcal{T}_h(P) = U_s[P]_s.$$

Here $\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}$, $\Theta\phi = 2\sum_{r \geq 1} \phi(rx)$, and $\mathcal{M}\Theta\phi_* = g$, with the original function spaces and Mellin convention. The degree-one map is the retained $\sigma_h U_s : E_h \hookrightarrow Q_{\text{ar}}$. The exact translated source vector is $\mathcal{T}_h(y^b) = (D - \rho)^b F_h$, and at general u the source differential is the specified $\Theta + u\mathcal{T}_h\partial_s\alpha_h^{-1}$ on $\alpha_h(\mathbb{C}[s])$. For $v_{\text{pol}} = \sum_{j < m} a_j (s - \rho)^j$, the original differential gives the full representative defect

$$v_{\text{pol}} L_u Q = L_u(v_{\text{pol}} Q) - u v'_{\text{pol}} Q.$$

If $v_{\text{pol}} p = hq + r$ for an original remainder p , its differential remainder is $r - uq'$, whereas the constant coefficient extension U_s returns r . SP.25–31 prove these identities and retain precisely the derivative term needed away from $u = 0$.

The exact finite-cover lattice map is also available:

$$e^{-c/v^n} \Pi_s(v^n) = WD_0 \text{diag}(v, v^2, \dots, v^m)P.$$

After the two displayed constant invertible changes, its cokernel is $\bigoplus_{a=0}^{m-1} \mathbb{C}\{v\}/(v^{a+1})$, of length $m(m+1)/2$. Its image lattice has rank- m fibre modulo v , while its inclusion in the ambient constant lattice induces zero modulo v . This is the complete lattice map between the retained marked fibre and the computed local boundary; the factored exponential remains an irregular factor. See SP.32–33.

In the unchanged source metric of the preceding calculation, the full matrix refinement is

$$T_{\text{per}}(u) = G_{\theta}^{-1} \Pi_s(u)^* \Pi_s(u) = e^{2 \operatorname{Re}(c/u)} G_{\theta}^{-1} P^* D(u)^* W^* W D(u) P.$$

It is positive and self-adjoint in G_{θ} , with the complete multiplier g/h in that Gram. For $N \geq m-1$, the enlarged polynomial source has the exact period factorization and kernel

$$\operatorname{Per}_N = \Pi_s J_{u,N}, \quad \ker J_{u,N} = L_u(\mathbb{C}[s]_{\leq N-m}).$$

Thus its period Gram has rank m ; on the displayed remainder frame it is positive definite. SP.34–36 prove this by the original Mellin source and the endpoint calculation for $u d(e^{\Phi_h/u} Q)$. The original relation space and source norm therefore remain in subsequent restriction calculations.

126.3 The exact finite-field boundary on the same primary phase

For the finite-field statement retain the specified coefficient homomorphism $R \rightarrow k_0 = \mathbb{F}_{Q_0}$, with $p > n$, including $\rho, 1/n!$, and every coefficient of the full Taylor unit and its inverse. Use the explicit constant extension

$$k = \mathbb{F}_Q, \quad Q = Q_0^d, \quad d = \operatorname{ord}_{(\mathbb{Z}/n\mathbb{Z})^\times}(Q_0),$$

so $n \mid Q-1$. Fix $\ell \neq p$, geometric Frobenius, and the nontrivial additive character ψ obtained from the specified one on k_0 by the field trace. SPF.1–29 compute the actual sheaf $\mathcal{F} = R^1 \pi_{s!} \mathcal{L}_{\psi}(\Phi_h(s)/u)$. With

$$X_n = \{\chi : k^\times \rightarrow \overline{\mathbb{Q}}_{\ell}^\times : \chi^n = 1\}, \quad G_k(\chi, \psi) = \sum_{z \in k^\times} \chi(z) \psi(z),$$

and $\mathcal{A}_{\gamma}$ denoting the geometrically constant line with geometric Frobenius eigenvalue γ , the exact parameter-sheaf isomorphism is

$$\mathcal{F} \simeq \mathcal{L}_{\psi}(c/u) \otimes \bigoplus_{\substack{\chi \in X_n \\ \chi \neq 1}} \mathcal{A}_{-\chi(n)G_k(\chi, \psi)} \otimes \mathcal{K}_{\chi}(u).$$

The Kummer convention has trace χ . SPF.6–19 prove the isomorphism using the original translation, the finite power map $y \mapsto y^n$, its character projectors including the zero stalk, and compact-support base change. The minus sign is the degree-one cohomological sign; $\chi(n)$ is the original coefficient factor. Both it and the common Artin–Schreier factor remain.

If the specialized $c \neq 0$, the common wild character has break one, so

$$V^{I_0} = 0, \quad \operatorname{Swan}_0(\mathcal{F}) = m.$$

If $c = 0$, the nontrivial tame Kummer characters instead give

$$V^{I_0} = 0, \quad \operatorname{Swan}_0(\mathcal{F}) = 0.$$

Writing $\psi(x) = \vartheta(\operatorname{Tr}_{k/\mathbb{F}_p}(bx))$, the explicit cover $u = v^n$, followed when needed by $z^p - z = bc/v^n$, kills all geometric inertia. Its restricted unipotent logarithm is zero, while its restricted invariant space is the full rank m . SPF.22–27 prove the conductor, original invariant space and finite-cover statements by the exact local ramification calculation. Finally SPF.28–29 prove $|G_k(\chi, \psi)|^2 = Q$ directly for every nontrivial χ ; all local eigenvalues consequently have the original weight one. These are completed local and weight calculations for the specified sheaf and coefficient specialization.

126.4 Continuation through the full mixed-support family

The preceding complete primary calculation now supplies actual boundary matrices, period maps, conductors, unit defects and source forms to the earlier family. The original independent coefficient faces, outer theta-leg labels, proper-source kernels and structural specialization remain those already defined above; every constant coefficient map retains the corresponding represented zero and its label.

For several distinct primary critical values, the continuing calculation includes the sector transitions and local extensions between the computed blocks, with their exact maps through the retained mixed faces. The single-primary tensor calculation now gives the following complete continuation on the original parameter line.

The one-factor calculation gives the original finite-field sheaf's exact decomposition, weight one, invariant-space vanishing and zero finite-cover logarithm. The ordered tensor calculation now carries that result through every positive tensor order on the same parameter line. Keeping $n = m + 1$, the original phase has constant kc , and the character on an ordered monomial form is $\zeta^{\sum_i (b_i + 1)}$, where $0 \leq b_i < m$ and $\zeta = e^{2\pi i/n}$. The complete sum of these characters gives the exact ordinary complex invariant dimension

$$d_{0,k} = \frac{1}{n} \sum_{j=0}^{n-1} \left(\sum_{a=1}^{n-1} \zeta^{ja} \right)^k = \frac{m^k + m(-1)^k}{m+1}. \quad (\text{SPBT.1})$$

The inner sum is m for $j = 0$ and -1 otherwise, proving the equality. It is zero at $k = 1$; for $m \geq 2$ it is nonzero at every $k \geq 2$, and for $m = 1$ it is one at even k and zero at odd k .

More precisely, let E_0 be the diagonal mask selecting $\sum_i (b_i + 1) \equiv 0 \pmod{n}$, let $P_k = P^{\otimes k}$ be the original Pascal coordinate map, and let U_k be the complete original source-unit matrix. The retained tensor period matrix Π_k , with all its Gamma constants and original contours, gives

$$Q_0 = P_k^{-1} E_0 P_k, \quad \widehat{Q}_0 = U_k Q_0 U_k^{-1}, \quad \mathcal{P}_0 \Pi_k U_k^{-1} = \Pi_k U_k^{-1} \widehat{Q}_0. \quad (\text{SPBT.2})$$

The diagonal power matrix in the exact tensor period formula commutes with E_0 , so multiplication of those matrices proves this identity. Thus $\widehat{Q}_0$ is the projector on the actual original-source jet, and its period observation is $\Pi_k U_k^{-1}$; neither unit nor inverse is removed. The terminal monomial $\prod_i (s_i - \rho)^{m-1}$ has character ζ^{-k} , and hence survives exactly when $n \mid k$. The original sum multiplication still acts on that same vector by $k\rho$, since multiplication by each $s_i - \rho$ kills it. Its dilation eigenvalue remains $a^{k\rho}$.

On the actual finite-field coefficient stage with $p > m + 1$, the entire ordered sheaf is the direct sum of the original Gauss lines for the ordered character tuples, tensored with the unchanged additive factor $\mathcal{L}_\psi(kc/u)$. The exact original-inertia projector is the tame average multiplied by its wild average; the latter is one when $kc = 0$, zero otherwise. Consequently

$$\dim V_k^{I_0} = \begin{cases} d_{0,k}, & kc = 0, \\ 0, & kc \neq 0, \end{cases} \quad \text{Swan}_0(V_k) = \begin{cases} 0, & kc = 0, \\ m^k, & kc \neq 0. \end{cases} \quad (\text{SPBT.3})$$

The wild average is $p^{-1} \sum_{a \in \mathbb{F}_p} \vartheta(-ka)$ when the original $c \neq 0$, which proves the two cases; for $c = 0$ the original additive torsor is trivial. The Swan value follows because every nontrivial $1/u$ Artin-Schreier character has break one, shared by all m^k ordered summands. Each nonzero invariant orbit block has its full product of the original negative Gauss constants and has weight k . The terminal character survives precisely for $n \mid k$ and $kc = 0$, hence for $pn \mid k$ in the branch $c \neq 0$.

The coefficient lattice now records the same original cyclic map as $T^r \mapsto r!UV_r$. In the actual coefficient localization $\mathcal{S} = A_{\ker \alpha}$ of the given coefficient datum, its image L_U lies in its saturation Λ_U , with the exact quotient $\Lambda_U/L_U \simeq \bigoplus_r \mathcal{S}/(p^{v_p(r!)}).$ The quotient of the full tensor target also retains

its free complementary summand, as proved in (BPC.5) and (BPC.9). The complete proof in (BPC.1)–(BPC.14) identifies its specialized kernel (T^p), including all the original unit coefficients and the Tor connecting map. The unequal-order and residual-collision forms are (PC30a)–(PC30g). These statements apply only on their actual coefficient-map domains; the phase denominators and the additional CRT denominators have the explicit extension tests in (BTF.9) and the preceding coefficient-domain calculation. The common cyclotomic projector maps in (BTF.6) relate the coefficient characters to the actual Gauss-line representation through their two base changes. They preserve the distinct coefficient and sheaf scalar targets. Thus one-factor vanishing is retained as its exact $k = 1$ case, and the tensor invariants, original arithmetic action and coefficient specialization are carried forward with their proved maps.

The continuing induced relation-form calculation on the weighted cyclic image retains the parameter defect (11), the transverse map, its rectangular period restriction, and all original source cross-pairings. The explicit primary formula for T_{per} above can now enter that calculation, while its complete coefficient Gram and restriction maps remain. An arithmetic Frobenius comparison and the uniform four-volume estimate still require their own calculations on those original objects; the completed primary boundary result has not performed those additional steps.

Source and verification record

The original packet-family inputs are those of *Tau Marked Product Four Endpoint*, 13 September 2026, NOTE.tex, read in full, with SHA256

40749e2a9d599a322e7b125eb43ad0878
a066a51b61da52cc3bb2ffb94cbd841.

The relevant primary source is Pierre Deligne, *La conjecture de Weil II*, Publications mathématiques de l’IHÉS 52 (1980), 137–252: 1.8.4, 1.8.8, 3.3.1–3.3.6, 3.7.2.3, 3.7.3, 6.1.13 and 6.2.1–6.2.6. The local typed text of those statements and surrounding proofs was read for this audit.

The companion exact symbolic checker verifies differential reduction, flatness, $\partial_t B_h = 0$, the trace and diagonal of B_h , the critical-value trace derivative, and complete jet divisibility for four polynomial fixtures of degrees 1 through 4, including repeated roots. All passed. These fixtures are explicitly not asserted to be arithmetic zero packets; the proofs here apply to the original h .

127 Joint trace control on the original source and relation spaces

Retain $h, k, \chi = \chi_{h,k}$ from the marked-product note. Here $q = \deg \chi \geq 1$ denotes the polynomial degree. Use the original coordinate $S = k/2 + iy$, the densities $m = w_h^{*k}$ and $r = r_{1/4}^{*k}$ with their literal masses, and $\mu_x = ((1-x)r + xm) dy$ for $0 \leq x \leq 1$. The common source is $H = \mathcal{P}_{2q}$ in the retained monomial basis. Its positive definite Gram and its original metric derivative are

$$M_x = M_0 + x\dot{M}, \quad M_0 = M_{2q}^\Gamma, \quad \dot{M} = M_{2q}^{\text{ar}} - M_{2q}^\Gamma, \quad T_x = M_x^{-1}\dot{M}. \quad (\text{SP1})$$

The equality $M_x T_x = \dot{M} = \dot{M}^*$ proves that T_x is self-adjoint in the M_x inner product. Its exact relation to the positive M_0 -self-adjoint operator $R = M_0^{-1}M_1$ is $T_x = (I + x(R - I))^{-1}(R - I)$, obtained by factoring $M_x = M_0(I + x(R - I))$. Thus its eigenvalues are $(r - 1)/(1 + x(r - 1))$ for the positive eigenvalues r of R , with their actual signs retained.

The precise arrow to the earlier AW source keeps H and every coefficient fixed, sends t_{AW} to x and u_{AW} to y , and sends the relation map by $B_N^{\text{SP}} = I_N B_N^{\text{AW}} : \mathcal{P}_{N-q} \rightarrow H$. The Gamma convolution constant is $c_a = 2^{1-2a}\Gamma(2a)$, so

$$r_{1/4}^{*k}(y) = \frac{c_{1/4}^k |\Gamma(k/4 + iy/2)|^2}{c_{k/4} 2\pi}, \quad c_{1/4} = \sqrt{2\pi}. \quad (\text{SP1a})$$

This is exactly AW3, including its mass $(2\pi)^{k/2}$; both arithmetic densities are w_h^{*k} with mass μ_h^k . Thus $M_x = M_{AW}(x)$, and $(B_N^{\text{SP}})^* M_x B_N^{\text{SP}} = (B_N^{\text{AW}})^* M_N B_N^{\text{AW}}$ with $M_N = I_N^* M_x I_N$.

127.1 All four endpoints as operators on one source

Let $I_N : \mathcal{P}_N \rightarrow H$ be literal coefficient inclusion, and let $B_N : \mathcal{P}_{N-q} \rightarrow H$ be multiplication by the original monic χ , followed by coefficient inclusion. Define

$$P_N = I_N(I_N^* M_x I_N)^{-1} I_N^* M_x, \quad Q_N = B_N(B_N^* M_x B_N)^{-1} B_N^* M_x, \quad Q_{q-1} = 0. \quad (\text{SP2})$$

The second formula is used for $N \geq q$; its Gram is invertible because multiplication by χ is injective on polynomials. Direct multiplication proves that these are the M_x -orthogonal projections onto the original source and relation subspaces. Within either family the subspaces are nested, so their orthogonal projections commute and their product is the smaller projection. Indeed the smaller subspace, its orthogonal complement inside the larger one, and the orthogonal complement of the larger one give three invariant summands on which this statement is immediate.

Let $V_N(x)$ be the original canonical quotient volume. In the fixed quotient-lift and monic-relation coordinates, block determinant gives

$$\log V_N(x) = \log \det(I_N^* M_x I_N) - \log \det(B_N^* M_x B_N). \quad (\text{SP3})$$

The relation determinant is one when its dimension is zero. The fixed monic change-of-basis determinant has modulus one, so SP3 retains every volume factor. Differentiation and cyclicity of finite matrix trace give

$$(\log V_N)' = \text{Tr}(T_x(P_N - Q_N)). \quad (\text{SP4})$$

For example $\text{Tr}(T_x P_N) = \text{Tr}((I_N^* M_x I_N)^{-1} I_N^* \dot{M} I_N)$; the relation formula uses precisely the same calculation. Set

$$F(x) = \log \frac{V_{q-1}(x) V_q(x)}{V_{2q-1}(x) V_{2q}(x)}, \quad \Delta_{h,k} = F(1) - F(0), \quad (\text{SP5})$$

and define two positive operators on this same source:

$$\mathcal{R}_x = Q_{2q-1} + Q_{2q} - Q_q, \quad \mathcal{P}_x = (P_{2q-1} - P_{q-1}) + (P_{2q} - P_q), \quad \mathcal{A}_x = \mathcal{R}_x - \mathcal{P}_x. \quad (\text{SP6})$$

The four original signs in SP4 give

$$F'(x) = \text{Tr}(T_x \mathcal{A}_x). \quad (\text{SP7})$$

For the original row $v = v_{2q}(y)$, the density identity has the exact metric factor

$$\mathbf{R}_x(y) - \mathbf{P}_x(y) = v \mathcal{A}_x M_x^{-1} v^*.$$

Indeed $P_N M_x^{-1} = I_N(I_N^* M_x I_N)^{-1} I_N^*$, and the same identity holds with B_N, Q_N . This recovers the marked-product kernels and proves the common-source matrix comparison.

127.2 Ranks, multiplicities and the retained overlap

The following complete spectra and the final condition-number coefficient were already established in AW7 and AW14. They are retained here with the exact source correspondence above; the actual cross-trace and intersection terms supply the added refinement.

The nested relation spaces in SP6 have dimensions 1, q , $q+1$. On the first space $\mathcal{R}_x$ has eigenvalue one; on the next orthogonal increment it has eigenvalue two with multiplicity $q-1$; on the last

increment it has eigenvalue one; elsewhere it is zero. The nested source increments in $\mathcal{P}_x$ give the same list. When $q = 1$, the multiplicity $q - 1$ is zero. Consequently

$$\begin{aligned} \text{rank } \mathcal{R}_x &= \text{rank } \mathcal{P}_x = q + 1, & \text{Tr } \mathcal{R}_x &= \text{Tr } \mathcal{P}_x = 2q, \\ \text{Tr } \mathcal{R}_x^2 &= \text{Tr } \mathcal{P}_x^2 = 4q - 2, & \text{Tr } \mathcal{A}_x &= 0, \\ \text{Tr } \mathcal{A}_x^2 &= 8q - 4 - 2 \text{Tr}(\mathcal{R}_x \mathcal{P}_x). \end{aligned} \quad (\text{SP8})$$

The equal kernel masses $2q$ are traces. The two positive operators have rank $q + 1$, with their multiplicity-two directions retained.

The overlap in SP8 is at least one. Each positive operator is at least the orthogonal projection onto its range, since its nonzero eigenvalues are one and two. The two ranges each have dimension $q + 1$ in dimension $2q + 1$, so their intersection has dimension at least one. Choose a unit vector in this intersection and complete it to an orthonormal basis of the first range. The trace of the product of the two range projections is the sum of squared norms of the second projection on this basis, hence at least one. For positive operators, replacing one factor by a larger positive factor cannot decrease the trace of the product: the difference is $\text{Tr}(B^{1/2}(A' - A)B^{1/2}) \geq 0$. Applying this twice proves the stated bound for the actual operators.

127.3 A bound that uses cancellation before estimating

Write $d_x = \lambda_{\max}(T_x) - \lambda_{\min}(T_x)$. Since $\text{Tr } \mathcal{A}_x = 0$, for every real c

$$F'(x) = \text{Tr}((T_x - cI)\mathcal{A}_x). \quad (\text{SP9})$$

Choose c to be the midpoint of the two extreme eigenvalues. In an M_x -orthonormal eigenbasis e_j of $\mathcal{A}_x$, with real eigenvalues α_j , one obtains

$$|F'(x)| \leq \sum_j |\alpha_j| |\langle e_j, (T_x - cI)e_j \rangle_{M_x}| \leq \frac{1}{2}d_x \sum_j |\alpha_j|.$$

This proves the trace-norm bound directly. Let L_x be the intersection of the two ranges in SP6, with $s_x = \dim L_x \geq 1$, and let E_{L_x} be its orthogonal projection in M_x . Each of $\mathcal{R}_x, \mathcal{P}_x$ is at least E_{L_x} . Thus $\mathcal{A}_x = (\mathcal{R}_x - E_{L_x}) - (\mathcal{P}_x - E_{L_x})$ is a difference of two positive operators of trace $2q - s_x$. The triangle inequality for trace norm gives $\|\mathcal{A}_x\|_1 \leq 4q - 2s_x \leq 4q - 2$. Cauchy-Schwarz on its at most $2q + 1$ eigenvalues gives the refinement

$$|F'(x)| \leq \frac{d_x}{2} \min \left\{ 4q - 2s_x, \sqrt{(2q + 1)(8q - 4 - 2 \text{Tr}(\mathcal{R}_x \mathcal{P}_x))} \right\}. \quad (\text{SP10})$$

The overlap is calculated from the unchanged source and relation Grams in SP2. Every cross-pairing remains in that expression.

The complete earlier AW13–AW16 bound applies to this same source through $(U, W, C) = (\mathcal{R}_x, \mathcal{P}_x, T_x)$. Write $c_1(x) \leq \dots \leq c_{2q+1}(x)$ for all eigenvalues of T_x in M_x and define

$$S_{\text{AW}}(x) = c_{q+2}(x) - c_q(x) + 2 \sum_{j=1}^{q-1} (c_{2q+2-j}(x) - c_j(x)), \quad S_{\text{SP}}(x) = \text{the right-hand side of (SP10)}. \quad (\text{SP10a})$$

Here is the complete retained spectral proof. For an orthogonal projection P of rank r , its diagonal values a_j in an orthonormal eigenbasis of T_x satisfy $0 \leq a_j \leq 1$ and $\sum_j a_j = r$. Thus $\text{Tr}(PT_x) = \sum_j c_j a_j$ is at least the sum of the smallest r and at most the sum of the largest r eigenvalues: moving a fixed diagonal mass from a smaller coefficient to a larger one increases this sum. Either $Z = \mathcal{R}_x$

or $Z = \mathcal{P}_x$ equals its range projection, of rank $q + 1$, plus its eigenvalue-two projection, of rank $q - 1$. Therefore

$$\sum_{j=1}^{q+1} c_j + \sum_{j=1}^{q-1} c_j \leq \text{Tr}(ZT_x) \leq \sum_{j=q+1}^{2q+1} c_j + \sum_{j=q+3}^{2q+1} c_j. \quad (\text{SP10b})$$

Subtracting the two extrema with their exact multiplicities gives $|F'(x)| \leq S_{\text{AW}}(x)$. Combining this bound with SP10 before integration proves

$$|F'(x)| \leq \min\{S_{\text{AW}}(x), S_{\text{SP}}(x)\}. \quad (\text{SP10c})$$

Positive smooth Gram matrices make the eigenvalues and overlaps bounded on $[0, 1]$; s_x is Borel since its rank strata are given by matrix minors. Hence the right side is integrable. The original source isometry of AW10 also yields the exact commutator identity $F' = \text{Tr}(W(T^{\text{iso}})^{-1}[C, T^{\text{iso}}])$. It follows from $U = T^{\text{iso}}W(T^{\text{iso}})^{-1}$ and cyclicity, with T^{iso} the explicit isometry and $C = T_x$ the metric derivative. Its full original observation remains $\mathcal{O} = \sigma_h^{\otimes k} \eta J_{2q}$ and has exact defect $\mathcal{O}T^{\text{iso}} - \mathcal{O} = \sigma_h^{\otimes k} \eta J_{2q}(T^{\text{iso}} - I)$ and kernel $\ker(\mathcal{O}T^{\text{iso}}) = (T^{\text{iso}})^{-1}(\chi\mathcal{P}_q)$. The defect follows by expansion and the kernel follows from injectivity of $\sigma_h^{\otimes k} \eta$ and $\ker J_{2q} = \chi\mathcal{P}_q$. Thus no additional cohomology-intertwining property of the metric isometry is used.

There is a closed integrated bound. Set $R = M_0^{-1}M_{2q}^{\text{ar}}$. It is positive and self-adjoint in the M_0 inner product, since $\langle v, Rv \rangle_{M_0} = \langle v, v \rangle_{M_{2q}^{\text{ar}}} > 0$. Let its smallest and largest eigenvalues be $r_{\min}, r_{\max} > 0$. The literal factorization of M_x gives

$$T_x = (I + x(R - I))^{-1}(R - I), \quad d_x = \frac{r_{\max} - 1}{1 + x(r_{\max} - 1)} - \frac{r_{\min} - 1}{1 + x(r_{\min} - 1)}. \quad (\text{SP11})$$

For fixed x , the function $(r - 1)/(1 + x(r - 1))$ is increasing on $r > 0$, its derivative being $(1 + x(r - 1))^{-2} > 0$. This proves the extreme-eigenvalue formula even though the inner product varies. Integration, including the identically zero integrand when an eigenvalue equals one, yields

$$\int_0^1 d_x dx = \log(r_{\max}/r_{\min}). \quad (\text{SP12})$$

Write $r_1 \leq \dots \leq r_{2q+1}$ for all positive eigenvalues of R , and retain

$$\mathcal{L}_q(R) = \log \frac{r_{q+2}}{r_q} + 2 \sum_{j=1}^{q-1} \log \frac{r_{2q+2-j}}{r_j}.$$

The ordered form of SP11 gives $c_j(x) = (r_j - 1)/(1 + x(r_j - 1))$ and $\int_0^1 c_j(x) dx = \log r_j$. Therefore SP7–SP12 and the full spectral proof above give both original-source controls

$$\boxed{|\Delta_{h,k}| \leq \int_0^1 \min\{S_{\text{AW}}(x), S_{\text{SP}}(x)\} dx \leq \mathcal{L}_q(R) \leq (2q - 1) \log \frac{r_{\max}}{r_{\min}},} \quad (\text{SP13})$$

$$|\Delta_{h,k}| \leq \frac{1}{2} \int_0^1 d_x \|\mathcal{R}_x - \mathcal{P}_x\|_1 dx \leq (2q - 1) \log \frac{r_{\max}}{r_{\min}}.$$

The first integral is also at most $\int_0^1 S_{\text{SP}}(x) dx$. Every logarithmic ratio in $\mathcal{L}_q$ is bounded by $\log(r_{\max}/r_{\min})$, with coefficient total $1 + 2(q - 1) = 2q - 1$; this proves the last inequality explicitly. The two displayed integral bounds each remain available: no ordering between the exact trace norm and the spectral refinement is assumed. When the Grams are proportional, every c_j agrees, both bounds are zero, and the correction is exactly zero without rescaling their original masses.

The exact trace norm and the centered Hilbert–Schmidt estimate are also retained before taking a minimum. On this same source define

$$\begin{aligned} S_{\text{tr}}(x) &= \frac{d_x}{2} \|\mathcal{R}_x - \mathcal{P}_x\|_1, \\ \Sigma(x) &= \text{Tr}(T_x^2) - \frac{(\text{Tr } T_x)^2}{2q+1}, \\ S_{\text{HS}}(x) &= \sqrt{\Sigma(x) \text{Tr}((\mathcal{R}_x - \mathcal{P}_x)^2)}. \end{aligned} \tag{SP13d}$$

The trace-norm inequality follows by subtracting the midpoint of the extreme eigenvalues from the metric derivative, since the trace of the signed projection difference is zero. In an orthonormal eigenbasis of that difference, every diagonal derivative entry is bounded in modulus by half the spectral diameter; summing with the absolute eigenvalues proves the assertion. For the other bound subtract the trace mean $\text{Tr}(T_x)/(2q+1)$ instead. The square of its Hilbert–Schmidt norm in the unchanged source metric is exactly $\Sigma(x)$. Hilbert–Schmidt Cauchy–Schwarz with the signed difference proves that its trace pairing is bounded by $S_{\text{HS}}(x)$. Positivity of both factors under the square root follows from their self-adjointness. Thus both functions bound the same absolute signed derivative on general positive source forms; the angle term below still uses the specified moment measures. These are RMT10a–10b and ISM25–26 through the already proved original coefficient and projection maps.

On the original moment source (SP1a), the later angle calculation propagates further at this endpoint. With $a_q = 2q - 1$ define

$$\begin{aligned} A(x) &= a_q \sqrt{1 - e^{-F(x)/a_q}} d_x, \\ J^{(5)} &= \int_0^1 \min\{S_{\text{AW}}(x), S_{\text{tr}}(x), S_{\text{SP}}(x), S_{\text{HS}}(x), A(x)\} dx, \\ I &= \int_0^1 \min \left\{ d_x, \frac{S_{\text{AW}}(x)}{a_q \sqrt{1 - e^{-F(x)/a_q}}}, \frac{S_{\text{SP}}(x)}{a_q \sqrt{1 - e^{-F(x)/a_q}}}, \right. \\ &\quad \left. \frac{S_{\text{tr}}(x)}{a_q \sqrt{1 - e^{-F(x)/a_q}}}, \frac{S_{\text{HS}}(x)}{a_q \sqrt{1 - e^{-F(x)/a_q}}} \right\} dx. \end{aligned} \tag{SP13a}$$

The exact map to RMT is $a_{\text{RMT}} = a_q$, $F = \mathcal{B}$, $T_x = C_x$ and $(\mathcal{R}_x, \mathcal{P}_x) = (U_x, W_x)$, with the same original moment measures by SP1a. RMT11–RMT12 proves $F > 0$ and $|F'| \leq A$: its full two angle lists keep the designated zero angle, and vanishing F would imply $1 \perp \chi \mathcal{P}_q$, contradicting $\int |\chi|^2 d\mu_x > 0$ through $\chi^{\#k}(S) = \sum_j \overline{\chi_j}(k-S)^j$. Thus the two-bound proof above remains valid for general positive forms, while on these actual moment forms its displayed first bound in SP13 strengthens to

$$|\Delta_{h,k}| \leq J^{(5)} \leq \int_0^1 \min\{S_{\text{AW}}(x), S_{\text{SP}}(x)\} dx. \tag{SP13b}$$

For every integer $\ell_N \geq 0$ the constructed signed approximation is applied on these exact endpoint forms as well. Use $\mathbf{M}_z = M_x|_{x=z}$, $\mathbf{C}_z = T_x|_{x=z}$, $\mathbf{A}_z = (\mathcal{R}_x - \mathcal{P}_x)|_{x=z}$, and $\mathbf{D} = R$. The same-source RMT/ISM function $\mathcal{B}$ is exactly F in SP5. Write $\mathbf{D} = (\mathbf{M}_0)^{-1} \mathbf{M}_1$, with its complete ordered positive eigenvalues $b_1, \dots, b_{2q+1}$, and let $\mathbf{A}_z$ be this same signed projection difference. Define

$$\begin{aligned} \alpha_z^\circ &= \frac{2(1-z) + z(b_1 + b_{2q+1})}{2}, \quad H_z^\circ = I - \frac{(1-z)I + z\mathbf{D}}{\alpha_z^\circ}, \\ C_z^{[\ell_N]} &= (\alpha_z^\circ)^{-1} \sum_{r=0}^{\ell_N} (H_z^\circ)^r (\mathbf{D} - I), \quad R_z^{[\ell_N]} = (H_z^\circ)^{\ell_N+1} \mathbf{C}_z, \\ E_z^{[\ell_N]} &= R_z^{[\ell_N]} - \frac{\text{Tr } R_z^{[\ell_N]}}{2q+1} I. \end{aligned} \tag{SP13ea}$$

The symbols $\alpha_z^\circ, H_z^\circ$ preserve every original source parameter and relation map; ℓ_N is only the finite series truncation. Multiplication of the finite geometric sum gives $C_z - C_z^{[\ell_N]} = R_z^{[\ell_N]}$. All factors are real functions of the positive relative operator D , hence self-adjoint in the original $M_z = M_0((1 - z)I + zD)$ metric. Since $\text{Tr } A_z = 0$, the derivative of the same four-volume function is its signed center $\text{Tr}(C_z^{[\ell_N]} A_z)$ plus $\text{Tr}(E_z^{[\ell_N]} A_z)$. Consequently

$$\begin{aligned} j_{\ell_N} &= \int_0^1 \text{Tr}(C_z^{[\ell_N]} A_z) dz, \\ e_{\ell_N} &= \int_0^1 \sqrt{\text{Tr}((E_z^{[\ell_N]})^2) \text{Tr}(A_z^2)} dz, \\ j_{\ell_N} - e_{\ell_N} &\leq \mathcal{B}(1) - \mathcal{B}(0) \leq j_{\ell_N} + e_{\ell_N}. \end{aligned} \tag{SP13eb}$$

For this block $\mathcal{B}$ denotes precisely the four-volume function identified above. The signed inequalities follow by Hilbert–Schmidt Cauchy–Schwarz in that unchanged metric and integration of the exact derivative. The full residual calculation ISM29–37, equivalently RMT19–21, uses $\vartheta = (b_{2q+1} - b_1)/(b_{2q+1} + b_1) < 1$ and $K_D = \sum_j (|b_j - 1|/\min\{1, b_j\})^2$ to prove

$$0 \leq e_{\ell_N} \leq \vartheta^{\ell_N+1} \sqrt{K_D(8q - 6)} \longrightarrow 0. \tag{SP13ec}$$

Indeed every eigenvalue of H_z° has modulus at most ϑ , centering the residual subtracts a nonnegative square from its squared Hilbert–Schmidt norm, and $\text{Tr}(A_z^2) \leq 8q - 6$ by the full flag spectra and the common range. This proves the bound with all eigenvalue multiplicities retained. The displayed integrals are exact; a numerical evaluation must retain its own integration error. Intersecting this proved signed interval with the already proved absolute and nonlinear intervals supplies the additional endpoint entries below, for every specified ℓ_N .

For $H_0 = 2 \text{arccosh}(e^{F(0)/(2a_q)})$, the derivative $[2 \text{arccosh}(e^{B/(2a_q)})]' = 1/(a_q \sqrt{1 - e^{-B/a_q}})$ and its inverse $2a_q \log \cosh(z/2)$ give the actual endpoint interval

$$\begin{aligned} F(1) &\geq \max \left\{ 0, F(0) - J^{(5)}, 2a_q \log \cosh \frac{\max\{0, H_0 - I\}}{2}, F(0) + j_{\ell_N} - e_{\ell_N} \right\}, \\ F(1) &\leq \min \left\{ F(0) + J^{(5)}, 2a_q \log \cosh \frac{H_0 + I}{2}, F(0) + j_{\ell_N} + e_{\ell_N} \right\}, \quad I \leq \log(r_{\max}/r_{\min}). \end{aligned} \tag{SP13c}$$

The nonlinear branches follow by dividing all five derivative bounds by the same positive factor, integrating, and applying the increasing inverse. Intersecting with the constructed signed interval (SP13eb) gives the additional signed branches; compactness and $F > 0$ justify every denominator. It is precisely RMT13–RMT22 on the stated unchanged original source, including the full local signed construction (SP13ea)–(SP13ec).

SP1–SP13 give finite two-sided control on every original packet. They do not bound the displayed condition number or projection overlap along the growing arithmetic family. The next calculation can use these exact quantities, their original moment formulae, and the newly retained singular-boundary geometry; none has been replaced by an assumed asymptotic estimate or an RH verdict.

128 Combining the existing spectral and overlap controls on the original source

This attachment records the exact comparison already established in the coordinating source intake. The complete earlier AW proof is retained in this reader; SP reproduces its spectra and final condition-number bound and adds the stated overlap refinement. Neither bound is discarded.

Fix the actual full packet h , tensor order $k \geq 1$, and its original cyclic polynomial χ of degree $q \geq 1$. The common coefficient space is $H = \mathcal{P}_{2q}$. Its integration coordinate is $S = k/2 + iy$. Write

$x \in [0, 1]$ for metric interpolation and reserve u for the geometric deformation parameter of BC. The exact AW/SP coordinate map is

$$y = u_{AW}, \quad x = t_{AW}, \quad H_{AW} \xrightarrow{\text{id}} H_{SP}. \quad (\text{ACM1})$$

This identity leaves every polynomial coefficient unchanged. The arithmetic density is w_h^{*k} in both calculations. For the reference density, the original constant $c_a = 2^{1-2a}\Gamma(2a)$ gives $c_{1/4} = \sqrt{2\pi}$, so the exact convolution formula is

$$r_{1/4}^{*k}(y) = \frac{c_{1/4}^k}{c_{k/4}} r_{k/4}(y) = \frac{(\sqrt{2\pi})^k}{c_{k/4}} \frac{|\Gamma(k/4 + iy/2)|^2}{2\pi}. \quad (\text{ACM2})$$

Consequently the densities, their masses and all monomial integrals coincide. In particular $M_{AW}(x) = M_{SP}(x) = M_x$ on H , and $M_{N,AW} = I_N^* M_x I_N$ on the original subspace $I_N : \mathcal{P}_N \hookrightarrow H$.

AW's relation map has codomain $\mathcal{P}_N$, whereas SP incorporates its inclusion into H . Their literal equality is

$$B_N^{SP} = I_N B_N^{AW}. \quad (\text{ACM3})$$

Substitution into the orthogonal projector formula gives

$$\begin{aligned} P_N &= I_N (I_N^* M_x I_N)^{-1} I_N^* M_x, \\ Q_N &= I_N B_N^{AW} ((B_N^{AW})^* I_N^* M_x I_N B_N^{AW})^{-1} (B_N^{AW})^* I_N^* M_x. \end{aligned} \quad (\text{ACM4})$$

The two definitions of each projector therefore agree, including $Q_{q-1} = 0$ for the zero relation domain. Put

$$\begin{aligned} U_x &= Q_{2q-1} + Q_{2q} - Q_q = \mathcal{R}_x^{SP}, \\ W_x &= (P_{2q-1} - P_{q-1}) + (P_{2q} - P_q) = \mathcal{P}_x^{SP}, \\ C_x &= M_x^{-1} \dot{M}_x = T_x^{SP}. \end{aligned} \quad (\text{ACM5})$$

These are AW's original U, W, C . Its independently constructed source isometry T_x^{iso} satisfies

$$(T_x^{\text{iso}})^* M_x T_x^{\text{iso}} = M_x, \quad U_x = T_x^{\text{iso}} W_x (T_x^{\text{iso}})^{-1}. \quad (\text{ACM6})$$

Thus cyclicity of the same finite trace proves

$$\text{Tr}((U_x - W_x)C_x) = \text{Tr}(W_x(T_x^{\text{iso}})^{-1}[C_x, T_x^{\text{iso}}]). \quad (\text{ACM7})$$

The original observation is still $\mathcal{O} = \sigma_h^{\otimes k} \eta J_{2q}$. Its exact difference and kernel after the isometry remain

$$\begin{aligned} \mathcal{O} T_x^{\text{iso}} - \mathcal{O} &= \sigma_h^{\otimes k} \eta J_{2q} (T_x^{\text{iso}} - I), \\ \ker(\mathcal{O} T_x^{\text{iso}}) &= (T_x^{\text{iso}})^{-1} (\chi \mathcal{P}_q). \end{aligned} \quad (\text{ACM8})$$

The first equality is expansion. The second follows because $\sigma_h^{\otimes k}$ and η are the original injections and $\ker J_{2q} = \chi \mathcal{P}_q$. This retains the actual cohomology defect of the isometry rather than assigning it an intertwining property.

Let $F(x)$ be the original logarithmic four-endpoint ratio and $\Delta_{h,k} = F(1) - F(0)$. Its signed identity is $F'(x) = \text{Tr}((U_x - W_x)C_x)$ by [AW6], or equivalently (SP4)–(SP5) and (ACM5). Both U_x, W_x have the complete spectrum 0 with multiplicity q , 1 with multiplicity 2, and 2 with multiplicity $q - 1$. All statements below also cover $q = 1$.

Write $c_1(x) \leq \dots \leq c_{2q+1}(x)$ for the eigenvalues of C_x in the original M_x metric and $d_x = c_{2q+1}(x) - c_1(x)$. Let $s_x = \dim(\text{ran } U_x \cap \text{ran } W_x)$. The two already proved pointwise bounds, on this identical source, are

$$\begin{aligned} S_{AW}(x) &= c_{q+2}(x) - c_q(x) + 2 \sum_{j=1}^{q-1} (c_{2q+2-j}(x) - c_j(x)), \\ S_{SP}(x) &= \frac{d_x}{2} \min \left\{ 4q - 2s_x, \sqrt{(2q+1)(8q-4-2\text{Tr}(U_x W_x))} \right\}. \end{aligned} \quad (\text{ACM9})$$

For completeness, their simultaneous application follows directly as follows. An orthogonal projection P of rank r satisfies $\sum_{j=1}^r c_j \leq \text{Tr}(PC_x) \leq \sum_{j=2q+2-r}^{2q+1} c_j$: in an orthonormal eigenbasis of C_x , its diagonal entries lie in $[0, 1]$ and have sum r , so moving their mass to the lowest or highest eigenvalues proves each inequality. Each of U_x, W_x is the sum of its range projection of rank $q + 1$ and its eigenvalue-two projection of rank $q - 1$. Apply these bounds to both sums and subtract their extrema to obtain $|F'(x)| \leq S_{\text{AW}}(x)$, with every multiplicity retained.

The range dimensions give $s_x \geq 1$. If E_x projects onto the intersection, then $U_x - E_x$ and $W_x - E_x$ are positive, each of trace $2q - s_x$. Therefore $\|U_x - W_x\|_1 \leq 4q - 2s_x$. The same complete spectra give

$$\text{Tr}(U_x - W_x) = 0, \quad \text{Tr}((U_x - W_x)^2) = 8q - 4 - 2\text{Tr}(U_x W_x). \quad (\text{ACM10})$$

Cauchy-Schwarz on all $2q + 1$ real eigenvalues gives the other trace-norm bound in (ACM9). Subtract the midpoint $(c_1 + c_{2q+1})I/2$ from C_x in the trace pairing; the first identity in (ACM10) leaves F' unchanged. Diagonalizing $U_x - W_x$ then bounds the pairing by $d_x \|U_x - W_x\|_1/2$. This proves $|F'(x)| \leq S_{\text{SP}}(x)$ in the same original metric.

Every subsequent bound is now evaluated on this identical path, including the centered Hilbert-Schmidt, angle and signed finite-residual controls. Retain the original monomial row $v(y) = (1, S, \dots, S^{2q})$, $S = k/2 + iy$, in the same H , and the original interpolation measure $d\mu_x(y) = ((1-x)r_{1/4}^{*k}(y) + xw_h^{*k}(y)) dy$. For compact notation put $n = 2q + 1$, $a_q = 2q - 1$, and define

$$\begin{aligned} T_q(x) &= \frac{1}{2} d_x \|U_x - W_x\|_{1, M_x}, \\ S_q(x) &= \sqrt{\left(\text{Tr}(C_x^2) - \frac{(\text{Tr } C_x)^2}{n} \right) \text{Tr}((U_x - W_x)^2)}, \\ z_x &= a_q \sqrt{1 - e^{-F(x)/a_q}}, \quad A_q(x) = z_x d_x, \\ J_q &= \int_0^1 \min\{S_{\text{AW}}(x), T_q(x), S_{\text{SP}}(x), S_q(x), A_q(x)\} dx, \\ I_q &= \int_0^1 \min\{d_x, S_{\text{AW}}(x)/z_x, T_q(x)/z_x, S_{\text{SP}}(x)/z_x, S_q(x)/z_x\} dx. \end{aligned} \quad (\text{ACM11a})$$

These symbols are exactly $E_q, T_q, O_q, S_q, A_q, J_q, I_q$ of (RMT9)-(RMT13), with $E_q = S_{\text{AW}}$ and $O_q = S_{\text{SP}}$. Equations (ACM1)-(ACM5) prove the operator and measure identities needed for that substitution. In particular they retain the actual inverse metric in the signed density $v(U_x - W_x)M_x^{-1}v^*$.

Here is the proof of the additional terms at this earlier use site. Trace zero in (ACM10) allows subtraction of $\text{Tr } C_x/n$ from C_x ; Hilbert-Schmidt Cauchy-Schwarz gives $|F'| \leq S_q$. The midpoint argument already proved gives $|F'| \leq T_q \leq S_{\text{SP}}$. Retain both complete q -entry angle lists of the minimum-section pairs $(q - 1, 2q)$ and $(q, 2q - 1)$. The second pair has a designated zero angle by the original ambient dimension. Each additional zero remains in its list. The exact projection-difference spectra give $|F'| \leq d_x \sum \sin \theta$ over the two lists. Their cosine-square determinants give $F = \sum -\log \cos^2 \theta$; applying concavity of $t \mapsto \sqrt{1 - e^{-t}}$ to the remaining $2q - 1$ entries gives $|F'| \leq A_q$, exactly as proved with every multiplicity in (RMT11). The designated zero still contributes its displayed zero to both scalar sums.

The denominator in (ACM11a) is strictly positive on this actual path. Indeed equality $F = 0$ makes both crossed minimum sections equal: their Gram difference is the squared norm of their difference, and every relative eigenvalue is at least one. Equality of their determinants makes every such eigenvalue one. In particular the constant remainder 1 would be orthogonal to $\chi \mathcal{P}_q$. The polynomial $\chi^{\#k}(S) = \overline{\chi(k - \bar{S})}$ has degree q and equals $\overline{\chi(S)}$ on $S = k/2 + iy$. That orthogonality would imply $\int |\chi|^2 d\mu_x = 0$, contradicting the positive Gram of the nonzero polynomial χ . This proves $F(x) > 0$ without inserting a new hypothesis. Compactness gives a positive minimum. All remaining functions are continuous except the intersection dimension, whose rank strata are Borel sets defined by matrix minors. Thus every displayed integral is finite.

The connection to the retained (J_*, I_*) is an exact identity, not an additional choice of estimate. Put $\Pi_N = P_N - Q_N$, the orthogonal projection onto the original minimum-section space at cutoff N . Substitution in (ACM5), including $Q_{q-1} = 0$, gives

$$U_x - W_x = (\Pi_{q-1} - \Pi_{2q}) + (\Pi_q - \Pi_{2q-1}).$$

For each pair of rank- q projections in H of dimension $2q + 1$, the complete difference spectrum consists of the positive and negative sine of each of its q principal angles and one additional ambient zero. All zero angles still contribute both of their zero entries. The triangle inequality for the trace norm therefore gives

$$\frac{1}{2} \|U_x - W_x\|_{1, M_x} \leq \sum_{j=1}^q \sin \theta_j + \sum_{j=1}^q \sin \varphi_j \leq a_q \sqrt{1 - e^{-F(x)/a_q}} = z_x. \quad (\text{ACM11b})$$

Here (θ_j) and (φ_j) are respectively the two complete angle lists just used; $\varphi_1 = 0$ is the designated forced zero. The last inequality is the same concavity calculation, and no other zero entry is removed. Consequently $T_q \leq A_q$ and the already proved $T_q \leq S_{SP}$ gives, pointwise and then by integration,

$$\begin{aligned} J_q &= \int_0^1 \min\{S_{AW}, T_q, S_q\} dx = J_*, \\ I_q &= \int_0^1 \frac{\min\{S_{AW}, T_q, S_q\}}{z_x} dx = I_*. \end{aligned} \quad (\text{ACM11c})$$

These are precisely the three terms in (AT21a)–(AT21c), through the already proved identical coefficients, measures and operators. The exact path dictionary is $B(x) = F(x)$, $a = a_q$ and $f_a(B(x)) = z_x$; it preserves the original initial value and every measure factor. For I_q , the omitted entry d_x is at least T_q/z_x by (ACM11b); the omitted overlap term is also at least T_q/z_x . Thus both equalities retain the same original nonlinear denominator.

Both bounds are finite and measurable on $[0, 1]$. Indeed the positive Grams and their inverses vary smoothly, the eigenvalues vary continuously, and the dimension s_x is a Borel function: in any fixed coefficient frame it is determined by the ranks of matrices of continuous functions, whose rank strata are given by vanishing and nonvanishing minors. Thus the triangle inequality for integration gives the combined, original-source control

$$|\Delta_{h,k}| \leq J_* \leq \underbrace{\int_0^1 \min\{S_{AW}(x), \frac{1}{2}d_x \|U_x - W_x\|_{1, M_x}\} dx}_{\mathfrak{C}_*} \leq \underbrace{\int_0^1 \min\{S_{AW}(x), S_{SP}(x)\} dx}_{\mathfrak{C}_*^{\text{ov}}}. \quad (\text{ACM11})$$

The first bound preserves the exact trace norm already present in (SP13); its proof above gives $d_x \|U_x - W_x\|_{1, M_x} / 2 \leq S_{SP}(x)$. The identity maps (ACM1)–(ACM5) identify these quantities with (AT18a), including the source density and its mass. If $b_1 \leq \dots \leq b_{2q+1}$ are the positive eigenvalues of $D = M_0^{-1}M_1$ in M_0 , the original interpolation gives

$$c_j(x) = \frac{b_j - 1}{1 - x + xb_j}, \quad \int_0^1 c_j(x) dx = \log b_j. \quad (\text{ACM12})$$

The order is preserved since differentiation of the displayed fraction with respect to b_j gives $(1 - x + xb_j)^{-2} > 0$. Integration of (ACM9) consequently yields

$$\begin{aligned} |\Delta_{h,k}| &\leq J_* \leq \mathfrak{C}_* \leq \mathfrak{C}_*^{\text{ov}} \leq \min \left\{ \mathcal{L}_q(D), \int_0^1 S_{SP}(x) dx \right\}, \\ \mathcal{L}_q(D) &= \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}. \end{aligned} \quad (\text{ACM13})$$

The same pointwise minimum also retains the individually integrated trace, centered variance and angle bounds. Termwise integration in (ACM12), with the original order and all multiplicities, proves

$$J_q \leq \min \left\{ \mathcal{L}_q(D), \int_0^1 T_q(x) dx, \int_0^1 S_{\text{SP}}(x) dx, \int_0^1 S_q(x) dx, \int_0^1 A_q(x) dx \right\} \quad (\text{ACM13a})$$

$$\mathcal{L}_q(D) \leq (2q-1) \log(b_{2q+1}/b_1).$$

The last inequality bounds each of the $1 + 2(q-1)$ logarithmic factors in the unchanged (ACM13) by $\log(b_{2q+1}/b_1)$. It is therefore valid also for $q = 1$, where the original sum is empty.

The empty sum at $q = 1$ is zero. No universal ordering of the two refinements is used: each bounds the same signed integrand, hence their pointwise minimum does. Their full original arithmetic moments, relative eigenvalues and overlap remain the actual terms to be evaluated along the growing packet family.

The actual moment interpolation above also satisfies the complete proof (AT21a)–(AT21e). With $a = 2q - 1$ its recursive additive minimum also retains the independently proved centered HS term S_{HS} in (AT21a), so $J_* \leq \mathfrak{C}_*$. The exact trace norm is at most both the overlap and full angle bounds. The nonlinear radius $I_* = \int_0^1 \min(S_{\text{spec}}, S_{\text{tr}}, S_{\text{HS}}) / [a \sqrt{1 - e^{-B(x)/a}}] dx$ is defined on the same strictly positive four-volume path, with $I_* \leq \log \kappa$. Thus the current endpoint consequence here is the simultaneous interval $\mathfrak{b}_*^- \leq B(1) \leq \mathfrak{b}_*^+$ of (AT21e), not only its additive corollary. The identity of the coefficient maps and original measures proved above verifies its hypotheses; no purity or tensor-uniform bound is supplied by this finite transport.

The following signed construction further intersects this same retained additive/nonlinear interval. By (ACM11c) its (J_q, I_q) are literally (J_*, I_*) ; hence no earlier endpoint or overlap bound is discarded.

The nonlinear coordinate also receives every one of these controls. For $B > 0$ put

$$\mathcal{H}_{a_q}(B) = 2 \operatorname{arcosh}(e^{B/(2a_q)}), \quad \Psi_{a_q}(t) = 2a_q \log \cosh(t/2) \quad (t \geq 0). \quad (\text{ACM14})$$

Their two inverse composites on the positive half-lines are identities. Direct differentiation gives

$$\mathcal{H}'_{a_q}(B) = \frac{1}{a_q \sqrt{1 - e^{-B/a_q}}}.$$

Dividing the five proved derivative bounds by z_x and integrating therefore gives $|\mathcal{H}_{a_q}(F(1)) - \mathcal{H}_{a_q}(F(0))| \leq I_q$. Moreover $I_q \leq \int dx = \log(b_n/b_1)$.

For every integer $p \geq 0$ retain the following specified finite signed construction, on the same source operators:

$$\begin{aligned} B_x^\circ &= (1-x)I + xD, & \alpha_x &= \tfrac{1}{2}(2(1-x) + x(b_1 + b_n)), & H_x^\circ &= I - B_x^\circ/\alpha_x, \\ C_x^{[p]} &= \alpha_x^{-1} \sum_{r=0}^p (H_x^\circ)^r (D - I), \\ R_x^{[p]} &= (H_x^\circ)^{p+1} C_x, & E_x^{[p]} &= R_x^{[p]} - \operatorname{Tr}(R_x^{[p]})I/n, \\ j_p &= \int_0^1 \operatorname{Tr}(C_x^{[p]}(U_x - W_x)) dx, \\ e_p &= \int_0^1 \sqrt{\operatorname{Tr}((E_x^{[p]})^2) \operatorname{Tr}((U_x - W_x)^2)} dx. \end{aligned} \quad (\text{ACM15})$$

The finite geometric identity proves $C_x - C_x^{[p]} = R_x^{[p]}$. Every factor is a real function of D , hence self-adjoint in M_x . Trace zero removes the centered scalar, so Hilbert–Schmidt Cauchy–Schwarz proves $j_p - e_p \leq \Delta_{h,k} \leq j_p + e_p$. Writing $\vartheta = (b_n - b_1)/(b_n + b_1) < 1$ and $K_D = \sum_{j=1}^n (|b_j - 1|/\min\{1, b_j\})^2$,

the full residual eigenvalues give $\text{Tr}((E_x^{[p]})^2) \leq \vartheta^{2p+2} K_D$. Both U_x, W_x dominate their range projections, whose intersection has dimension at least one, so $\text{Tr}(U_x W_x) \geq 1$. Equation (ACM10) then gives $e_p \leq \vartheta^{p+1} \sqrt{K_D(8q-6)} \rightarrow 0$. This retains the exact signed center and its controlled residual, with no assumption of uniformity in the tensor order.

Put $F_0 = F(0)$ and $H_0 = \mathcal{H}_{a_q}(F_0)$. For every $p \geq 0$ define the actual simultaneous endpoint functions

$$\begin{aligned}\beta_p^- &= \max\{0, F_0 - J_q, \Psi_{a_q}(\max\{0, H_0 - I_q\}), F_0 + j_p - e_p\}, \\ \beta_p^+ &= \min\{F_0 + J_q, \Psi_{a_q}(H_0 + I_q), F_0 + j_p + e_p\}.\end{aligned}\tag{ACM16}$$

The preceding additive, nonlinear and signed inequalities prove $\beta_p^- \leq F(1) \leq \beta_p^+$ by taking their intersection. Both original angle lists, source masses, relation maps and arithmetic Taylor unit remain fixed. At $D = cI$ all diameter and residual terms vanish: each quotient volume is multiplied by the same scalar power q , which cancels with the four signs. The formulas then give $F(1) = F_0$ exactly. Numerical integration of a signed center must retain its own integration error; (ACM15) specifies exact integrals.

128.1 The literal graph augmentation on this finite coefficient source

The following additional calculation uses the full quartet domain of PGB.1: $\gamma > 2, 0 < \delta < 1/2, m, k \geq 1$. It leaves the preceding Gamma-to-arithmetic formulas on their entire stated domain. Here χ is the literal monic polynomial

$$\chi(S) = \prod_{a,b=0}^k (S - k/2 - (2a - k)\delta - i(2b - k)\gamma)^{1+k(m-1)}.\tag{ACM17}$$

Thus (HT2) and PGB.1 have identical roots, multiplicities, leading coefficient, increasing remainder frame and remainder map; their coefficient identification is the identity, including every nilpotent primary coordinate. Retain $g = 2\xi, v_h = g/h, \Phi' = h, \Phi(0) = 0, s_i = 1/2 + it_i, \Sigma = \sum_i s_i$ and $\tau_k = \sum_i \Phi(s_i)$. The integration measure in the full source is $\prod_i dt_i/(2\pi)$, and

$$\begin{aligned}(\mathcal{V}P)(\mathbf{t}) &= \left(\prod_i v_h(s_i)\right) P(\Sigma), \\ L_{\text{obs}}x &= \left(\prod_i v_h(s_i)\right) \sum_{b=0}^{q-1} x_b \text{rem}_{h(s_1), \dots, h(s_k)}(\tau_k \Sigma^b), \\ D_{\text{def}}P &= \tau_k \mathcal{V}P - L_{\text{obs}} J_{2q} P, \quad H = \mathcal{P}_{2q}, \quad M^{\text{ar}} = \mathcal{V}^* \mathcal{V}.\end{aligned}\tag{ACM18}$$

The symbols L_{obs} and D_{def} denote exactly L and D_{2q} of PGB.2; neither is the circle circumference or the positive relative matrix below. PGB.2 and its leading-coefficient argument prove that these columns lie in the stated Hilbert source and that D_{def} is injective. In particular every following finite Gram exists and is positive. On the unchanged coefficient space define the actual affine path

$$M_x^{\text{gr}} = M^{\text{ar}} + x D_{\text{def}}^* D_{\text{def}}, \quad 0 \leq x \leq 1, \quad \mathcal{V}_x^{\text{gr}} P = (\mathcal{V}P, \sqrt{x} D_{\text{def}} P).\tag{ACM19}$$

Its Gram is exactly M_x^{gr} , by the orthogonal direct-sum norm; no mixed term was omitted. At $x = 1$ this is the unchanged graph of PGB.2. The restriction to $\mathcal{P}_N$ uses the literal I_N and has defect $D_{\text{def}} I_N = D_N$: monic remainders satisfy $J_{2q} I_N = J_N$, proving this equality directly in (ACM18). Its relation columns are $I_N B_N^{\text{AW}}$, exactly as in (ACM3).

Use (ACM4)–(ACM5) with this new, explicitly specified form and put $U_x^{\text{gr}} = Q_{2q-1} + Q_{2q} - Q_q$ and $W_x^{\text{gr}} = P_{2q-1} - P_{q-1} + P_{2q} - P_q$. Let $G_N(x)$ denote the quotient Gram of its restriction and set

$$\begin{aligned}F_{\text{gr}}(x) &= \log \det G_{q-1}(x) + \log \det G_q(x) - \log \det G_{2q-1}(x) - \log \det G_{2q}(x), \\ C_x^{\text{gr}} &= (M_x^{\text{gr}})^{-1} D_{\text{def}}^* D_{\text{def}}, \quad A_x^{\text{gr}} = U_x^{\text{gr}} - W_x^{\text{gr}}, \\ \Gamma_k^{\text{gr}} &= F_{\text{gr}}(1) - F_{\text{gr}}(0) = \hat{\mathcal{B}}_k - \mathcal{B}_k.\end{aligned}\tag{ACM20}$$

Here $\widehat{\mathcal{B}}_k$ is the four-endpoint logarithm of $\widehat{G}_N$ in PGB.26, and $\mathcal{B}_k$ is that of the original arithmetic source. To prove the derivative at this use site, the minimum section $R_N(x)$ satisfies $J_N R_N = I$ and $B_N^* M_N(x) R_N = 0$. Differentiating the first equality puts $\dot{R}_N$ in the relation space. The two cross terms in $d(R_N^* M_N R_N)/dx$ therefore vanish by the second equality, and $\dot{G}_N = R_N^* \dot{M}_N R_N$. Jacobi's determinant formula and finite trace cyclicity give $d \log \det G_N/dx = \text{Tr}((P_N - Q_N)C_x^{\text{gr}})$. Taking the four signs proves

$$F'_{\text{gr}}(x) = \text{Tr}(A_x^{\text{gr}} C_x^{\text{gr}}). \quad (\text{ACM21})$$

The flag inclusions imply that each difference of nested orthogonal projections is an orthogonal projection. In particular Q_q has rank one and is contained in both Q_{2q-1} and Q_{2q} . The original dimensions give the complete spectra $0^{[q]}, 1^{[2]}, 2^{[q-1]}$ for $U_x^{\text{gr}}, W_x^{\text{gr}}$. Their traces agree, so $\text{Tr} A_x^{\text{gr}} = 0$ and

$$\text{Tr}((A_x^{\text{gr}})^2) = 8q - 4 - 2 \text{Tr}(U_x^{\text{gr}} W_x^{\text{gr}}). \quad (\text{ACM22})$$

These arguments use positive finite forms and the same flags; they do not use a scalar moment representation of the graph norm. Hence the proofs at (ACM9)–(ACM11a) apply to their spectral, trace-norm, overlap and centered Hilbert–Schmidt terms. Explicitly let $c_1^{\text{gr}} \leq \dots \leq c_n^{\text{gr}}$ be the full eigenvalue list of C_x^{gr} , $n = 2q + 1$, and let $d_x^{\text{gr}} = c_n^{\text{gr}} - c_1^{\text{gr}}$ and $s_x^{\text{gr}} = \dim(\text{ran } U_x^{\text{gr}} \cap \text{ran } W_x^{\text{gr}})$. Set

$$\begin{aligned} E_{\text{gr}}(x) &= c_{q+2}^{\text{gr}} - c_q^{\text{gr}} + 2 \sum_{j=1}^{q-1} (c_{2q+2-j}^{\text{gr}} - c_j^{\text{gr}}), \\ T_{\text{gr}}(x) &= \frac{1}{2} d_x^{\text{gr}} \|A_x^{\text{gr}}\|_{1, M_x^{\text{gr}}}, \\ O_{\text{gr}}(x) &= \frac{1}{2} d_x^{\text{gr}} \min \left\{ 4q - 2s_x^{\text{gr}}, \sqrt{n \text{Tr}((A_x^{\text{gr}})^2)} \right\}, \\ S_{\text{gr}}(x) &= \sqrt{\left(\text{Tr}((C_x^{\text{gr}})^2) - \frac{(\text{Tr} C_x^{\text{gr}})^2}{n} \right) \text{Tr}((A_x^{\text{gr}})^2)}, \\ J_{\text{gr}} &= \int_0^1 \min\{E_{\text{gr}}, T_{\text{gr}}, O_{\text{gr}}, S_{\text{gr}}\} dx. \end{aligned} \quad (\text{ACM23})$$

Rank-stratum measurability and continuity of the other entries prove integrability exactly as before. The four pointwise trace proofs give $|\Gamma_k^{\text{gr}}| \leq J_{\text{gr}}$.

For a specified integer $p \geq 0$, this same path also has an actual signed finite approximation. Put

$$\begin{aligned} D^{\text{gr}} &= (M^{\text{ar}})^{-1} (M^{\text{ar}} + D_{\text{def}}^* D_{\text{def}}), \quad 1 < b_1^{\text{gr}} \leq \dots \leq b_n^{\text{gr}}, \\ B_x^{\text{gr}} &= (1-x)I + xD^{\text{gr}}, \quad \alpha_x^{\text{gr}} = 1-x + \frac{x}{2}(b_1^{\text{gr}} + b_n^{\text{gr}}), \\ H_x^{\text{gr}} &= I - B_x^{\text{gr}}/\alpha_x^{\text{gr}}, \quad C_x^{[p],\text{gr}} = (\alpha_x^{\text{gr}})^{-1} \sum_{r=0}^p (H_x^{\text{gr}})^r (D^{\text{gr}} - I), \\ R_x^{[p],\text{gr}} &= (H_x^{\text{gr}})^{p+1} C_x^{\text{gr}}, \quad E_x^{[p],\text{gr}} = R_x^{[p],\text{gr}} - \text{Tr}(R_x^{[p],\text{gr}})I/n, \\ j_{p,\text{gr}} &= \int_0^1 \text{Tr}(C_x^{[p],\text{gr}} A_x^{\text{gr}}) dx, \\ e_{p,\text{gr}} &= \int_0^1 \sqrt{\text{Tr}((E_x^{[p],\text{gr}})^2) \text{Tr}((A_x^{\text{gr}})^2)} dx. \end{aligned} \quad (\text{ACM24})$$

The strict lower bound for b_1^{gr} follows from injectivity of D_{def} in this finite dimension. The finite geometric identity gives $C_x^{\text{gr}} - C_x^{[p],\text{gr}} = R_x^{[p],\text{gr}}$. All these factors are real functions of the same D^{gr} , so they are self-adjoint for M_x^{gr} . Pairing the last identity with the trace-zero A_x^{gr} and applying Hilbert–Schmidt Cauchy–Schwarz proves

$$j_{p,\text{gr}} - e_{p,\text{gr}} \leq \Gamma_k^{\text{gr}} \leq j_{p,\text{gr}} + e_{p,\text{gr}}. \quad (\text{ACM25})$$

For completeness set

$$\vartheta_{\text{gr}} = \frac{b_n^{\text{gr}} - b_1^{\text{gr}}}{b_n^{\text{gr}} + b_1^{\text{gr}}}, \quad K_{\text{gr}} = \sum_{j=1}^n \left(\frac{|b_j^{\text{gr}} - 1|}{\min\{1, b_j^{\text{gr}}\}} \right)^2.$$

The eigenvalue formula $c_j^{\text{gr}}(x) = (b_j^{\text{gr}} - 1)/(1 - x + xb_j^{\text{gr}})$ shows $\|H_x^{\text{gr}}\| \leq \vartheta_{\text{gr}} < 1$ and $\text{Tr}((E_x^{[p],\text{gr}})^2) \leq \vartheta_{\text{gr}}^{2p+2} K_{\text{gr}}$. The range intersection has dimension at least one. Since each of $U_x^{\text{gr}}, W_x^{\text{gr}}$ dominates its range projection, the positive-product trace inequality gives $\text{Tr}(U_x^{\text{gr}} W_x^{\text{gr}}) \geq 1$. Together with (ACM22), this proves

$$e_{p,\text{gr}} \leq \vartheta_{\text{gr}}^{p+1} \sqrt{K_{\text{gr}}(8q - 6)} \rightarrow 0. \quad (\text{ACM26})$$

Thus the two actual signed endpoints

$$g_{p,\text{gr}}^- := \max\{-J_{\text{gr}}, j_{p,\text{gr}} - e_{p,\text{gr}}\}, \quad g_{p,\text{gr}}^+ := \min\{J_{\text{gr}}, j_{p,\text{gr}} + e_{p,\text{gr}}\} \quad (\text{ACM27})$$

satisfy $g_{p,\text{gr}}^- \leq \Gamma_k^{\text{gr}} \leq g_{p,\text{gr}}^+$. This calculation uses no division by the angle coordinate of the new graph form. The moment-path nonlinear formulas (ACM14)–(ACM16) retain their original scope. All integrals in (ACM23)–(ACM27) are exact integrals of the displayed finite matrices; numerical evaluation must add its own certified integration error.

128.2 The complete original relation rows in the graph endpoint control

Keep exactly the domain and coefficient identity of (ACM17)–(ACM20). The symbols in this paragraph include a superscript *rel* so that the monic relation polynomial is never confused with a consecutive quotient-volume ratio. They are the literal objects of (PGRT.2)–(PGRT.8):

$$\begin{aligned} r_k(u) &= \int_{\sum t_i=u} (1 + |\tau_k|^2) \prod_i w_h(t_i), \quad F_b = \text{rem}_{h(s_1), \dots, h(s_k)}(\tau_k \Sigma^b), \\ z_b(u) &= \int_{\sum t_i=u} \overline{\tau_k} F_b \prod_i w_h(t_i), \quad g_x = z(u)x/r_k(u), \quad F^0 x = (sx)(k/2 + iu) - g_x(u), \\ d_j^{\text{rel}} &= \chi p_{j+1-q}, \quad a_j^{\text{rel}} = \int |d_j^{\text{rel}}(k/2 + iu)|^2 r_k(u) du > 0, \\ (\alpha_j^{\text{rel}})_b &= \int \overline{d_j^{\text{rel}}(k/2 + iu)} ((k/2 + iu)^b r_k(u) - z_b(u)) du, \quad j \geq q-1, \quad 0 \leq b < q. \end{aligned} \quad (\text{ACM28})$$

Here $s : E \rightarrow \mathcal{P}_{q-1}$ is the original monic remainder section, p_n is the unique monic polynomial of degree n orthogonal to lower polynomials for $|\chi|^2 r_k du$, and the fibre integral eliminates t_k with its original Lebesgue measure. For $k = 1$ it is evaluation. The constant factors are $w_h(t) = |v_h(1/2 + it)|^2/(2\pi)$ throughout. Each coefficient is absolutely integrable by the proved polynomial exponential moments and Cauchy–Schwarz applied to F^0 . Expanding the full polynomials in these integrals gives the finite products of the original one-factor moments in (PGS.35) and (PGS.38), without dropping their conjugate or cross terms. The coefficients of p_n are obtained from its positive finite lower-polynomial Gram system. This is the exact finite arithmetic evaluation of each row.

The complete weighted density proof (PGRT.3)–(PGRT.6) gives

$$\widehat{G}_N - \Omega_k = \sum_{j=N}^{\infty} (a_j^{\text{rel}})^{-1} (\alpha_j^{\text{rel}})^* \alpha_j^{\text{rel}}, \quad \Omega_k = K_{\text{low}} + D_{\text{mix}}^* D_{\text{mix}} > 0. \quad (\text{ACM29})$$

The series converges in the original finite matrix operator norm. Specifically, the relation columns are a complete orthogonal family in $L^2(r_k du)$; the coefficient of $F^0 x$ on its j th column is $(a_j^{\text{rel}})^{-1} \alpha_j^{\text{rel}} x$. Removing the first $N - q + 1$ columns is precisely minimization over the original relations $\chi \mathcal{P}_{N-q}$.

Parseval gives the displayed quadratic forms, and polarization gives their matrices. The trace of the remaining positive tail is the sum of the squared tails of the q fixed frame vectors, hence tends to zero and bounds its operator norm. The positive completed term and its mixed realization are the same as (HC22), with full proof in PGMB.

For $q - 1 \leq j \leq 2q - 1$ put

$$\begin{aligned} l_j^{\text{rel}} &= (a_j^{\text{rel}})^{-1} \alpha_j^{\text{rel}} \widehat{G}_{q-1}^{-1} (\alpha_j^{\text{rel}})^*, \\ u_j^{\text{rel}} &= (a_j^{\text{rel}})^{-1} \alpha_j^{\text{rel}} \widehat{G}_{2q}^{-1} (\alpha_j^{\text{rel}})^*, \\ Z_{2q}^{\text{mix}} x &= (D_{\text{mix}} x, f_{2q} x), \\ u_j^{\text{rel}} &= (a_j^{\text{rel}})^{-1} \alpha_j^{\text{rel}} K_{\text{low}}^{-1} (\alpha_j^{\text{rel}})^* \\ &\quad - (a_j^{\text{rel}})^{-1} \left\| (I + Z_{2q}^{\text{mix}} K_{\text{low}}^{-1} (Z_{2q}^{\text{mix}})^*)^{-1/2} Z_{2q}^{\text{mix}} K_{\text{low}}^{-1} (\alpha_j^{\text{rel}})^* \right\|^2. \end{aligned} \tag{ACM30}$$

The domain of Z_{2q}^{mix} is the original E , and its ordered target is the mixed weighted Hilbert space of (HC22) followed by $L^2(r_k du)$. In particular it retains the finite tail as well as the mixed component. To prove the subtraction, write $K = K_{\text{low}}$ and $Z = Z_{2q}^{\text{mix}}$. The identity $\widehat{G}_{2q} = K + Z^* Z$ gives

$$(K + Z^* Z)^{-1} = K^{-1} - K^{-1} Z^* (I + Z K^{-1} Z^*)^{-1} Z K^{-1}.$$

Multiplication by $K + Z^* Z$ cancels the leftover factor $Z^* Z K^{-1} - Z^* (I + Z K^{-1} Z^*) (I + Z K^{-1} Z^*)^{-1} Z K^{-1}$. The target inverse exists because it is the identity off the finite-dimensional range of Z and is positive with eigenvalues at least one on that range. Pairing with the specified row proves (ACM30). If $k \geq 2$ and $\alpha_j^{\text{rel}} \neq 0$, the subtracted squared norm is strictly positive: D_{mix} is injective by the full fixed-sum calculation PGM.6–9, and the displayed inverse square root has zero kernel. For $k = 1$ its mixed component is zero but its finite tail is retained. A zero row gives zero in both terms. These statements retain the original strictness domain and the whole negative term.

Use the endpoint weights $\omega_{q-1} = \omega_{2q-1} = 1$ and $\omega_j = 2$ for $q \leq j \leq 2q - 2$, and define

$$\begin{aligned} L_k^{\text{rel}} &= \sum_{j=q-1}^{2q-1} \omega_j \log(1 + l_j^{\text{rel}}), \quad U_{k,2q}^{\text{rel}} = \sum_{j=q-1}^{2q-1} \omega_j \log(1 + u_j^{\text{rel}}), \\ L_k^{\text{rel}} &\leq \widehat{\mathcal{B}}_k \leq U_{k,2q}^{\text{rel}}, \\ L_k^{\text{rel}} - g_{s,\text{gr}}^+ &\leq \mathcal{B}_k \leq U_{k,2q}^{\text{rel}} - g_{s,\text{gr}}^- \quad (s \geq 0). \end{aligned} \tag{ACM31}$$

To verify every index, (ACM29) gives $\widehat{G}_j = \widehat{G}_{j+1} + (a_j^{\text{rel}})^{-1} (\alpha_j^{\text{rel}})^* \alpha_j^{\text{rel}}$. The rank-one determinant identity therefore gives the j th decrement $\log(1 + (a_j^{\text{rel}})^{-1} \alpha_j^{\text{rel}} \widehat{G}_{j+1}^{-1} (\alpha_j^{\text{rel}})^*)$. Since $\widehat{G}_{2q} \preceq \widehat{G}_{j+1} \preceq \widehat{G}_{q-1}$, inverse order bounds its argument between $1 + l_j^{\text{rel}}$ and $1 + u_j^{\text{rel}}$. Inverse order follows by congruence with the smaller positive form, inversion of its positive eigenvalues, and reversal of that congruence. Summing the decrements from $q - 1$ to $2q - 2$ and from q to $2q - 1$ gives precisely the displayed weights. The full quartet in (ACM17) has $q \geq 4$, so the listed endpoints and interior have these literal ranges. Finally (ACM20) says $\mathcal{B}_k = \widehat{\mathcal{B}}_k - \Gamma_k^{\text{gr}}$. Subtracting (ACM27) yields the last line, with its ordered negative $g_{s,\text{gr}}^-$ term intact. This is a finite relation-row bound on the same arithmetic scalar; it does not replace the exact value of $\widehat{\mathcal{B}}_k$ when that value is retained.

All retained relation correlations in the same inverse. The complete calculation PGRC.1–18 now sharpens the row enclosure (ACM31) by evaluating its full cross terms. Keep $H = \widehat{G}_{2q}$, $I = \{q - 1, \dots, 2q - 1\}$ and put $C_{ij} = \alpha_i^{\text{rel}} H^{-1} (\alpha_j^{\text{rel}})^*$. For an ordered subset $J \subset I$ let A_J have the

corresponding original rows, let $D_J = \text{diag}(a_i^{\text{rel}} : i \in J)$, and define

$$\begin{aligned} H_J &= H + A_J^* D_J^{-1} A_J, \quad B_J = D_J + C_{JJ}, \\ V_J : (E, H_J) &\longrightarrow (E, H) \oplus (\mathbb{C}^J, D_J^{-1}), \quad V_J x = (x, A_J x), \\ V_J^\dagger(y, z) &= H_J^{-1}(Hy + A_J^* D_J^{-1} z), \\ V_J^\dagger V_J &= I_E, \quad \ker V_J = 0, \quad \ker V_J^\dagger = \{(y, z) : Hy + A_J^* D_J^{-1} z = 0\}. \end{aligned} \tag{ACM32}$$

The norm expansion proves the Gram H_J and the adjoint; multiplication proves the inverse on the image and both kernel descriptions. Empty subsets mean the zero-dimensional coordinate space and its unique empty inverses. For every subset, direct multiplication also proves $H_J^{-1} = H^{-1} - H^{-1} A_J^* B_J^{-1} A_J H^{-1}$: the extra middle factor is $D_J^{-1} - B_J^{-1} - D_J^{-1} C_{JJ} B_J^{-1} = 0$ because $I + D_J^{-1} C_{JJ} = D_J^{-1} B_J$.

Let $J_j = \{j+1, \dots, 2q-1\}$. For $J \subset J_j$ put $r_j(J) = C_{jJ} B_J^{-1} C_{Jj}$ and $v_j(J) = (C_{jj} - r_j(J))/a_j^{\text{rel}}$. The inverse identity proves $v_j(J) = \alpha_j^{\text{rel}} H_J^{-1} (\alpha_j^{\text{rel}})^* / a_j^{\text{rel}} \geq 0$. Telescoping (ACM29) identifies $H_{J_j} = \widehat{G}_{j+1}$. Thus the exact decrement parameter is

$$\eta_j = \frac{C_{jj} - C_{jJ_j} (D_{J_j} + C_{J_j J_j})^{-1} C_{J_j j}}{a_j^{\text{rel}}}. \tag{ACM33}$$

For disjoint $J, K \subset J_j$, keep the remaining block and row

$$\begin{aligned} S_{K|J} &= D_K + C_{KK} - C_{KJ} B_J^{-1} C_{JK} = D_K + A_K H_J^{-1} A_K^* \succeq D_K > 0, \\ e_{j,K|J} &= C_{jK} - C_{jJ} B_J^{-1} C_{JK} = \alpha_j^{\text{rel}} H_J^{-1} A_K^*, \\ r_j(J \cup K) - r_j(J) &= e_{j,K|J} S_{K|J}^{-1} e_{j,K|J}^*, \\ 0 \leq r_j(J \cup K) - r_j(J) &\leq \sum_{i \in K} |(e_{j,K|J})_i|^2 / a_i^{\text{rel}}. \end{aligned} \tag{ACM34}$$

Substitution of the proved inverse gives the first two lines. For interleaved disjoint subsets, first use the exact coordinate map $P_{J,K} : \mathbb{C}^{J \cup K} \rightarrow \mathbb{C}^J \oplus \mathbb{C}^K$, $z \mapsto (z|_J, z|_K)$, with inverse reassembling the coordinates in their inherited order. This is an isometry for the retained diagonal lengths: its two squared norms sum to the original sum over $J \cup K$. On coefficient matrices it is a permutation, so $P_{J,K} (D_{J \cup K} + C_{J \cup K, J \cup K}) P_{J,K}^{-1}$ is exactly the displayed two-block matrix. Conjugating the inverse and applying the same restriction to the row leaves the scalar $r_j(J \cup K)$ unchanged. To prove the third line, solve the resulting two block equations $B_J x + C_{JK} y = C_{Jj}$ and $C_{KJ} x + (D_K + C_{KK}) y = C_{Kj}$. The first gives $x = B_J^{-1} (C_{Jj} - C_{JK} y)$ and the second then gives $y = S_{K|J}^{-1} e_{j,K|J}^*$. Pairing with (C_{jJ}, C_{jK}) proves exactly the displayed quadratic correction. Inverse order from $S_{K|J} \succeq D_K$ gives the final inequality. In particular all cross subtractions are retained even when they vanish.

Choose actual finite subsets $J(j) \subset J_j$, let $K(j) = J_j \setminus J(j)$, and set

$$\begin{aligned} \bar{\eta}_j &= v_j(J(j)), \quad \underline{\eta}_j = \max \left\{ l_j^{\text{rel}}, v_j(J(j)) - \sum_{i \in K(j)} \frac{|(e_{j,K(j)|J(j)})_i|^2}{a_j^{\text{rel}} a_i^{\text{rel}}} \right\}, \\ L_k^{\text{corr}}(J) &= \sum_{j=q-1}^{2q-1} \omega_j \log(1 + \underline{\eta}_j), \quad U_k^{\text{corr}}(J) = \sum_{j=q-1}^{2q-1} \omega_j \log(1 + \bar{\eta}_j), \\ L_k^{\text{rel}} &\leq L_k^{\text{corr}}(J) \leq \widehat{B}_k \leq U_k^{\text{corr}}(J) \leq U_{k,2q}^{\text{rel}}. \end{aligned} \tag{ACM35}$$

The last line of (ACM34) with $J \cup K = J_j$ proves $0 \leq \underline{\eta}_j \leq \eta_j \leq \bar{\eta}_j$. Moreover $\underline{\eta}_j \geq l_j^{\text{rel}}$ and $\bar{\eta}_j \leq C_{jj}/a_j^{\text{rel}} = u_j^{\text{rel}}$. Increasing logarithms and the unchanged endpoint weights prove all the

inequalities in (ACM35). If every $J(j) = J_j$, the remaining block is empty and both new bounds equal the exact graph volume. Insertion of one further index b subtracts exactly

$$\frac{|C_{jb} - C_{jJ}B_J^{-1}C_{Jb}|^2}{a_j^{\text{rel}}(a_b^{\text{rel}} + C_{bb} - C_{bJ}B_J^{-1}C_{Jb})}$$

from $v_j(J)$, by (ACM34). Its denominator is positive. Thus successive upper bounds decrease and become exact after at most q later-row insertions for each row; retaining the maximum of all previous valid lower bounds makes that retained sequence increasing as well.

In particular the exact $a_j^{\text{rel}}\eta_j$ is the nonnegative $\alpha_j^{\text{rel}}K_{\text{low}}^{-1}(\alpha_j^{\text{rel}})^*$ minus the full squared norm in (ACM30) minus $C_{jJ_j}(D_{J_j} + C_{J_jJ_j})^{-1}C_{J_jj}$. The latter vanishes exactly when $C_{J_jj} = 0$, because its inverse matrix is positive. This proves that both negative corrections occur in the same original inverse quantity. Their signs and equality cases are retained. The matrix C in the correlation subtraction is computed using $\hat{G}_{2q}^{-1}$, with its full mixed term; it is never replaced there by K_{low}^{-1} .

At every independent coefficient face $(W, S; A)$ the coefficient inclusions and zero entries act componentwise on these same linear source maps. Retain the original source F_h with $\mathcal{M}F_h = g/h$, $D_i = -x_i\partial_{x_i}$, $h(D)F_h = \Theta\phi_*$, and $\mathcal{V}P = P(D_1 + \cdots + D_k)F_h^{\otimes k}$ from (ISM1). The full Taylor unit in that observation is unchanged. The original minimum-section difference is a relation χQ ; successive monic division constructs $\chi(\sum s_i)Q(\sum s_i) = \sum_i h(s_i)Q_i(\mathbf{s})$. Its original primitive is $\sum_i (-1)^{i-1}Q_i(D_1, \dots, D_k)(F_h^{\otimes(i-1)} \otimes \phi_* \otimes F_h^{\otimes(k-i)})$. The tensor differential contributes the same sign and therefore recovers the relation. The differential operators commute with the original tensor differential, and $h(D_i)F_h = \Theta\phi_*$, proving that its image is exactly $\mathcal{V}(\chi Q)$. For the original two-leg complex, use the degree-zero map $j_+(v) = (v, 0)$ and degree-one identity into $[V \oplus \hat{V} \rightarrow \mathcal{B}]$, whose differential is $\Theta(\phi - \mathcal{F}^{-1}\hat{\psi})$. The tensor cochain map preserves every sign and gives the same top boundary. The one-factor two-leg differential has the entire diagonal kernel $(v, \mathcal{F}v)$: its zero equation is equivalent to $\phi = \mathcal{F}^{-1}\hat{\psi}$ by injectivity of Θ , and every such diagonal pair has zero differential. When the two compared top representatives lie in an admitted proper subcomplex $\mathbf{C}_{W,S;A}^\bullet$ of the fixed full coefficient carrier, their residual is the class in $(d\mathbf{C}_{\text{full}}^{k-1} \cap \mathbf{C}_{W,S;A}^k)/d\mathbf{C}_{W,S;A}^{k-1}$, with its complete two-leg primitive retained. The inclusion-induced map sends a numerator representative to its class in $\mathbf{C}_{W,S;A}^k/d\mathbf{C}_{W,S;A}^{k-1}$. Its image is exactly the kernel of the map to the full top quotient: mapping to zero there means being a full boundary. Its inverse uses that same representative, and both are well-defined because their denominator is the identical $d\mathbf{C}_{W,S;A}^{k-1}$. This proves the stated kernel isomorphism, as in the complete coefficient and source maps (ISM38)–(ISM43). Consequently none of the metric estimates deletes this residual, the full diagonal degree-zero source, or an empty mask's outer label.

129 The actual single-primary marked family and its complete boundary monodromy

This calculation specializes the original marked polynomial family to a single selected zero with its complete order. The parameter t is fixed at its original value zero. The variable s , its ascending monomial basis, the primitive with value zero at $s = 0$, and the original theta source are retained. A translation below is a displayed coordinate isomorphism on that same family; its constant term and contour transport are part of the calculation.

129.1 The actual packet and the exact Pascal map

Let ρ be a selected actual nontrivial zero of $g = 2\xi$, of complete order $m \geq 1$. Put

$$n = m + 1, \quad h(s) = (s - \rho)^m, \quad E_h = \mathbb{C}[s]/((s - \rho)^m), \quad A_s = M_s : E_h \rightarrow E_h. \quad (\text{SP.1})$$

The original polynomial primitive is exactly

$$\Phi_h(s) = \frac{(s - \rho)^n - (-\rho)^n}{n} = \frac{y^n}{n} + c, \quad y = s - \rho, \quad c = -\frac{(-\rho)^n}{n}. \quad (\text{SP.2})$$

Differentiation gives $\Phi'_h = h$, and substitution $s = 0$ gives $\Phi_h(0) = 0$. Thus its constant has not been reassigned. Since a nontrivial zero ρ is nonzero, this complex number c is nonzero; later coefficient specializations may send it to zero and are treated separately.

Write $e_s = (1, s, \dots, s^{m-1})$ and $e_y = (1, y, \dots, y^{m-1})$ as ordered rows. The coefficient map from the former basis to the latter is the explicit Pascal matrix

$$e_s = e_y P, \quad P_{ab} = \begin{cases} \binom{b}{a} \rho^{b-a}, & 0 \leq a \leq b < m, \\ 0, & a > b, \end{cases} \quad (P^{-1})_{ab} = \begin{cases} \binom{b}{a} (-\rho)^{b-a}, & a \leq b, \\ 0, & a > b. \end{cases} \quad (\text{SP.3})$$

The binomial theorem proves the first identity. Substituting $s = y + \rho$ and $y = s - \rho$ in succession gives the identity on every monomial, proving the inverse formula. Both matrices have diagonal entries one and determinant one. If x_s is an original coefficient column, its new coordinates are exactly $x_y = P x_s$.

The polynomial-exponential complex at $t = 0$ is

$$\mathbb{C}[u, s] \xrightarrow{L_u} \mathbb{C}[u, s] ds, \quad L_u = u \partial_s + (s - \rho)^m. \quad (\text{SP.4})$$

Under the same translation $ds = dy$ and $L_u = u \partial_y + y^m$. For a nonzero polynomial Q , the degree of $L_u Q$ in s is exactly $\deg Q + m$, with the same leading coefficient. Successive subtraction of its leading monomials therefore gives a unique remainder of degree below m . The complex is injective in degree zero and its degree-one cohomology is the free module

$$\mathcal{H} = \bigoplus_{b=0}^{m-1} \mathbb{C}[u] [s^b ds], \quad \mathcal{H}/u\mathcal{H} = E_h ds. \quad (\text{SP.5})$$

The unique-remainder proof also verifies the equality after specialization: at $u = 0$ the differential is multiplication by the original h , retaining its complete primary order.

129.2 The two boundary coefficients in the unchanged basis

The BC connection is defined by monic division of $\Phi_h(s)s^b$ by $h(s)$. Here that division is explicit:

$$\Phi_h(s)s^b = h(s) \frac{(s - \rho)s^b}{n} + cs^b, \quad q_b(s) = \frac{(s - \rho)s^b}{n}, \quad r_b(s) = cs^b. \quad (\text{SP.6})$$

For $0 \leq b < m$, its quotient derivative is already a remainder:

$$q'_b(s) = \frac{(b+1)s^b - b\rho s^{b-1}}{n}, \quad (\text{SP.7})$$

where the second term is zero for $b = 0$. Subtracting $L_u q_b$ in (SP.6) proves $[\Phi_h s^b] = [cs^b - u q'_b]$ in (SP.5). Thus the exact coefficient matrices and connection are

$$C_s = cI_m, \quad (B_s)_{bb} = \frac{b+1}{n}, \quad (B_s)_{b-1,b} = -\frac{b\rho}{n} \quad (1 \leq b < m), \quad \nabla_u = \partial_u - \frac{cI_m}{u^2} + \frac{B_s}{u}, \quad (\text{SP.8})$$

and all other entries of B_s are zero. The induced degree-one formula comes from the original chain connection $\nabla_u^1 = \partial_u - \Phi_h/u^2$ and $\nabla_u^0 = \partial_u - \Phi_h/u^2 + 1/u$. Indeed $[L_u, \partial_u] = -\partial_s$ and $[L_u, -\Phi_h/u^2] = -h/u$, so $\nabla_u^1 L_u = L_u \nabla_u^0$. This proves the connection on the stated complex, with the degree-zero correction and the marked scalar retained.

In the y -coordinates, the same division of $(y^n/n + c)y^a$ gives the quotient y^{a+1}/n . Consequently

$$PB_sP^{-1} = \text{diag}(\beta_0, \dots, \beta_{m-1}), \quad \beta_a = \frac{a+1}{n}, \quad PC_sP^{-1} = cI_m, \quad \text{Tr } B_s = \frac{m}{2}. \quad (\text{SP.9})$$

This also proves the matrix conjugation directly, without replacing the original matrix by one having the same eigenvalues.

129.3 The original ordered contours and their exact translation

Fix a branch $\log u = \log |u| + i \arg u$ on a simply connected sector of $\mathbb{C}^\times$. Put

$$\vartheta_j = \frac{\arg u + \pi}{n} + \frac{2\pi j}{n}, \quad \ell_j = \{re^{i\vartheta_j} : 0 \leq r < \infty\}, \quad \Gamma_j = -\ell_0 + \ell_j \quad (1 \leq j \leq m), \quad (\text{SP.10})$$

with each ℓ_j oriented toward infinity. These are the original ordered contours in the s -plane. Their periods, in the original monomial columns, are

$$(\Pi_s(u))_{jb} = \int_{\Gamma_j} e^{\Phi_h(s)/u} s^b ds, \quad 1 \leq j \leq m, \quad 0 \leq b < m. \quad (\text{SP.11})$$

We prove the translation needed to evaluate these exact contours. For $a \in [0, 1]$, translate the broken contour by $a\rho$. Its two ends remain in the same ordered decay sectors, while its junction moves from 0 to $a\rho$. Truncate its two rays at radius R . Cauchy's theorem applies to the quadrilateral swept by each finite ray because the integrand is entire in s . The two junction paths have opposite orientations in $-\ell_0 + \ell_j$ and cancel. Each remaining connector has length at most $|\rho|$ and lies at $s = Re^{i\vartheta_l} + a\rho$, $l = 0, j$. Uniformly for $a \in [0, 1]$,

$$\text{Re} \frac{\Phi_h(s)}{u} = -\frac{R^n}{n|u|} + O(R^{n-1}) + O(1). \quad (\text{SP.12})$$

This follows by expanding $(Re^{i\vartheta_l} + (a-1)\rho)^n$, whose leading term divided by nu has the displayed negative real value. The polynomial factor is $O((1+R)^b)$; the connector integrals therefore tend to zero as $R \rightarrow \infty$. The same estimate proves absolute convergence of all rays. It follows that each period over its original Γ_j equals the period over $\rho + \Gamma_j$. This is the exact sector-preserving contour deformation, with the original orientation and junction cancellation.

On the latter contour set $s = \rho + y$. The binomial expansion is exactly (SP.3), while (SP.2) retains the factor $e^{c/u}$. Let

$$\zeta = e^{2\pi i/n}, \quad W_{ja} = \zeta^{j(a+1)} - 1, \quad d_a = n^{\beta_a-1} e^{\pi i \beta_a} \Gamma(\beta_a), \quad D(u) = \text{diag}(d_a u^{\beta_a})_{a=0}^{m-1}. \quad (\text{SP.13})$$

On the j -th y -ray, the substitution $v = r^n/(n|u|)$, with its specified positive real radial variable, gives

$$\int_{\ell_j} e^{y^n/(nu)} y^a dy = n^{\beta_a-1} e^{\pi i \beta_a} \Gamma(\beta_a) u^{\beta_a} \zeta^{j(a+1)}.$$

Subtracting the $j = 0$ ray proves the complete ordered period matrix in the original columns:

$$\Pi_s(u) = e^{c/u} W D(u) P. \quad (\text{SP.14})$$

Every factor in this equality has been specified, including the original primitive constant, the gamma constants, all powers of ρ , and the ordered contour phase.

For completeness, W is invertible. If its columns have a linear relation with coefficients $a_1, \dots, a_m$, then $\sum_{r=1}^m a_r (z^r - 1)$ vanishes at every nontrivial n -th root of unity. It also vanishes at 1. Its degree is at most $m = n - 1$; division by the degree- n polynomial $z^n - 1$, or the elementary bound on the

number of roots of a nonzero polynomial, makes it the zero polynomial. All its coefficients a_r are zero. The gamma factors in (SP.13) are positive-real gamma values times nonzero constants, since $0 < \beta_a < 1$. Thus (SP.14) is invertible for every $u \neq 0$. Its determinant is exactly

$$\det \Pi_s(u) = K_m u^{m/2} e^{mc/u}, \quad K_m = n^{-m/2} e^{\pi i m/2} \left(\prod_{a=0}^{m-1} \Gamma(\beta_a) \right) \det W \neq 0. \quad (\text{SP.15})$$

Here $\sum_a \beta_a = m/2$ and $\det P = 1$ prove every factor. This is the single-primary value of the original BC determinant, with $\text{Tr } C_s = mc$.

129.4 Complete monodromy, its finite cover, and the boundary invariants

Under one positive circuit of $u = 0$, the ordered decay rays move ℓ_j to ℓ_{j+1} , with indices modulo n . Thus their transported relative cycles satisfy

$$\Gamma_j \mapsto \begin{cases} \Gamma_{j+1} - \Gamma_1, & 1 \leq j < m, \\ -\Gamma_1, & j = m. \end{cases} \quad (\text{SP.16})$$

The equality follows by writing each as $-\ell_1 + \ell_{j+1}$ and subtracting the defining $-\ell_0 + \ell_1$. It remains valid for $m = 1$, when the second case is the single map $\Gamma_1 \mapsto -\Gamma_1$. Let M_{cyc} be the matrix whose rows record (SP.16). The constant exponential is single-valued on $\mathbb{C}^\times$. Equation (SP.14) therefore gives

$$\Pi_s^{\text{cont}} = M_{\text{cyc}} \Pi_s, \quad M_{\text{cyc}} = W \text{diag}(\zeta, \zeta^2, \dots, \zeta^m) W^{-1}, \quad M_{\text{cyc}}^n = I, \quad \ker(M_{\text{cyc}} - I) = 0. \quad (\text{SP.17})$$

For example the row difference in (SP.16), applied to the column $W_{\bullet a}$, is $\zeta^{a+1}(\zeta^{j(a+1)} - 1)$, proving the stated diagonalization directly. None of $\zeta, \dots, \zeta^m$ equals one.

The signs for horizontal coefficient solutions can also be specified without an implicit duality convention. The connection (SP.8) acts on coefficient columns. Its horizontal equation is $x'_s = (cI/u^2 - B_s/u)x_s$, whose fundamental matrix is

$$H_s(u) = P^{-1} e^{-c/u} \text{diag}(u^{-\beta_a})_{a=0}^{m-1}. \quad (\text{SP.18})$$

Differentiate it and use (SP.9) to verify the equation. Its coefficient monodromy is conjugate to $\text{diag}(\zeta^{-1}, \dots, \zeta^{-m})$. This is the inverse convention to the period-cycle action in (SP.17). Its eigenvalue set is the same set of all nontrivial n -th roots, so it too has zero invariants.

On the finite ramified cover $u = v^n$, the pulled-back connection in the y -basis is exactly

$$\partial_v - \frac{nc}{v^{n+1}} I_m + \frac{1}{v} \text{diag}(1, 2, \dots, m). \quad (\text{SP.19})$$

The meromorphic basis change $x_y = \text{diag}(v^{-1}, \dots, v^{-m})z$ cancels precisely the integer diagonal term and leaves $\partial_v - nc v^{-n-1} I_m$. Its horizontal factor remains e^{-c/v^n} . It is not a meromorphic gauge removing that irregular factor when $c \neq 0$. Analytic continuation of the displayed fundamental matrix around $v = 0$ is, nevertheless, the identity. Thus the actual finite-cover unipotent monodromy logarithm is exactly

$$N_{\text{boundary}} = 0. \quad (\text{SP.20})$$

There is no uncomputed sector transition in this one-critical-value calculation: (SP.18) is an exact diagonal fundamental solution on every branch, and after (SP.19) all columns have the same explicit scalar exponential and integer powers. On two overlapping sectors with the same branch they are identical. This proves the absence of additional Stokes factors for this specified family; it is not a claim about a packet with several distinct critical values.

Let $j : \Delta^\times \hookrightarrow \Delta$ be a small complex disc punctured at zero, and let $\mathcal{V}_{\text{an}}$ denote either the period local system or its horizontal dual, with the convention just specified. Its stalk at zero under ordinary j_* is the invariant subspace: a local section is a vector unchanged by a circuit of the puncture. Equation (SP.17) or (SP.18) proves

$$(j_* \mathcal{V}_{\text{an}})_0 = 0, \quad (j! \mathcal{V}_{\text{an}})_0 = 0. \quad (\text{SP.21})$$

Moreover the circle cochain complex is $[\mathbb{C}^m \xrightarrow{M-I} \mathbb{C}^m]$; cutting the circle at one point and identifying its endpoints by M gives exactly this cellular differential. Since $M - I$ is invertible, both its kernel and cokernel are zero. Thus the derived local invariant and coinvariant groups also vanish. This statement concerns the local system specified above and does not replace the marked algebraic fibre $\mathcal{H}/u\mathcal{H}$ in (SP.5).

129.5 The same full marked fibre retains the arithmetic nilpotent

In the y -basis, let J_m be the matrix of multiplication by y on $\mathbb{C}[y]/y^m$; explicitly $(J_m)_{a+1,a} = 1$ for $0 \leq a < m-1$, with all other entries zero. Then

$$A_s = P^{-1}(\rho I_m + J_m)P, \quad N_{\text{ar}} := A_s - \rho I_m = P^{-1}J_mP, \quad J_m^m = 0, \quad J_m^{m-1} \neq 0. \quad (\text{SP.22})$$

For $m = 1$, the last statement means $J_1^0 = I_1 \neq 0$ and $J_1 = 0$; its nilpotency index is one. These identities follow by applying multiplication to each of the ordered monomials; no monodromy identification is used. They reconstruct the full original companion multiplication matrix, since the polynomial identity $(s - \rho)^m = 0$ determines its last column and (SP.3) its complete change of coordinates.

The relation between this arithmetic action and the boundary connection is also explicit. From $\beta_{a+1} - \beta_a = 1/n$,

$$[B_s, A_s] = \frac{1}{n} N_{\text{ar}}, \quad [\nabla_u, A_s] = \frac{N_{\text{ar}}}{nu}. \quad (\text{SP.23})$$

The first identity is verified on every y^a , including the last one where $J_m y^{m-1} = 0$, and then conjugated by P . The scalar $C_s = cI$ commutes with A_s , and A_s is constant in u , proving the second. Thus for $m > 1$ this marked arithmetic action is not a horizontal endomorphism of the displayed boundary connection. The exact nonhorizontal term has been computed, rather than discarding the action.

It can be transported through the actual period isomorphism. Set $D_0 = \text{diag}(d_a)$, with the constants in (SP.13), and

$$K_0 = W D_0 J_m D_0^{-1} W^{-1}.$$

The scalar exponential cancels by its actual inverse in conjugation, and (SP.14) gives

$$\Pi_s A_s \Pi_s^{-1} = \rho I_m + u^{1/n} K_0, \quad K_0^m = 0, \quad K_0^{m-1} \neq 0, \quad M_{\text{cyc}} K_0 M_{\text{cyc}}^{-1} = \zeta K_0. \quad (\text{SP.24})$$

Indeed the $(a+1, a)$ entry of $\text{diag}(u^\beta) J_m \text{diag}(u^{-\beta})$ is $u^{1/n}$. The same calculation with ζ^{a+1} proves the last identity. Differentiating (SP.24) retains the exact $1/(nu)$ commutator in (SP.23). This is the concrete connection between the nonzero arithmetic nilpotent and the finite boundary monodromy, on the same rank- m space at each $u \neq 0$.

129.6 The complete Taylor unit and the original theta source

The entire quotient and its full Taylor coefficients are

$$v_h(s) = \frac{g(s)}{(s - \rho)^m}, \quad a_j = \frac{v_h^{(j)}(\rho)}{j!} = \frac{g^{(m+j)}(\rho)}{(m+j)!} \quad (0 \leq j < m), \quad a_0 \neq 0. \quad (\text{SP.25})$$

The equality follows by dividing the convergent Taylor series of g , whose first nonzero term is of order m . In the unchanged marked fibre its multiplication matrix is

$$U_s = P^{-1} \left(\sum_{j=0}^{m-1} a_j J_m^j \right) P, \quad U_s^{-1} = P^{-1} \left(\sum_{j=0}^{m-1} b_j J_m^j \right) P, \quad b_0 = a_0^{-1}, \quad b_r = -a_0^{-1} \sum_{j=1}^r a_j b_{r-j}. \quad (\text{SP.26})$$

Multiplying the two finite series proves the inverse: the constant coefficient is one and every coefficient of J_m^r , $1 \leq r < m$, is zero by the displayed recursion. Terms of degree at least m vanish by $J_m^m = 0$. All coefficients a_j , including their derivative constants, remain in the same matrix. When $u \neq 0$, the occurrence of this same U_s on the displayed remainder lattice means its constant coefficient extension in that specified basis. It is not an assertion of an unrecorded multiplication operation on twisted polynomial cohomology. The exact multiplication defect is calculated below.

Retain the original function spaces $V, \mathcal{B}$, Euler operator $D = -x\partial_x$, Fourier convention, theta map $\Theta\phi(x) = 2 \sum_{r \geq 1} \phi(rx)$, and seed

$$\phi_* = (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2}, \quad \mathcal{M}\Theta\phi_* = g, \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}.$$

Specifically V is the even Schwartz subspace with $\phi(0) = \int \phi = 0$, and $\mathcal{B}$ consists of smooth functions on $\mathbb{R}_{>0}$ with finite seminorms $\sup_{x>0} x^b |D^r F(x)|$ for every integer b and every nonnegative integer r . The original iterated Euler inverse gives $F_h \in \mathcal{B}$ with $\mathcal{M}F_h = v_h$. The actual polynomial maps are

$$\alpha_h(P) = P(D)\phi_*, \quad \mathcal{T}_h(P) = P(D)F_h, \quad \Theta\alpha_h(P) = \mathcal{T}_h(hP), \quad J_h \mathcal{T}_h(P) = U_s[P]_s. \quad (\text{SP.27})$$

Here $J_h = j_h \mathcal{M}$ and $[P]_s$ is the original remainder coordinate column. These are the inherited exact Euler/theta identities in original marked equations (18)–(19) and BC's source square. In particular $[\mathbb{C}[s] \xrightarrow{h} \mathbb{C}[s]ds]$ maps to $[V \xrightarrow{\Theta} \mathcal{B}]$ by $(\alpha_h, \mathcal{T}_h)$. Its degree-one injection is $\sigma_h U_s : E_h \hookrightarrow Q_{\text{ar}} = \mathcal{B}/\Theta V$, where σ_h is the original corrected section.

The coordinate change is realized on these exact source vectors:

$$\mathcal{T}_h(y^b) = (D - \rho)^b F_h, \quad (\mathcal{T}_h(s^b))_{b=0}^{m-1} = (\mathcal{T}_h(y^a))_{a=0}^{m-1} P. \quad (\text{SP.28})$$

The binomial theorem for the commuting scalar ρ and operator D proves both identities. Thus the Pascal map, full nilpotent and Taylor unit have explicit source representatives on the same theta complex. At general u , the original source deformation is still $\Theta + u\mathcal{T}_h\partial_s\alpha_h^{-1}$ on $\alpha_h(\mathbb{C}[s])$; its square with (SP.4) commutes. There is no assertion that the unit-valued coefficient map turns this deformed differential into the undeformed theta map.

Under the period map, (SP.26) has the exact image

$$\Pi_s U_s \Pi_s^{-1} = \sum_{j=0}^{m-1} a_j u^{j/n} K_0^j, \quad [\nabla_u, U_s] = \frac{1}{nu} P^{-1} \left(\sum_{j=1}^{m-1} j a_j J_m^j \right) P. \quad (\text{SP.29})$$

The first follows by taking powers in (SP.24); the second uses $[B_y, J_m^j] = (j/n) J_m^j$, proved by induction from (SP.23). These formulas specify exactly how every Taylor coefficient is transported and why its arithmetic multiplication is not silently identified with a constant flat monodromy operator.

More explicitly put $v_{\text{pol}}(s) = \sum_{j=0}^{m-1} a_j (s - \rho)^j$, the exact original Taylor remainder of v_h . For every polynomial $Q(s)$, the Leibniz rule in the original differential gives

$$v_{\text{pol}} L_u Q = L_u(v_{\text{pol}} Q) - uv'_{\text{pol}} Q. \quad (\text{SP.30})$$

Indeed the $h v_{\text{pol}} Q$ terms agree and the derivative of $v_{\text{pol}} Q$ contributes exactly the additional $uv'_{\text{pol}} Q$. At the marked fibre $u = 0$ this is ordinary multiplication of the full class $v_h \in E_h^\times$, with inverse

(SP.26). Away from that fibre it records precisely the derivative term needed to compare multiplication on representatives with the specified coefficient extension U_s . For a remainder polynomial p of degree less than m , divide $v_{\text{pol}}p = hq + r$ monically. The degree of q is at most $m - 2$, with $q = 0$ when the product has degree less than m . Consequently q' already has degree below m , and

$$[v_{\text{pol}}p]_{\mathcal{H}_u} = [r - uq']_{\mathcal{H}_u}. \quad (\text{SP.31})$$

Subtracting $L_u q = hq + uq'$ proves the identity with its specified correction. The constant matrix U_s gives the coefficient r ; (SP.31) computes exactly its difference from multiplying these representatives and then taking the differential remainder. No term involving v'_h or its Taylor coefficients has been deleted.

129.7 The finite-cover lattice and the original source metric

The marked lattice also has an explicit image on the cover $u = v^n$. After retaining and factoring its common scalar e^{c/v^n} in the period expression, its columns are

$$e^{-c/v^n} \Pi_s(v^n) = WD_0 \text{diag}(v, v^2, \dots, v^m)P. \quad (\text{SP.32})$$

This is an equality on the punctured disc that also defines a holomorphic matrix on the whole v -disc. The constant invertible matrices WD_0, P identify its image lattice with $\bigoplus_{a=0}^{m-1} v^{a+1} \mathbb{C}\{v\}$. Its cokernel in the displayed ambient holomorphic free module is consequently

$$\bigoplus_{a=0}^{m-1} \mathbb{C}\{v\}/(v^{a+1}), \quad \text{length} = \sum_{a=0}^{m-1} (a+1) = \frac{m(m+1)}{2}. \quad (\text{SP.33})$$

Both assertions follow by multiplying by those constant inverses and computing the image and quotient in each one-dimensional coordinate. The image lattice itself has a rank- m quotient by multiplication by v , as does the pulled-back marked lattice. Its inclusion into the ambient constant lattice induces zero modulo v , since every column contains a positive power of v . Thus the vanishing boundary invariants and the nonzero marked fibre have their exact lattice map and cokernel recorded; neither is used to erase the other's coefficients. The scalar exponential factored in (SP.32) remains an irregular factor and is not being declared a meromorphic gauge.

In the original source norm, retain the positive matrix

$$(G_\theta)_{ab} = \frac{1}{2\pi} \int_{\mathbb{R}} \overline{(1/2 + it)}^a (1/2 + it)^b |v_h(1/2 + it)|^2 dt, \quad 0 \leq a, b < m. \quad (\text{SP.34})$$

Mellin–Plancherel identifies this with the Gram of $\mathcal{T}_h(s^b)$ in the actual $L^2(dx)$ source. The source moments are finite by the inherited arithmetic source estimates. A zero polynomial-vector norm would make its entire Mellin transform Pv_h zero; since $v_h \neq 0$, this forces $P = 0$. Hence G_θ is positive definite, with its original mass and full multiplier retained. The actual comparison endomorphism is

$$T_{\text{per}}(u) = G_\theta^{-1} \Pi_s(u)^* \Pi_s(u) = e^{2\text{Re}(c/u)} G_\theta^{-1} P^* D(u)^* W^* W D(u) P. \quad (\text{SP.35})$$

Its positivity and self-adjointness are in G_θ : $x^* G_\theta T_{\text{per}} x = \|\Pi_s x\|^2 > 0$ for $x \neq 0$. The ratio of its largest and smallest eigenvalues is unchanged by its explicit positive scalar $e^{2\text{Re}(c/u)}$. Every other factor in (SP.35), including the original Pascal matrix and G_θ , remains. In particular the scalar cancellation alone gives no estimate for that ratio.

Fix $u \neq 0$. For a larger polynomial source $\mathbb{C}[s]_{\leq N}$, $N \geq m - 1$, let $J_{u,N}$ be the unique differential remainder for (SP.4). It is onto the same m -dimensional remainder module and has exact kernel

$$\ker J_{u,N} = L_u(\mathbb{C}[s]_{\leq N-m}), \quad \text{Per}_N = \Pi_s(u) J_{u,N}. \quad (\text{SP.36})$$

When $N = m - 1$ the relation space is zero. The degree argument for (SP.5) proves the kernel and surjectivity. For the period factorization, each polynomial differential relation has integral

$$\int_{\Gamma_j} e^{\Phi_h/u} L_u Q ds = u \int_{\Gamma_j} d(e^{\Phi_h/u} Q) = 0;$$

the endpoint values vanish by the same polynomial decay estimate (SP.12), and the junction endpoints cancel with the original orientations. Thus the period Gram at degree N has rank exactly m , with kernel (SP.36). Its restriction to the displayed m -dimensional remainder frame is positive definite. It is not a positive definite Gram on an enlarged source with more columns.

129.8 Support labels and the scope of the computed boundary

All constant coefficient maps above act at each original nonbottom support label by $(A, x) \mapsto (A, fx)$, with external $\tau \mapsto \tau$. The Pascal matrix, its inverse, the finite Taylor-unit matrix and its inverse preserve the labelled coefficient space. A killed coefficient is its represented zero at that label. The coefficient specialization at $u = 0, t = 0$ sends represented parameter values to the represented zero e , as in the original marked structural map $\mathbb{F}_{1,\tau} \rightarrow G(\mathbb{C}[u, t]) \rightarrow G(\mathbb{C})$. It does not send the marked primary fibre to external absence.

Equations (SP.17)–(SP.21) compute the actual one-factor boundary monodromy, invariant stalk and finite-cover nilpotent logarithm. Equations (SP.22)–(SP.33) reconstruct the original arithmetic action, full Taylor unit, theta representatives and marked lattice through explicit maps. They do not identify N_{boundary} with N_{ar} . These conclusions are restricted to this complete single-primary packet at $t = 0$; tensor products may multiply its characters to the trivial character, and no assertion of vanishing tensor invariants is made.

130 The finite-field sheaf of the single-primary phase

130.1 Specified coefficient specialization and all constants

Let the specified single primary polynomial be

$$h(s) = (s - \rho)^m, \quad m \geq 1, \quad n = m + 1. \quad (\text{SPF.1})$$

Retain the given coefficient ring R , including ρ , $1/n!$, and every coefficient of the full Taylor class $v_h = j_h(g/h)$ and its inverse in the retained m -dimensional remainder basis. The finite-field datum for this calculation is the specified ring homomorphism $\alpha : R \rightarrow k_0 = \mathbf{F}_{Q_0}$, of characteristic $p > n$. All coefficients, including the unit and its inverse, are mapped by this same homomorphism. We continue to write ρ for $\alpha(\rho)$. At $t = 0$, the specified primitive with value zero at $s = 0$ is exactly

$$\Phi(s) = \frac{(s - \rho)^n - (-\rho)^n}{n}, \quad \Phi'(s) = h(s), \quad c = -\frac{(-\rho)^n}{n}. \quad (\text{SPF.2})$$

In particular, the constant c is retained throughout. The only constant-field extension we require is

$$k = \mathbf{F}_Q, \quad Q = Q_0^d, \quad d = \text{ord}_{(\mathbf{Z}/n\mathbf{Z})^\times}(Q_0). \quad (\text{SPF.3})$$

Thus $n \mid Q - 1$. This is an explicit finite extension because $\gcd(Q_0, n) = 1$. All original coefficients are mapped by $R \xrightarrow{\alpha} k_0 \hookrightarrow k$.

Fix $\ell \neq p$, work over $\overline{\mathbf{Q}}_\ell$, and fix a nontrivial additive character $\psi_0 : k_0 \rightarrow \overline{\mathbf{Q}}_\ell^\times$. On k use $\psi = \psi_0 \circ \text{Tr}_{k/k_0}$. For a further extension $k_r = \mathbf{F}_{Q^r}$, write

$$\psi_r = \psi \circ \text{Tr}_{k_r/k}, \quad \chi_r = \chi \circ \text{N}_{k_r/k}. \quad (\text{SPF.4})$$

Every Frobenius below is geometric Frobenius, the inverse of $x \mapsto x^{Q^r}$ at a k_r -rational point. Define $\mathcal{L}_\psi(f)$ by the Artin–Schreier torsor convention whose trace there is $\psi_r(f)$. Define the multiplicative Kummer sheaf $\mathcal{K}_\chi$ by the convention whose trace there is $\chi_r(x)$. These conventions fix both inverse characters and cohomological signs.

Let

$$\begin{aligned} \pi_s : \mathbf{A}_s^1 \times \mathbf{G}_{m,u} &\longrightarrow \mathbf{G}_{m,u}, \\ \mathcal{F}_0 &= R^1 \pi_{s!} \mathcal{L}_{\psi_0}(\Phi(s)/u) \quad \text{over } k_0, \\ \mathcal{F} &= (\mathcal{F}_0)_k = R^1 \pi_{s!} \mathcal{L}_\psi(\Phi(s)/u) \quad \text{over } k. \end{aligned} \quad (\text{SPF.5})$$

The equality is compact-support base change. Our computation concerns this precise sheaf. It does not replace the specified phase by an expression involving g/h , and does not remove that unit from the original coefficient ring.

The source isomorphism

$$T : \mathbf{A}_y^1 \times \mathbf{G}_{m,u} \longrightarrow \mathbf{A}_s^1 \times \mathbf{G}_{m,u}, \quad T(y, u) = (y + \rho, u), \quad T^{-1}(s, u) = (s - \rho, u) \quad (\text{SPF.6})$$

fixes the coefficient ring and satisfies $\pi_s T = \pi_y$. It preserves compact supports because it is an isomorphism. For any original coefficient function $v(s)$, the transported function is exactly $v(y + \rho)$; for an invertible such function the inverse is exactly $v^{-1}(y + \rho)$. Direct substitution into (SPF.2), and the additive torsor tensor-product law, give

$$T^* \mathcal{L}_\psi(\Phi(s)/u) = \mathcal{L}_\psi(y^n/(nu)) \otimes \pi_y^* \mathcal{L}_\psi(c/u). \quad (\text{SPF.7})$$

The tensor-product law follows by adding two torsor coordinates: if $z_i^p - z_i = f_i$, their sum satisfies the equation for $f_1 + f_2$; the associated one-dimensional character representations multiply. Projection formula therefore yields

$$\mathcal{F} = \mathcal{L}_\psi(c/u) \otimes R^1 \pi_{y!} \mathcal{L}_\psi(y^n/(nu)). \quad (\text{SPF.8})$$

130.2 The actual power-map splitting, including its zero stalk

Put $X_n = \{\chi : k^\times \rightarrow \overline{\mathbf{Q}}_\ell^\times : \chi^n = 1\}$, so $\#X_n = n$, and let $q : \mathbf{A}_y^1 \rightarrow \mathbf{A}_z^1$ be $z = y^n$. Let $j : \mathbf{G}_{m,z} \hookrightarrow \mathbf{A}_z^1$. Then the following is an isomorphism of sheaves over k , not merely an equality of trace functions:

$$q_* \overline{\mathbf{Q}}_\ell \simeq \overline{\mathbf{Q}}_{\ell, \mathbf{A}_z^1} \oplus \bigoplus_{\substack{\chi \in X_n \\ \chi \neq 1}} j_! \mathcal{K}_\chi. \quad (\text{SPF.9})$$

Here is the explicit splitting. The deck group on $\mathbf{G}_m$ is $\mu_n(k)$. On the stalk with basis e_r , indexed by $r^n = z$, set $D_\zeta e_r = e_{\zeta r}$. For $\chi \in X_n$ there is a unique character $\lambda_\chi : \mu_n(k) \rightarrow \overline{\mathbf{Q}}_\ell^\times$ with

$$\lambda_\chi(x^{(Q-1)/n}) = \chi(x) \quad (x \in k^\times), \quad e_\chi = \frac{1}{n} \sum_{\zeta \in \mu_n(k)} \lambda_\chi(\zeta) D_\zeta. \quad (\text{SPF.10})$$

Uniqueness and existence follow because $x \mapsto x^{(Q-1)/n}$ surjects onto $\mu_n(k)$, with kernel the subgroup of n th powers, on which χ is trivial. Character orthogonality gives $e_\chi e_{\chi'} = \delta_{\chi, \chi'} e_\chi$ and $\sum_{\chi \in X_n} e_\chi = 1$. Its image is the λ_χ^{-1} -eigenline of the operators D_ζ . For $z = x \in k_r^\times$, a chosen root has $r^{Q^r} = x^{(Q^r-1)/n} r$; geometric Frobenius consequently acts on this eigenline by $\lambda_\chi(x^{(Q^r-1)/n}) = \chi_r(x)$. It is therefore the stated Kummer summand with the stated descent convention.

At $z = 0$, the geometric fibre of q has one point. Its constant-sheaf stalk has trivial deck action. Thus e_χ has zero image there for $\chi \neq 1$, and the trivial projector has a one-dimensional stalk. The unit map from the constant sheaf identifies the latter summand with the constant sheaf on $\mathbf{A}_z^1$. Each other summand is canonically $j_! \mathcal{K}_\chi$: the adjunction map is an isomorphism at every geometric stalk, on $\mathbf{G}_m$ and at zero. Finally, q is finite, so its higher direct images on this sheaf vanish; the argument has neither suppressed the ramified fibre nor added a term at it.

130.3 Compact-support cohomology and the negative Gauss line

For a nonzero scalar a , write

$$\mathcal{E}_{\chi,a} = \mathcal{K}_{\chi}(z) \otimes \mathcal{L}_{\psi}(az) \quad \text{on } \mathbf{G}_{m,z}, \quad H_{\chi} = H_c^1(\mathbf{G}_{m,\bar{k}}, \mathcal{E}_{\chi,1}). \quad (\text{SPF.11})$$

For $\chi \neq 1$ one has

$$H_c^i(\mathbf{G}_{m,\bar{k}}, \mathcal{E}_{\chi,a}) = 0 \ (i \neq 1), \quad \dim H_{\chi} = 1. \quad (\text{SPF.12})$$

We give the complete application of the curve formulas. A lisse sheaf on the connected, nonproper curve $\mathbf{G}_m$ has no nonzero compactly supported section: a nonzero locally constant section has support the whole curve. Thus $H_c^0 = 0$. Poincaré duality identifies H_c^2 with the Tate-twisted dual of the global invariants of the dual sheaf. Those invariants are zero, since the Artin–Schreier factor at infinity has nontrivial wild inertia and the Kummer factor is tame. The Swan conductors at zero and infinity are respectively 0 and 1. The second value also follows from the direct local calculation below, with the local parameter z^{-1} and nonzero numerator a . The Euler–Poincaré formula for this rank-one sheaf gives

$$\chi_c(\mathbf{G}_m, \mathcal{E}_{\chi,a}) = 1 \cdot \chi_c(\mathbf{G}_m, \bar{\mathbf{Q}}_{\ell}) - \text{Swan}_0 - \text{Swan}_{\infty} = 0 - 0 - 1 = -1. \quad (\text{SPF.13})$$

Together with the two vanishing groups and the cohomological dimension bound for a curve, this proves (SPF.12). The formulas used here, including their proofs and geometric Frobenius convention, are in Katz, *Gauss Sums, Kloosterman Sums, and Monodromy Groups*, Sections 2.1–2.3, especially 2.3.1–2.3.3.

The trivial summand of (SPF.9) instead contributes

$$H_c^i(\mathbf{A}_k^1, \mathcal{L}_{\psi}(az)) = 0 \quad \text{for every } i, \ a \neq 0. \quad (\text{SPF.14})$$

Indeed $H_c^0 = 0$ for the same support reason, $H_c^2 = 0$ by its nontrivial wild inertia at infinity and duality, and Euler–Poincaré gives $1 - 1 = 0$, hence $H_c^1 = 0$. This proves why the final rank is $n - 1$, with no trivial character contribution.

Set

$$G_k(\chi, \psi) = \sum_{z \in k^{\times}} \chi(z) \psi(z). \quad (\text{SPF.15})$$

The trace formula, with (SPF.12), gives the exact one-dimensional geometric Frobenius action

$$\text{Fr}_Q | H_{\chi} = -G_k(\chi, \psi). \quad (\text{SPF.16})$$

The minus sign is the cohomological sign in degree one. There is no Tate twist in this identity.

This computation is an isomorphism of the entire parameter sheaf. On $\mathbf{G}_{m,z} \times \mathbf{G}_{m,a}$, use the source isomorphism $(z, a) \mapsto (w = az, a)$, whose inverse is $(w, a) \mapsto (w/a, a)$. The multiplicative Kummer torsor law gives

$$\mathcal{K}_{\chi}(w/a) \otimes \mathcal{L}_{\psi}(w) \simeq \text{pr}_w^*(\mathcal{K}_{\chi}(w) \otimes \mathcal{L}_{\psi}(w)) \otimes \text{pr}_a^* \mathcal{K}_{\chi^{-1}}(a). \quad (\text{SPF.17})$$

This law follows by multiplying or dividing the root coordinates of Kummer torsors; the associated character representations multiply or invert accordingly. The isomorphism preserves compact supports in every fibre, so projection formula and base change identify the parameter sheaf with $H_{\chi} \otimes \mathcal{K}_{\chi^{-1}}(a)$. Here H_{χ} is the pullback from $\text{Spec } k$ of the one-dimensional Galois module in (SPF.16); it is geometrically constant.

130.4 The exact decomposition on the original parameter

For a nonzero scalar γ , denote by $\mathcal{A}_\gamma$ the geometrically constant one-dimensional sheaf with geometric Fr_Q -eigenvalue γ . In its use below γ is the actual eigenvalue in (SPF.16), or that eigenvalue times a root of unity, so this notation denotes an existing continuous Galois representation. Combining the preceding source maps with $a = 1/(nu)$ gives

$$\mathcal{F} \simeq \mathcal{L}_\psi(c/u) \otimes \bigoplus_{\substack{\chi \in X_n \\ \chi \neq 1}} \mathcal{A}_{-G_k(\chi, \psi)} \otimes \mathcal{K}_{\chi^{-1}}(1/(nu)). \quad (\text{SPF.18})$$

In particular, $\mathcal{F}$ is lisse of rank $n - 1 = m$. The inverse Kummer character here is essential. Since inversion twice returns χ and multiplication by the constant n has trace $\chi(n)$, the same isomorphism on $\mathbf{G}_{m,u}$ is exactly

$$\mathcal{F} \simeq \mathcal{L}_\psi(c/u) \otimes \bigoplus_{\substack{\chi \in X_n \\ \chi \neq 1}} \mathcal{A}_{-\chi(n)G_k(\chi, \psi)} \otimes \mathcal{K}_\chi(u). \quad (\text{SPF.19})$$

Neither the factor n nor the additive factor c/u has been dropped.

For completeness this determines every finite-extension trace. Applying the trace formula to the base change of the one-dimensional group H_χ proves directly

$$-G_{k_r}(\chi_r, \psi_r) = (-G_k(\chi, \psi))^r. \quad (\text{SPF.20})$$

Thus the usual lifting sign is derived from this actual group, without an independent convention for a normalized Gauss sum. For $u \in k_r^\times$,

$$\begin{aligned} \text{Tr}(\text{Fr}_{Q^r, u} | \mathcal{F}_{\bar{u}}) &= - \sum_{s \in k_r} \psi_r(\Phi(s)/u) \\ &= -\psi_r(c/u) \sum_{\substack{\chi \in X_n \\ \chi \neq 1}} \chi_r(nu) G_{k_r}(\chi_r, \psi_r) \\ &= \psi_r(c/u) \sum_{\substack{\chi \in X_n \\ \chi \neq 1}} (-\chi(n)G_k(\chi, \psi))^r \chi_r(u). \end{aligned} \quad (\text{SPF.21})$$

To verify the middle equality also by finite sums, translate s to $y = s - \rho$. The number of n th roots of $z \in k_r^\times$ is $\sum_{\chi \in X_n} \chi_r(z)$. There is one root at zero. The trivial-character part is $1 + \sum_{z \neq 0} \psi_r(az) = 0$. For each other character the change of variable $w = az$ gives $\chi_r(a)^{-1} G_{k_r}(\chi_r, \psi_r)$; here $a^{-1} = nu$. In the last equality, $\chi_r(n) = \chi(n)^r$, since $n \in k^\times$ and its extension-field norm is n^r .

130.5 Inertia at zero, including a zero constant specialization

Let I_0 denote geometric inertia over $\bar{k}((u))$, let P_0 be its wild subgroup, and let $V = \mathcal{F}_{\bar{\eta}}$. Write $\psi(x) = \vartheta(\text{Tr}_{k/\mathbf{F}_p}(bx))$, where $\vartheta : \mathbf{F}_p \rightarrow \bar{\mathbf{Q}}_\ell^\times$ is a fixed nontrivial additive character and $b \in k^\times$. Such a unique b exists by nondegeneracy of the finite-field trace pairing. Then $\mathcal{L}_\psi(c/u) = \mathcal{L}_\vartheta(bc/u)$. Put $d_0 = bc$.

First suppose $c \neq 0$. The Artin–Schreier equation

$$z^p - z = d_0/u \quad (\text{SPF.22})$$

defines a degree- p extension of $\bar{k}((u))$. Indeed $f^p - f = d_0/u$ has no Laurent-series solution: if f has a pole of order $r > 0$, then $f^p - f$ has pole order pr , whereas the right side has order one; if f has no pole, neither does $f^p - f$. An Artin–Schreier polynomial of prime degree with no root is irreducible,

since its roots form one translate of $\mathbf{F}_p$ and its Galois group is a subgroup of that group, hence has order either one or p .

Let v_E be its integer-valued normalized valuation, and write $v_E(u) = e$ for the ramification index. The equation forces $v_E(z) < 0$, hence $p v_E(z) = -e$. Thus $p \mid e$; since $1 \leq e \leq [E : \bar{k}((u))] = p$, one has $e = p$ and $v_E(z) = -1$. The extension is therefore totally ramified and z^{-1} is a uniformizer. For $\sigma_a(z) = z + a$, $a \in \mathbf{F}_p^\times$,

$$v_E(\sigma_a(z^{-1}) - z^{-1}) = v_E\left(\frac{-a}{z(z+a)}\right) = 2. \quad (\text{SPF.23})$$

The lower ramification groups are consequently $G_0 = G_1 = \mathbf{F}_p$, $G_2 = 1$; their unique positive upper break is one. Every nontrivial character of this group has Swan conductor one. In particular the character ε_{d_0} supplied by $\mathcal{L}_{\vartheta}(d_0/u)$ is nontrivial on P_0 . All geometrically constant factors of (SPF.19) are trivial on I_0 , and all Kummer factors are trivial on P_0 . Thus

$$V|_{P_0} \simeq \varepsilon_{d_0}^{\oplus(n-1)}, \quad V^{P_0} = 0, \quad V^{I_0} = 0, \quad \text{Swan}_0(\mathcal{F}) = n - 1 \quad (c \neq 0). \quad (\text{SPF.24})$$

The first vanishing follows explicitly by choosing $\sigma \in P_0$ with $\varepsilon_{d_0}(\sigma) \neq 1$: an invariant vector v would satisfy $(\varepsilon_{d_0}(\sigma) - 1)v = 0$, hence $v = 0$. Swan conductors add under direct sum.

Now suppose $c = 0$. This occurs exactly when $\rho = 0$ in the specified residue field, since $n \neq 0$ there. The additive factor is the constant sheaf, and

$$V|_{I_0} \simeq \bigoplus_{\substack{\chi \in X_n \\ \chi \neq 1}} \mathcal{K}_\chi|_{I_0}, \quad V^{I_0} = 0, \quad \text{Swan}_0(\mathcal{F}) = 0 \quad (c = 0). \quad (\text{SPF.25})$$

Each displayed character is nontrivial on tame inertia: the totally ramified Kummer cover $u = v^n$ has deck group μ_n , and its summand is the nontrivial λ_χ^{-1} -character proved in (SPF.10). An invariant in a direct sum of these eigenlines has invariant components in each, hence is zero. Thus this specialization does not produce an invariant line.

Here is one finite cover that kills all geometric inertia in either case and keeps track of the additive factor:

$$u = v^n, \quad z^p - z = \frac{bc}{v^n}. \quad (\text{SPF.26})$$

Both maps are finite etale on the punctured u -line or its pullback: their derivatives there are $nv^{n-1} \neq 0$ and $-1 \neq 0$. The pullback of $\mathcal{K}_\chi(u)$ is $\mathcal{K}_{\chi^n}(v)$, hence constant. The pullback of the Artin-Schreier factor is trivialized by the displayed torsor itself. For $c = 0$, the first map alone suffices and the second is a disjoint trivial torsor. For $c \neq 0$, the second map remains a nontrivial degree- p extension after the first: its right side has pole order n , and $p \nmid n$, so the preceding pole-order argument applies. The composite has degree np . Constants $\mathcal{A}_{-\chi(n)G_k}$ can retain arithmetic Frobenius action; they have no geometric inertia action.

On the resulting finite-index subgroup of I_0 , every monodromy matrix is the identity. Its unipotent logarithm is therefore exactly

$$N = \log(1) = 0. \quad (\text{SPF.27})$$

Equivalently, the original inertia representation has finite image and is a direct sum of finite-order characters, so its unipotent part is already the identity. Formula (SPF.27) and the vanishing $V^{I_0} = 0$ hold simultaneously. Invariants refer to the original group I_0 ; after the cover its restricted representation is trivial, so the new inertia invariants are the whole rank- m vector space.

130.6 Purity proved by the exact Gauss calculation

For every complex embedding of the cyclotomic field of the character values, and every nontrivial χ ,

$$|G_k(\chi, \psi)|^2 = \sum_{t \in k^\times} \chi(t) \sum_{y \in k^\times} \psi((t-1)y) = (Q-1) - \sum_{\substack{t \in k^\times \\ t \neq 1}} \chi(t) = Q. \quad (\text{SPF.28})$$

The first equality expands the square of the sum, uses the complex conjugates $\overline{\chi(y)} = \chi(y)^{-1}$ and $\overline{\psi(y)} = \psi(-y)$, and sets $x = ty$. The inner sum is $Q - 1$ at $t = 1$ and -1 otherwise, by nontrivial additive-character orthogonality. Multiplicative-character orthogonality gives $\sum_{t \neq 0} \chi(t) = 0$, so the sum over $t \neq 1$ is -1 . This proves every equality, with the original unscaled Gauss sum.

Every local eigenvalue in (SPF.21) is

$$\psi_r(c/u) \left(-\chi(n) G_k(\chi, \psi) \right)^r \chi_r(u), \quad \left| \psi_r(c/u) \left(-\chi(n) G_k(\chi, \psi) \right)^r \chi_r(u) \right| = Q^{r/2}. \quad (\text{SPF.29})$$

All character factors have absolute value one, and (SPF.28) gives the last equality. Thus the specified sheaf is pointwise pure of weight one. No division by $Q^{1/2}$, half Tate twist, or change of the original phase was made. Over k_0 the same purity follows as well: for a closed point of degree e , pass to a constant extension in which its Frobenius has a positive power covered by (SPF.29). If its original eigenvalue is β and that power is r , the computed equality $|\beta^r| = Q_0^{er/2}$ implies $|\beta| = Q_0^{e/2}$. The inertia calculation is geometric and is unchanged by constant-field extension.

This establishes the exact finite-field decomposition, purity, invariant-space vanishing, and finite-cover logarithm of the sheaf in (SPF.5). The finite-field parameter and its Frobenius eigenvalues have been constructed here. No complex off-critical zeta zero or identification of such a zero with one of these finite-field Frobenius eigenvalues is constructed by this calculation.

Primary sources for the cohomological foundations. The compact-support curve formulas and geometric Frobenius convention used above are Katz, *Gauss Sums, Kloosterman Sums, and Monodromy Groups* (Annals of Mathematics Studies 116), Sections 2.1–2.3; the unscaled Gauss convention is Section 4.0. The Artin–Schreier torsor construction is the exact sequence in the Stacks Project, Section 59.63, tag 0A3J; the Kummer torsor construction is Section 59.28, tag 03PK. All specializations, source maps, power-map projectors, Gauss factors, and local ramification computations needed for this particular sheaf have been proved above.

131 Ordered tensor primary packets: invariant characters and the actual arithmetic action

This calculation takes the ordered tensor product of the complete single-primary marked family, with a common parameter u and with every original t -parameter fixed at zero. It does not pass to a symmetric quotient. Its source is the full packet attached to a selected actual zero when such a packet is given; it asserts the existence of no zero off the critical line. The constant in the original primitive, the original monomial coordinates, and the full source unit are retained.

131.1 The original ordered family and its period matrix

Let ρ be the selected zero of $g = 2\xi$ of complete order $m \geq 1$, put $N = m + 1$, and let $k \geq 1$ be an integer. For $1 \leq i \leq k$, put $y_i = s_i - \rho$. The precise phase and marked algebra are

$$\begin{aligned} h(s) &= (s - \rho)^m, & c &= -\frac{(-\rho)^N}{N}, \\ \Phi_k(s_1, \dots, s_k) &= \sum_{i=1}^k \frac{(s_i - \rho)^N - (-\rho)^N}{N} = \sum_{i=1}^k \frac{y_i^N}{N} + kc, \\ E_k &= \mathbb{C}[s_1, \dots, s_k] / (h(s_1), \dots, h(s_k)). \end{aligned} \quad (\text{TP.1})$$

Each primitive is zero at its original base point $s_i = 0$. Index every ordered basis lexicographically by $\mathbf{b} = (b_1, \dots, b_k) \in \{0, \dots, m-1\}^k$. Write $s^{\mathbf{b}} = \prod_i s_i^{b_i}$, $y^{\mathbf{b}} = \prod_i y_i^{b_i}$, $|\mathbf{b}| = \sum_i b_i$, and $L(\mathbf{b}) = |\mathbf{b}| + k$. The unchanged top differential is $ds_1 \wedge \dots \wedge ds_k = dy_1 \wedge \dots \wedge dy_k$.

The one-factor Pascal matrix and its ordered tensor power are

$$P_{ab} = \begin{cases} \binom{b}{a} \rho^{b-a} & a \leq b, \\ 0 & a > b, \end{cases} \quad (P^{-1})_{ab} = \begin{cases} \binom{b}{a} (-\rho)^{b-a} & a \leq b, \\ 0 & a > b, \end{cases} \quad P_k = P^{\otimes k}. \quad (\text{TP.2})$$

Here all one-factor indices run from zero to $m - 1$. The binomial theorem gives $e_s = e_y P_k$, where e_s, e_y are the ordered rows of monomials. Substitution in both directions proves the inverse formula, and $\det P = 1$. Coefficient columns therefore satisfy $x_y = P_k x_s$, with no change of the polynomial object.

The ordered exponential complex is the tensor product over $\mathbb{C}[u]$ of the two-term complexes with differential

$$L_i = u \partial_{s_i} + h(s_i). \quad (\text{TP.3})$$

Equivalently its total differential on polynomial forms is $u d + d\Phi_k \wedge$, with the usual ordered wedge signs. The operators L_i commute for different indices, proving that the square of this differential is zero. In one variable the leading degree of $L_i Q$, for $Q \neq 0$, is $\deg Q + m$, with the same leading coefficient. Monic subtraction therefore gives a unique remainder of degree below m . This decomposes the two-term complex as a contractible complex mapping isomorphically onto its image, plus a free $\mathbb{C}[u]$ -module of rank m in degree one. To see contractibility explicitly, send an image element $L_i Q$ back to its unique Q , and send its remainder to zero. Tensoring a contracting homotopy with the identity contracts every summand having a contractible factor; the total-complex signs cancel the differentials in the other factors. Consequently all cohomology vanishes except in degree k , where

$$\mathcal{H}_k = \bigoplus_{\mathbf{b}} \mathbb{C}[u][s^{\mathbf{b}} ds_1 \wedge \cdots \wedge ds_k], \quad \mathcal{H}_k / u \mathcal{H}_k = E_k ds_1 \wedge \cdots \wedge ds_k. \quad (\text{TP.4})$$

In particular its rank is m^k , and every primary order is retained.

Fix a branch of $u^{1/N}$ on a sector of $u \neq 0$, let $\zeta = e^{2\pi i/N}$, and for $0 \leq a < m$ define

$$\beta_a = \frac{a+1}{N}, \quad d_a = N^{\beta_a-1} e^{\pi i \beta_a} \Gamma(\beta_a), \quad W_{ja} = \zeta^{j(a+1)} - 1 \quad (1 \leq j \leq m), \quad D(u) = \text{diag}(d_a u^{\beta_a}). \quad (\text{TP.5})$$

Use the original rays at angles $(\arg u + \pi)/N + 2\pi j/N$, oriented outwards, and the original relative contour $\Gamma_j = -\ell_0 + \ell_j$. The ordered product contour is $\Gamma_{j_1} \times \cdots \times \Gamma_{j_k}$, with its product orientation. There is no permutation of its factors or top form. The full original period matrix is

$$\Pi_k(u) = e^{kc/u} W_k D_k(u) P_k, \quad W_k = W^{\otimes k}, \quad D_k(u) = D(u)^{\otimes k}. \quad (\text{TP.6})$$

Here is a direct verification retaining the original contours. In each variable, translate its contour to $\rho + \Gamma_j$. Cauchy's theorem on the finite quadrilateral swept by each ray applies to the entire integrand. The junction connectors cancel between the negative and positive rays. At their remote endpoints $s = R e^{i\vartheta} + a\rho$, $0 \leq a \leq 1$, the exponent has real part $-R^N/(N|u|) + O(R^{N-1}) + O(1)$, uniformly in a . Each connector has length at most $|\rho|$; its polynomially weighted integral tends to zero. Absolute integrability on each ray follows from the same estimate. Translation is thus a proved contour equality, preserving the scalar $e^{c/u}$. On the translated ray the substitution $v = r^N/(N|u|)$ gives precisely $d_a u^{\beta_a} \zeta^{j(a+1)}$; subtracting the zeroth ray gives the entry of $W D(u)$. The Pascal expansion gives the factor P . Absolute convergence permits Fubini on every product contour and proves (TP.6), including its orientation and all constants.

The matrix W is invertible: a relation among its columns gives a polynomial $\sum_{r=1}^m a_r (z^r - 1)$ of degree at most $m = N - 1$, vanishing at every N -th root of unity, including one. A nonzero polynomial cannot have more roots than its degree, so each $a_r = 0$. Every $d_a \neq 0$, since $0 < \beta_a < 1$. Thus (TP.6) is invertible for every $u \neq 0$. For reference its determinant, without discarding its scalar, is

$$\det \Pi_k(u) = K_m^{km^{k-1}} u^{km^k/2} e^{km^k c/u}, \quad K_m = N^{-m/2} e^{\pi i m/2} \left(\prod_{a=0}^{m-1} \Gamma(\beta_a) \right) \det W. \quad (\text{TP.7})$$

Indeed $\sum_a \beta_a = m/2$, and $\det(X \otimes Y) = (\det X)^{\dim Y} (\det Y)^{\dim X}$. The latter identity follows first on triangular matrices by multiplying their diagonal entries and then on all complex matrices by triangularizing them separately. Applying it repeatedly proves the displayed exponent km^{k-1} , also when $m = 1$.

131.2 Full monodromy and the exact character projectors

Let B_s have column b equal to $((b+1)s^b - b\rho s^{b-1})/N$ in the original basis, and let $B_k = \sum_i I^{\otimes(i-1)} \otimes B_s \otimes I^{\otimes(k-i)}$. The exact connection on (TP.4) is

$$\nabla_u = \partial_u - \frac{kc}{u^2}I + \frac{B_k}{u}, \quad P_k B_k P_k^{-1} = \text{diag}(L(\mathbf{b})/N). \quad (\text{TP.8})$$

For one factor, divide $\Phi(s)s^b$ monically by $h(s)$: the quotient is $(s - \rho)s^b/N$ and the remainder is cs^b . Subtracting its L_u -image gives $[\Phi s^b] = [cs^b - u((s - \rho)s^b/N)']$. This is exactly $\partial_u - \Phi/u^2$ on cohomology and gives the stated column. The binomial coordinate map makes this column diagonal with entries β_a . Summing the tensor-factor connections proves (TP.8).

On one positive circuit of $u = 0$, each relative contour changes by $\Gamma_j \mapsto \Gamma_{j+1} - \Gamma_1$ for $j < m$, and $\Gamma_m \mapsto -\Gamma_1$. This follows directly by advancing each ray index by one modulo N . Applying this to the columns of W gives eigenvalue ζ^{a+1} . Consequently the full period-cycle monodromy is

$$\Pi_k^{\text{cont}} = M_k \Pi_k, \quad M_k = W_k \text{diag}(\zeta^{L(\mathbf{b})}) W_k^{-1}, \quad M_k^N = I. \quad (\text{TP.9})$$

The scalar $e^{kc/u}$ is single-valued and has not been removed. The horizontal coefficient fundamental matrix is $P_k^{-1} e^{-kc/u} \text{diag}(u^{-L(\mathbf{b})/N})$, as follows by differentiation using (TP.8). Its monodromy has the inverse eigenvalues. Both conventions have the same invariant indices, namely $N \mid L(\mathbf{b})$.

For a residue $r \in \mathbb{Z}/N\mathbb{Z}$, define the diagonal mask E_r on the y -basis by $E_r y^{\mathbf{b}} = \mathbf{1}_{L(\mathbf{b}) \equiv r} y^{\mathbf{b}}$. The period-space and marked-space projectors are, respectively,

$$\begin{aligned} \mathcal{P}_r &= \frac{1}{N} \sum_{j=0}^{N-1} \zeta^{-rj} M_k^j = W_k E_r W_k^{-1}, \\ Q_r &= P_k^{-1} E_r P_k, \quad \mathcal{P}_r \Pi_k = \Pi_k Q_r. \end{aligned} \quad (\text{TP.10})$$

The geometric sum of N -th roots is N when its exponent is divisible by N and zero otherwise; this proves the first equality and the identities $Q_r Q_t = \mathbf{1}_{r=t} Q_r$, $\sum_r Q_r = I$, and the same identities for $\mathcal{P}_r$. The diagonal matrix $D_k(u)$ commutes with every E_r , proving the last equality. In particular the pulled-back projector is constant in u . These are algebraic projectors; no orthogonality in the original theta-source metric is assumed.

Their dimensions are exactly

$$d_r = \text{rank } Q_r = \begin{cases} (m^k + m(-1)^k)/N, & r = 0, \\ (m^k - (-1)^k)/N, & r \neq 0. \end{cases} \quad (\text{TP.11})$$

In fact the character sum giving the number of ordered tuples is $N^{-1} \sum_{j=0}^{N-1} \zeta^{-rj} (\sum_{l=1}^{N-1} \zeta^{jl})^k$. Its inner sum is m at $j = 0$ and -1 otherwise. The sum of the remaining outer characters is m for $r = 0$ and -1 for $r \neq 0$. This proves (TP.11) as an actual integer count, including all small values of m, k .

The ordinary invariant stalk of this punctured-disc local system is $\ker(M_k - I) = \text{im } \mathcal{P}_0$, of dimension d_0 . Its coinvariant space is identified with that same summand by $\mathcal{P}_0$: on every other summand $M_k - I$ is invertible. Thus both circle cohomology groups have dimension d_0 . On the cover $u = v^N$, (TP.8) becomes

$$\partial_v - \frac{Nkc}{v^{N+1}}I + \frac{1}{v} \text{diag}(L(\mathbf{b})). \quad (\text{TP.12})$$

The basis change by $\text{diag}(v^{-L(\mathbf{b})})$ removes precisely the integer residue. The remaining exact horizontal scalar is e^{-kc/v^N} . It is not a meromorphic gauge removing the irregular term when $kc \neq 0$. Nevertheless all displayed solutions are single-valued on this cover, so its analytic monodromy is the identity and its unipotent logarithm is zero. The exact diagonal solution leaves no additional sector transition to determine for this tensor of the one-critical-value family. The invariant and coinvariant statements above refer to the ordinary local system; they do not impose an unmentioned growth condition at the puncture.

131.3 The arithmetic action moves the invariant character

Let J be the matrix of multiplication by y on $\mathbb{C}[y]/y^m$: $J_{a+1,a} = 1$, all other entries zero. Put $J_i = I^{\otimes(i-1)} \otimes J \otimes I^{\otimes(k-i)}$, $J_{\text{tot}} = \sum_i J_i$, and

$$R_k = P_k^{-1} J_{\text{tot}} P_k, \quad A_k = M_{s_1+\dots+s_k} = k\rho I + R_k. \quad (\text{TP.13})$$

This is multiplication in the original algebra (TP.1), since $s_i = \rho + y_i$. No geometric nilpotent replaces R_k . Put $K = k(m-1)$. The commuting nilpotents have the exact multinomial powers

$$J_{\text{tot}}^r y^{\mathbf{b}} = \sum_{\substack{\alpha \in \mathbb{Z}_{\geq 0}^k, |\alpha|=r \\ b_i + \alpha_i \leq m-1 \ (1 \leq i \leq k)}} \frac{r!}{\prod_i \alpha_i!} y^{\mathbf{b}+\alpha}, \quad R_k^{K+1} = 0, \quad R_k^K \neq 0. \quad (\text{TP.14})$$

Expansion of the commuting operators proves the sum. A term with an exponent at least m vanishes in (TP.1), giving its exact index restrictions. At $r = K$, the input one has nonzero top coefficient $K!/((m-1)!)^k$; at larger r no tuple survives. This also proves the conventions when $K = 0$: $R_k^0 = I \neq 0$ and $R_k = 0$.

Define $D_0 = \text{diag}(d_a)$ and $K_0 = W D_0 J D_0^{-1} W^{-1}$, and let K_{tot} be the sum of its ordered factor placements. The actual period transport of the arithmetic action is

$$\Pi_k A_k \Pi_k^{-1} = k\rho I + u^{1/N} K_{\text{tot}}, \quad M_k K_{\text{tot}} M_k^{-1} = \zeta K_{\text{tot}}. \quad (\text{TP.15})$$

Conjugating J by $\text{diag}(u^{\beta_a})$ multiplies each nonzero entry by $u^{\beta_{a+1}-\beta_a} = u^{1/N}$; the tensor placements give the first identity. Replacing these powers by ζ^{a+1} gives the second. The scalar $e^{kc/u}$ cancels by its displayed inverse in this conjugation. Equivalently the exact connection commutator is

$$[B_k, A_k] = R_k/N, \quad [\nabla_u, A_k] = R_k/(Nu). \quad (\text{TP.16})$$

These follow on each monomial from the difference of its two residue eigenvalues, including each truncated top term, and then from (TP.8). Thus the arithmetic action is explicitly related to the boundary connection, with its precise nonhorizontal term.

Multiplication by a surviving y_i increases L by one. For all residues and integers $r \geq 0$, this gives

$$\begin{aligned} Q_t R_k^r &= R_k^r Q_{t-r}, & [Q_0, A_k] &= R_k(Q_{-1} - Q_0), \\ Q_0 A_k Q_0 &= k\rho Q_0, & (I - Q_0) A_k Q_0 &= R_k Q_0 = Q_1 R_k Q_0. \end{aligned} \quad (\text{TP.17})$$

All subscripts are taken modulo N . The first identity holds on every basis monomial, including zero output terms. The other identities follow from it and from $N \geq 2$. They calculate both the compression and the outgoing map. In particular a scalar compression is not an assertion that the invariant plane is preserved.

For a precise nonvanishing statement put

$$d_{\min} = N \lceil k/N \rceil - k \in \{0, \dots, N-1\}. \quad (\text{TP.18})$$

The possible degrees $|\mathbf{b}|$ fill every integer from zero to K : distribute any such integer successively into the k slots, never exceeding their capacity $m-1$. Thus $Q_0 \neq 0$ exactly when $d_{\min} \leq K$. Moreover

$R_k Q_0 \neq 0$ exactly when $d_{\min} < K$. If strict inequality holds, a tuple of that degree has an unfilled slot, and (TP.14) with $r = 1$ gives nonzero output with no cancellation, since its distinct monomials have positive integer coefficients. If equality holds, the only possible invariant tuple is the top one and every J_i kills it. This proves both directions.

For $k = 1$ we have $d_{\min} = m > K = m - 1$, so there are no invariants. For $m = 1$, $R_k = 0$ and the unique tensor character is invariant exactly when k is even. For every $m \geq 2$, $k \geq 2$, instead,

$$Q_0 \neq 0, \quad R_k Q_0 \neq 0. \quad (\text{TP.19})$$

Indeed at $k = 2$, $d_{\min} = m - 1 < 2m - 2 = K$. For $k \geq 3$, $K = k(m - 1) \geq m + 1 = N$, while $d_{\min} \leq N - 1$. This proves (TP.19), including $m = 2$, $k = 3$, the smallest equality case for the capacity bound.

131.4 The complete compressed dilation, including every return power

Work on $V_0 = \text{im } Q_0$. If this space is zero, all the following compressed maps are the unique zero maps. Suppose it is nonzero and put

$$q_* = \left\lfloor \frac{K - d_{\min}}{N} \right\rfloor = \lfloor km/N \rfloor - \lceil k/N \rceil, \quad T = Q_0 R_k^N Q_0|_{V_0}. \quad (\text{TP.20})$$

Since R_k^N commutes with Q_0 , $T^q = Q_0 R_k^{qN} Q_0|_{V_0}$. For every $0 \leq q \leq q_*$ this map is nonzero; for $q > q_*$ it is zero. To prove nonvanishing, choose an invariant tuple of minimum degree. Its remaining capacities sum to $K - d_{\min}$, so an increment tuple of size qN can be distributed within them. Its term in (TP.14) is nonzero and cannot cancel. For vanishing, every input has degree at least $d_{\min}$, so all output terms exceed capacity when $qN > K - d_{\min}$. Thus the nilpotency index of T is exactly $q_* + 1$, with the identity zeroth power when $q_* = 0$.

For $a > 0$, define the original ordered dilation on functions by simultaneous replacement $x_i \mapsto x_i/a$. Its generator is $\sum_i D_i$, with $D_i = -x_i \partial_{x_i}$, and hence its action on this marked packet is a^{A_k} . Write $z = \log a$. The complete compression is the finite expression

$$Q_0 a^{A_k} Q_0|_{V_0} = a^{k\rho} \sum_{q=0}^{q_*} \frac{z^{qN}}{(qN)!} T^q. \quad (\text{TP.21})$$

Indeed $a^{A_k} = a^{k\rho} \sum_{r=0}^K z^r R_k^r / r!$ by (TP.14). The first identity in (TP.17) kills its compression unless $N \mid r$, and (TP.20) determines exactly which surviving powers are nonzero. Equivalently, the sum without its scalar is the restriction of $N^{-1} \sum_{j=0}^{N-1} \exp(\zeta^j z R_k) Q_0$; the same root-of-unity sum proves this equality. In the original y -monomial coordinates its exact entry, from invariant $\mathbf{b}$ to invariant $\mathbf{d}$, is

$$\begin{cases} a^{k\rho} \frac{z^{|\mathbf{d}|-|\mathbf{b}|}}{\prod_i (d_i - b_i)!}, & d_i \geq b_i \text{ for all } i, \\ 0, & \text{otherwise.} \end{cases} \quad (\text{TP.22})$$

The two invariant conditions make the exponent divisible by N . Formula (TP.14) cancels its total factorial against that of the exponential and proves (TP.22). Conjugation by the explicit columns of P_k^{-1} returns this same matrix to the original s -basis.

In particular $k = 2$ always has $q_* = 0$, so (TP.21) is scalar even though (TP.19) proves nonzero outgoing arithmetic action when $m \geq 2$. Conversely nonconstant returns do occur: for $m = 2$, $N = 3$, $k = 3$, V_0 is spanned in the y -basis by 1 and $y_1 y_2 y_3$, and $R_k^3(1) = 6y_1 y_2 y_3$. The compression is exactly $a^{3\rho}(I + z^3 T/6)$, with that nonzero T . When $q_* \geq 1$, the compressed maps are not a one-parameter representation: after removing the scalar, their derivative at $z = 0$ is zero but their coefficient of z^N is the nonzero $T/N!$. A differentiable matrix-valued function F with $F(0) = I$ and

$F(z + w) = F(z)F(w)$ satisfies $F'(z) = F(z)F'(0)$ by differentiating in w ; zero derivative at zero would make it constant. This proves the asserted failure without identifying compression with a quotient action.

131.5 The full Taylor unit and its exact original-source projector

Retain the entire quotient $v_h = g/h$ and all coefficients of its marked Taylor class:

$$a_j = \frac{v_h^{(j)}(\rho)}{j!} = \frac{g^{(m+j)}(\rho)}{(m+j)!} \quad (0 \leq j < m), \quad a_0 \neq 0, \quad U_s = P^{-1} \left(\sum_{j=0}^{m-1} a_j J^j \right) P, \quad U_k = U_s^{\otimes k}. \quad (\text{TP.23})$$

The Taylor expansion at the complete-order zero proves the derivative equality. The inverse coefficients are $b_0 = a_0^{-1}$ and $b_r = -a_0^{-1} \sum_{j=1}^r a_j b_{r-j}$; multiplying the finite series modulo J^m proves the inverse. Thus (TP.23) is invertible and keeps every coefficient. It commutes with A_k , since all its factors are polynomials in the commuting multiplication matrices.

For a multi-index $\mathbf{j} \in \{0, \dots, m-1\}^k$, write $a_{\mathbf{j}} = \prod_i a_{j_i}$ and let $R_i = P_k^{-1} J_i P_k$, so $R_k = \sum_i R_i$. The full graded unit, its period transport and its connection defect are

$$\begin{aligned} U_k &= \sum_{\mathbf{j}} a_{\mathbf{j}} \prod_i R_i^{j_i}, \\ \Pi_k U_k \Pi_k^{-1} &= \sum_{\mathbf{j}} a_{\mathbf{j}} u^{|\mathbf{j}|/N} \prod_i K_i^{j_i}, \\ [\nabla_u, U_k] &= \frac{1}{Nu} \sum_{\mathbf{j}} |\mathbf{j}| a_{\mathbf{j}} \prod_i R_i^{j_i}. \end{aligned} \quad (\text{TP.24})$$

Here K_i is the corresponding placement of K_0 . The first equality expands the tensor product, the second uses (TP.15) factor by factor, and the third follows from the residue difference $|\mathbf{j}|/N$ on each surviving monomial. Zero terms at the truncation boundary satisfy the identities as well.

The actual source maps can now be specified. On the original one-variable spaces retain $D = -x\partial_x$, $\Theta\phi(x) = 2 \sum_{r \geq 1} \phi(rx)$, $\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}$, and the original F_h with Mellin transform v_h . Here the Mellin convention is $\mathcal{M}F(s) = \int_0^\infty F(x)x^s dx/x$. The source V is the even Schwartz subspace with $\phi(0) = \int \phi = 0$; the target $\mathcal{B}$ has all seminorms $\sup_{x>0} x^b |D^r F(x)|$ finite for every integer b and nonnegative integer r . The inherited original source identity is $\mathcal{M}\Theta\phi_* = g$, and the exact Euler inverse constructs this $F_h \in \mathcal{B}$. Define the actual finite-packet maps on multivariate polynomials by

$$\begin{aligned} \mathcal{T}_k(f) &= f(D_1, \dots, D_k) \prod_{i=1}^k F_h(x_i), \\ \alpha_k(f) &= f(D_1, \dots, D_k) \prod_{i=1}^k \phi_*(x_i), \\ \mathcal{J}_k \mathcal{T}_k(f) &= U_k[f]_s. \end{aligned} \quad (\text{TP.25})$$

Here $\mathcal{J}_k$ means the multivariable Mellin transform followed by reduction modulo all $h(s_i)$, and $[f]_s$ is the unchanged remainder column. Every displayed source lies in the original smooth product source; it is an explicit finite sum of tensor functions, not an assertion that the whole completed source equals its algebraic tensor product. Integration by parts gives $\mathcal{M}(D_i F) = s_i \mathcal{M}F$; all endpoint terms vanish by the stated seminorms. Fubini then gives $\mathcal{M}_k \mathcal{T}_k(f) = f(s) \prod_i v_h(s_i)$. Its full jet is exactly the last equality of (TP.25). The factorwise identities $\Theta\alpha_h(f) = \mathcal{T}_h(hf)$ give the ordered tensor source square with every usual total-complex sign. The corrected one-factor section σ_h therefore gives the

actual degree- k injection $\sigma_h^{\otimes k} U_k$ on this finite tensor packet. This retains the original full unit; it is not set equal to the identity.

In particular, if x_s is a marked coefficient column and $q = U_k x_s$ is its actual theta-jet coordinate, the period observation of that source is $\Pi_k U_k^{-1} q$. Its exact invariant projector is

$$\widehat{Q}_0 = U_k Q_0 U_k^{-1}, \quad \mathcal{P}_0 \Pi_k U_k^{-1} = \Pi_k U_k^{-1} \widehat{Q}_0, \quad [\widehat{Q}_0, A_k] = U_k [Q_0, A_k] U_k^{-1}. \quad (\text{TP.26})$$

The first two formulas follow by substituting $q = U_k x_s$ into (TP.10). The last uses the proved commutation of U_k with A_k . Thus the actual invariant source plane is $U_k \text{im } Q_0$, with the same exact arithmetic leakage conjugated through its original unit. On the cohomology image the corresponding projector is $\sigma_h^{\otimes k} \widehat{Q}_0 (\sigma_h^{\otimes k})^{-1}$, where the inverse is only on that injective image. Its maps are fully specified.

For comparison, when $V_0 \neq 0$, compressing the coefficient matrix U_k by Q_0 is another concrete operation. Its full expression on V_0 is

$$Q_0 U_k Q_0|_{V_0} = a_0^k I_{V_0} + Z, \quad Z = \sum_{\substack{\mathbf{j} \neq 0 \\ N || \mathbf{j}}} a_{\mathbf{j}} Q_0 \prod_i R_i^{j_i} Q_0 \Big|_{V_0}, \quad Z^{q_*+1} = 0. \quad (\text{TP.27})$$

Every omitted term changes the character and so is killed by (TP.10); every term of Z raises degree by at least N . The degree bound defining q_* proves its stated vanishing power, without requiring any a_j other than a_0 to be nonzero. Its exact inverse is $a_0^{-k} \sum_{r=0}^{q_*} (-a_0^{-k} Z)^r$. Multiplying this finite geometric series proves the claim. This inverse is not substituted for the full U_k^{-1} in (TP.26).

Finally the difference between marked coefficient multiplication and multiplication of twisted representatives is also explicit. Put $v_{\text{pol}}(s) = \sum_{j=0}^{m-1} a_j (s - \rho)^j$ and $V_{\text{pol}} = \prod_i v_{\text{pol}}(s_i)$. For every polynomial f , the actual differential obeys

$$V_{\text{pol}} L_i f = L_i (V_{\text{pol}} f) - u(\partial_{s_i} V_{\text{pol}}) f. \quad (\text{TP.28})$$

This is the Leibniz rule, with the full derivative term. To compute its complete remainder, divide in one variable $v_{\text{pol}} s^b = h q_b + r_b$, with $\deg r_b < m$. Let H_s have column b the original coordinate column of q'_b . Since $\deg q_b \leq m - 2$, q'_b is already a remainder. Subtracting $L_u q_b = h q_b + u q'_b$ gives $[v_{\text{pol}} s^b] = [r_b - u q'_b]$. For explicit coefficients in the y -basis,

$$(H_y)_{ab} = \begin{cases} (a+1)a_{a+m+1-b}, & 0 \leq a+m+1-b < m, \\ 0, & \text{otherwise,} \end{cases} \quad H_s = P^{-1} H_y P, \quad (\text{TP.29})$$

$$\text{Rem}_u(V_{\text{pol}} \cdot) = (U_s - u H_s)^{\otimes k}.$$

on the retained original remainder frame. Indeed the quotient of $v_{\text{pol}} y^b$ has terms $a_j y^{j+b-m}$ exactly when $j+b \geq m$; differentiating gives the stated matrix entry. The tensor formula follows by replacing the factors successively; their variables are distinct and their top-form order stays fixed. This proves the exact full representative correction on the same frame. It does not assert that multiplication descends on arbitrary twisted-cohomology representatives.

131.6 The original terminal class on its exact invariant subsequence

The complete tensor primary algebra contains its original terminal jet

$$\tau_k = \prod_{i=1}^k y_i^{m-1}, \quad R_k \tau_k = 0, \quad A_k \tau_k = k \rho \tau_k, \quad U_k \tau_k = a_0^k \tau_k. \quad (\text{TP.30})$$

Its displayed coefficient in the retained basis is one, so it is nonzero. Each multiplication by y_i kills it, proving the next two statements by (TP.13). Every positive Taylor term in (TP.23) also kills it, proving the last statement with its full scalar. Since $L(m-1, \dots, m-1) = km \equiv -k \pmod{N}$,

$$Q_0 \tau_k = \widehat{Q}_0 \tau_k = \begin{cases} \tau_k, & N \mid k, \\ 0, & N \nmid k. \end{cases} \quad (\text{TP.31})$$

The equality for Q_0 is its diagonal-mask definition, and that for $\widehat{Q}_0$ follows from $U_k^{-1} \tau_k = a_0^{-k} \tau_k$ in (TP.26). Thus on the infinite subsequence $k = N\ell, \ell \geq 1$, the same nonzero arithmetic terminal class lies in the actual boundary-invariant plane, in both marked and original jet coordinates.

Its complete period vector is

$$\Pi_k \tau_k = e^{kc/u} d_{m-1}^k u^{km/N} (W_{\bullet, m-1})^{\otimes k}, \quad d_{m-1} = N^{-1/N} e^{\pi i m/N} \Gamma(m/N), \quad W_{j, m-1} = \zeta^{-j} - 1. \quad (\text{TP.32})$$

This is column $(m-1, \dots, m-1)$ of (TP.6) in its specified y -coordinates. Every entry $W_{j, m-1}$ is nonzero, so the vector remains nonzero for $u \neq 0$. Its period-cycle monodromy is multiplication by $\zeta^{km} = \zeta^{-k}$, agreeing with (TP.31). For the original corrected-section class $u_\rho^{\otimes k} = \sigma_h^{\otimes k} \tau_k$, the period observation defined in (TP.26) is precisely $a_0^{-k} \Pi_k \tau_k$, not the vector with this scalar omitted.

For the comparison with the original MAI/PAM counterfactual branch, retain its selected $\rho = 1/2 + \delta + i\gamma$, with $0 < \delta < 1/2$ and $\gamma > 0$, reached by its original reflection and conjugation arrows. Let h_0 be its original reflected quartet packet containing the same order- m zero, put $w = h_0/h$, and retain its original CRT idempotent e_ρ . The map $E_h \rightarrow e_\rho E_{h_0}$, $[f] \mapsto e_\rho[f]$, is an isomorphism with inverse reduction modulo h : the idempotent is one on this primary factor and zero on all the other factors. This proves both composites directly on every CRT component. Moreover $w(\rho) \neq 0$, and the exact unit relation on this factor is $(g/h_0) = v_h/w$; the inverse of the class of w is its unique truncated Taylor inverse. Thus this local passage retains the whole original unit, not only its constant coefficient.

Write $K = k(m-1)$ as before. The original amplified terminal coefficient is

$$c_{h_0, k} = \frac{K!}{((m-1)!)^k} ((g/h_0)(\rho))^k \neq 0, \quad \eta_k v_k = c_{h_0, k} \tau_k, \quad \mathcal{I}_k v_k = c_{h_0, k} u_\rho^{\otimes k}. \quad (\text{TP.33})$$

Here $v_k, \eta_k, \mathcal{I}_k$ are the original cyclic terminal vector, coefficient map and cohomology map of MAI6a. The selected quartet corner $k\rho$ arises only by choosing ρ in every tensor factor, as in that construction. The first equality for that map is also its direct local calculation: (TP.14) at $r = K$ leaves precisely $K!/((m-1)!)^k \prod_i y_i^{m-1}$; the original complete unit acts on that terminal monomial by $((g/h_0)(\rho))^k$. All other Taylor terms vanish because they exceed a retained primary order. The original corrected-section transition $\sigma_{h_0} \iota_{h, h_0} = \sigma_h$ carries this identity to the second cohomology equality. Thus the original source period observation of this specified amplified vector is exactly

$$c_{h_0, k} a_0^{-k} \Pi_k \tau_k = \frac{K!}{((m-1)!)^k} \left(\frac{(g/h_0)(\rho)}{(g/h)(\rho)} \right)^k e^{kc/u} d_{m-1}^k u^{km/N} (W_{\bullet, m-1})^{\otimes k}. \quad (\text{TP.34})$$

Every factor is retained and nonzero over $\mathbb{C}$. The ratio of unit values is $w(\rho)^{-1}$, as follows from the full unit relation above. No rescaling of the original vector was used to get (TP.34).

For $a > 0$, (TP.30) gives $a^{A_k} \tau_k = a^{k\rho} \tau_k$; the original source action has the same equality after applying its established theta-boundary homotopy and passing to cohomology. If $\delta = \text{Re } \rho - 1/2$, its exact discrepancy is

$$\log \left(\frac{|a^{k\rho}|^2}{a^k} \right) = 2k\delta \log a. \quad (\text{TP.35})$$

This follows by taking the real part of $k\rho \log a$. On $k = N\ell$, it holds on the same nonzero original terminal class inside the boundary-invariant plane. The invariant projection therefore does not eliminate that discrepancy. This calculation supplies no bound on it by a constant independent of k .

131.7 The exact rank of arithmetic departure from the invariant plane

Let $E_{k,d}$ be the span of $y^{\mathbf{b}}$ with $|\mathbf{b}| = d$, and define $h_d = \dim E_{k,d}$, with $h_d = 0$ outside $0 \leq d \leq K$. The exact coefficient count is

$$\sum_{d=0}^K h_d t^d = (1 + t + \cdots + t^{m-1})^k. \quad (\text{TP.36})$$

Expanding the product proves it by the ordered monomial basis. To compute the rank of J_{tot} on these levels, define on one factor $Fy^b = b(m-b)y^{b-1}$, with $F1 = 0$, and use the positive diagonal form with $\|y^b\|^2 = b!(m-1)!/(m-1-b)!$. The ratio of consecutive diagonal entries is $(b+1)(m-1-b)$; hence the adjoint of J is exactly F . This form is used only to prove a basis-independent algebraic rank. It is not substituted for the original theta-source norm.

Use the tensor product of these forms and put $F_{\text{tot}} = \sum_i F_i$. Direct evaluation on each one-factor monomial gives $[F, J]y^b = (m-1-2b)y^b$. Operators in different factors commute, so on degree d this proves

$$\|J_{\text{tot}}x\|^2 - \|F_{\text{tot}}x\|^2 = (K-2d)\|x\|^2 \quad (x \in E_{k,d}). \quad (\text{TP.37})$$

If $d < K/2$, the identity makes J_{tot} injective on $E_{k,d}$. If $d+1 > K/2$, its reversed identity makes F_{tot} injective on $E_{k,d+1}$, so its adjoint $J_{\text{tot}} : E_{k,d} \rightarrow E_{k,d+1}$ is surjective: $(\text{im } J_{\text{tot}})^\perp = \ker(F_{\text{tot}}|_{E_{k,d+1}}) = 0$. Every integer d satisfies one or both of these inequalities, including the central degree. It follows that

$$\text{rank}(J_{\text{tot}} : E_{k,d} \rightarrow E_{k,d+1}) = \min(h_d, h_{d+1}). \quad (\text{TP.38})$$

No unimodality assumption is used; the necessary dimension inequalities follow from the proved injectivity or surjectivity.

The invariant degrees have $d+k \equiv 0 \pmod{N}$. Their outgoing images have distinct degrees, so the direct-sum decomposition and (TP.38) give the full departure rank and its exact kernel:

$$\begin{aligned} \text{rank}(R_k Q_0) &= \sum_{\substack{0 \leq d \leq K \\ N|d+k}} \min(h_d, h_{d+1}), \\ \dim(\ker R_k \cap \text{im } Q_0) &= \sum_{\substack{0 \leq d \leq K \\ N|d+k}} \max(h_d - h_{d+1}, 0). \end{aligned} \quad (\text{TP.39})$$

Conjugation by P_k , then by the original U_k in (TP.26), preserves these ranks and kernels on the actual marked and original-source invariant planes.

For example, when $k=2, m \geq 2$, the sole invariant degree is $m-1$, and the exact kernel is the line

$$\mathbb{C}\omega_m, \quad \omega_m = \sum_{i=0}^{m-1} (-1)^i y_1^i y_2^{m-1-i}, \quad (y_1 + y_2)\omega_m = 0 \quad \text{in } E_2. \quad (\text{TP.40})$$

The interior coefficients cancel pairwise, and the two end terms have exponent m , so vanish. For a general input $\sum_i c_i y_1^i y_2^{m-1-i}$, the output coefficients are $c_{j-1} + c_j, 1 \leq j < m$. Its kernel therefore has exactly the stated alternating coefficients and dimension one, and its rank is $m-1$. This is a nonzero arithmetic eigenclass of eigenvalue 2ρ already lying in the boundary-invariant plane. It coexists with the nonzero departure on the remaining $m-1$ directions and with the scalar compressed dilation of (TP.21).

Every constant coefficient map above acts at each original nonbottom split-support label by $(A, x) \mapsto (A, fx)$, and fixes the external absence symbol τ . Its killed coefficient remains the represented zero at that label. The marked specialization $u=0$ is the original represented-zero specialization; none of these projector computations replaces it by external absence. Equations (TP.10), (TP.17), (TP.21) and (TP.26) specify the exact maps relating boundary invariants, the full arithmetic action, its dilation and the original source. The dimension of that invariant space alone supplies no conclusion about the location of the selected zero.

132 Ordered tensors of the actual single-primary finite-field sheaf

132.1 The original coefficient map and the common parameter

Retain the specified coefficient map $R \rightarrow k_0 = \mathbf{F}_{Q_0}$ of characteristic p , the full Taylor class $v_h = j_h(g/h)$ and its inverse in the retained m -dimensional remainder basis, and every other original coefficient. Write

$$N = m + 1 \geq 2, \quad p > N, \quad h(s) = (s - \rho)^m, \quad \Phi(s) = \frac{(s - \rho)^N - (-\rho)^N}{N}, \quad c = -\frac{(-\rho)^N}{N}. \quad (\text{TPF.1})$$

The same coefficient map supplies ρ, c, N^{-1} . In particular, no coefficient of an infinite analytic function is being adjoined in place of its specified full Taylor class. Set

$$d = \text{ord}_{(\mathbf{Z}/N\mathbf{Z})^\times}(Q_0), \quad L = \mathbf{F}_Q, \quad Q = Q_0^d, \quad N \mid Q - 1. \quad (\text{TPF.2})$$

This is defined since $p > N$ implies $\gcd(Q_0, N) = 1$. Fix $\ell \neq p$, coefficients $\overline{\mathbf{Q}}_\ell$, and a nontrivial additive character $\psi_0 : k_0 \rightarrow \overline{\mathbf{Q}}_\ell^\times$. Put $\psi = \psi_0 \circ \text{Tr}_{L/k_0}$. Every Frobenius below is geometric Frobenius. Kummer sheaves $\mathcal{K}_\chi$ have trace χ on $L^\times$; over finite extensions their characters extend by norm. Artin–Schreier characters extend by trace.

Let $\pi : \mathbf{A}_s^1 \times \mathbf{G}_{m,u} \rightarrow \mathbf{G}_{m,u}$ be projection and retain

$$\mathcal{F}_0 = R^1 \pi_! \mathcal{L}_{\psi_0}(\Phi(s)/u), \quad \mathcal{T}_{0,k} = \mathcal{F}_0^{\otimes k}, \quad k \geq 1. \quad (\text{TPF.3})$$

The positive integer k has no restriction relative to p or N . The tensor is ordered and taken on this one common u -line. No symmetric, alternating, or sum-coordinate quotient is taken. Write $\mathcal{F} = (\mathcal{F}_0)_L$ and $\mathcal{T}_k = (\mathcal{T}_{0,k})_L$. The complete single-primary calculation SPF gives

$$\mathcal{F} \simeq \mathcal{L}_\psi(c/u) \otimes \bigoplus_{\substack{\chi \in X_N \\ \chi \neq 1}} \mathcal{A}_{a_\chi} \otimes \mathcal{K}_\chi(u), \quad X_N = \{\chi : L^\times \rightarrow \overline{\mathbf{Q}}_\ell^\times : \chi^N = 1\}, \quad (\text{TPF.4})$$

where all constants are exactly

$$G_L(\chi, \psi) = \sum_{z \in L^\times} \chi(z) \psi(z), \quad a_\chi = -\chi(N) G_L(\chi, \psi). \quad (\text{TPF.5})$$

Here $\mathcal{A}_a$ is the geometrically constant line with geometric Fr_Q -eigenvalue a . SPF proves this isomorphism using the finite power-map idempotents, the support-preserving translation $s = y + \rho$, and $w = z/(Nu)$. Its minus sign comes from compact cohomology in degree one. In particular, all $R^i \pi_!$ vanish for $i \neq 1$. We use that proved single-primary result without changing its source or phase.

The relative compact-support Kunneth map consequently gives the precise source realization

$$\mathcal{T}_{0,k} \simeq R^k \Pi_! \mathcal{L}_{\psi_0} \left(\frac{\sum_{i=1}^k \Phi(s_i)}{u} \right), \quad \Pi : \mathbf{A}_{s_1, \dots, s_k}^k \times \mathbf{G}_{m,u} \longrightarrow \mathbf{G}_{m,u}. \quad (\text{TPF.6})$$

Indeed the derived relative Kunneth isomorphism tensors the k complexes $R\pi_! \mathcal{L}_{\psi_0}(\Phi/u)$, each concentrated in degree one; their tensor is concentrated in degree k . The external product of the additive sheaves is the sheaf of the sum of their functions, by addition of Artin–Schreier torsor coordinates. No factors are reordered, so no permutation sign is inserted. The source theorem is SGA 4, Expose XVII, 5.4.3 and its finite-family version 5.4.4.1: apply it at the finite coefficient levels of these lisse ℓ -adic sheaves and then pass to the ℓ -adic system and invert ℓ . Here every projection is compactifiable by $\mathbf{P}^1 \times \mathbf{G}_m \rightarrow \mathbf{G}_m$; the product compactification is $(\mathbf{P}^1)^k \times \mathbf{G}_m$. The coordinate isomorphism on this same source is

$$(y_1, \dots, y_k, u) \longmapsto (y_1 + \rho, \dots, y_k + \rho, u), \quad \frac{\sum_i \Phi(s_i)}{u} = \frac{\sum_i y_i^N}{Nu} + \frac{kc}{u}. \quad (\text{TPF.7})$$

Its inverse subtracts ρ in every coordinate, and it preserves compact supports. Each original coefficient function is pulled back by this literal substitution, and its inverse is pulled back by the same map.

132.2 Every ordered character tuple and its exact constant

Define

$$\begin{aligned} \Omega_k &= (X_N \setminus \{1\})^k, & r_k &= (N-1)^k, \\ \eta_{\chi} &= \prod_{i=1}^k \chi_i, & A_{\chi} &= \prod_{i=1}^k (-\chi_i(N) G_L(\chi_i, \psi)), & w_k &= kc \in k_0. \end{aligned} \quad (\text{TPF.8})$$

Thus k is reduced in characteristic p only when it multiplies the field element c . Its integer value still counts all k tensor factors and remains in every cohomological sign. Distributing the ordered tensor in (TPF.4), and using the additive and multiplicative torsor tensor laws, proves

$$\boxed{\mathcal{T}_k \simeq \mathcal{L}_{\psi}(w_k/u) \otimes \bigoplus_{\chi \in \Omega_k} \mathcal{A}_{A_{\chi}} \otimes \mathcal{K}_{\eta_{\chi}}(u).} \quad (\text{TPF.9})$$

Different ordered tuples remain different summands, even when their product characters or constants agree. This sheaf is lisse of rank r_k .

For $L_a = \mathbf{F}_{Q^a}$, put $\psi_a = \psi \circ \text{Tr}_{L_a/L}$ and $\chi_{i,a} = \chi_i \circ N_{L_a/L}$. At $u \in L_a^{\times}$, the eigenvalue on the tuple summand is exactly

$$\psi_a(w_k/u) A_{\chi}^a \prod_i \chi_{i,a}(u). \quad (\text{TPF.10})$$

SPF proves $-G_{L_a}(\chi_{i,a}, \psi_a) = (-G_L(\chi_i, \psi))^a$ by its one-dimensional compact cohomology. Also $\chi_{i,a}(N) = \chi_i(N)^a$. These two equalities prove the stated extension-field constant, without replacing a negative Gauss sum by the negative of its a th power. The trace identity on the actual ordered source is consequently

$$\text{Tr}(\text{Fr}_{Q^a, u} | \mathcal{T}_k) = (-1)^k \sum_{(s_1, \dots, s_k) \in L_a^k} \psi_a \left(\frac{\sum_i \Phi(s_i)}{u} \right). \quad (\text{TPF.11})$$

To check its sign directly, the original sum factors into k one-variable sums, each the negative of the trace on $\mathcal{F}$. Multiplying gives precisely $(-1)^k$.

132.3 Original inertia, its tame projector, and multiplicities

Let I_0 be geometric inertia over $\bar{k}_0((u))$, and put $V_k = (\mathcal{T}_{0,k})_{\bar{\eta}}$. Choose $\vartheta : \mathbf{F}_p \rightarrow \bar{\mathbf{Q}}_{\ell}^{\times}$ nontrivial and the unique $b \in k_0^{\times}$ satisfying

$$\psi_0(x) = \vartheta(\text{Tr}_{k_0/\mathbf{F}_p}(bx)). \quad (\text{TPF.12})$$

Nondegeneracy of the finite-field trace pairing supplies this unique b ; after extension to L the same b represents ψ .

First let $c \neq 0$. Keep the original cover for $\mathcal{F}$, before taking a tensor:

$$u = v^N, \quad z^p - z = \frac{bc}{v^N}. \quad (\text{TPF.13})$$

The Kummer degree is N . Over $\bar{k}_0((v))$ the Artin–Schreier polynomial has no root, since its right side has pole order N , prime to p , while a pole of $f^p - f$ has order divisible by p . Its degree is therefore p . The total extension has degree Np , and the Np displayed automorphisms

$$(\zeta, a) : (v, z) \mapsto (\zeta v, z + a), \quad \zeta \in \mu_N, a \in \mathbf{F}_p \quad (\text{TPF.14})$$

commute and exhaust its Galois group $\Gamma = \mu_N \times \mathbf{F}_p$. This is a quotient of the original geometric inertia: the Kummer part is totally ramified, and if e is the ramification index of the Artin–Schreier extension over $\bar{k}_0((v))$, its defining equation gives $p v_E(z) = -Ne$. Since $\gcd(p, N) = 1$ and $1 \leq e \leq p$, it follows that $e = p$.

For $\chi \in X_N$, let $\lambda_\chi : \mu_N(L) \rightarrow \overline{\mathbf{Q}}_\ell^\times$ be uniquely specified by $\lambda_\chi(x^{(Q-1)/N}) = \chi(x)$. Under the geometric Frobenius convention fixed above, the exact action on the tuple line in (TPF.9) is

$$\rho_k(\zeta, a)|_\chi = \lambda_{\eta_\chi}(\zeta)^{-1} \vartheta(-ka). \quad (\text{TPF.15})$$

The Kummer inverse is the power-map projector convention of SPF: with $D_\zeta e_r = e_{\zeta r}$, its χ -projector is $N^{-1} \sum_\zeta \lambda_\chi(\zeta) D_\zeta$, whose image has eigencharacter λ_χ^{-1} . For the Artin-Schreier torsor $z^p - z = f$, the projector $p^{-1} \sum_a \vartheta(a) D_a$ has eigencharacter ϑ^{-1} . At a finite-field point geometric Frobenius translates the torsor coordinate by $-\text{Tr}(f)$, giving trace $\vartheta(\text{Tr}(f))$. Thus its action is $\vartheta(-a)$, and k ordered tensor factors give $\vartheta(-ka)$, proving every sign in (TPF.15).

When $c = 0$, the original additive torsor is trivial. The geometric inertia action instead factors through the Kummer quotient μ_N , with the exact action $\lambda_{\eta_\chi}^{-1}$; there is no nontrivial wild factor.

Let T_ζ denote the action of $(\zeta, 0)$ in (TPF.15), or its Kummer action when $c = 0$. Its exact tame projector is

$$P_{0,k}^{\text{tame}} = \frac{1}{N} \sum_{\zeta \in \mu_N} T_\zeta, \quad P_{0,k}^{\text{tame}}|_\chi = \begin{cases} 1, & \eta_\chi = 1, \\ 0, & \eta_\chi \neq 1. \end{cases} \quad (\text{TPF.16})$$

Character orthogonality proves the second formula and idempotence. In the case $c \neq 0$, the true original inertia projector is

$$\begin{aligned} P_{I_0,k} &= \frac{1}{Np} \sum_{\zeta \in \mu_N} \sum_{a \in \mathbf{F}_p} \rho_k(\zeta, a) \\ &= P_{0,k}^{\text{tame}} \left(\frac{1}{p} \sum_{a \in \mathbf{F}_p} \vartheta(-ka) \right) = \begin{cases} P_{0,k}^{\text{tame}}, & p \mid k, \\ 0, & p \nmid k. \end{cases} \end{aligned} \quad (\text{TPF.17})$$

Division by Np occurs in the characteristic-zero coefficient field, regardless of the prime ℓ . For $c = 0$, the true projector is $P_{I_0,k} = P_{0,k}^{\text{tame}}$. This calculates it inside the original representation; the tame projector alone is not substituted for full inertia when its wild character is nontrivial.

Here are all tame multiplicities. Identify the cyclic group X_N with the additive group $\mathbf{Z}/N\mathbf{Z}$ using a chosen generator. A tuple is an ordered sequence $(j_1, \dots, j_k)$, each $1 \leq j_i < N$. For $t \in \mathbf{Z}/N\mathbf{Z}$, let $D_{k,t}$ count those with $\sum_i j_i = t$. Choose any primitive complex N th root ω . The elementary root-of-unity filter yields

$$\begin{aligned} D_{k,t} &= \frac{1}{N} \sum_{a=0}^{N-1} \omega^{-at} \left(\sum_{j=1}^{N-1} \omega^{aj} \right)^k \\ &= \begin{cases} \frac{(N-1)^k + (N-1)(-1)^k}{N}, & t = 0, \\ \frac{(N-1)^k - (-1)^k}{N}, & t \neq 0. \end{cases} \end{aligned} \quad (\text{TPF.18})$$

The filter follows by summing $N^{-1} \sum_a \omega^{a(\sum j_i - t)}$, which is one when the congruence holds and zero otherwise. At $a = 0$ the inner sum is $N - 1$; for every other a it is -1 . Finally $\sum_{a=1}^{N-1} \omega^{-at}$ is $N - 1$ for $t = 0$ and -1 otherwise. This proves the count, including all repeated tuple occurrences.

Put $d_{0,k} = D_{k,0}$. Since a field has no nonzero nilpotents and $N \neq 0$, $c = 0$ holds exactly when $\rho = 0$ after the given specialization. Consequently

$$w_k = 0 \iff (c = 0 \text{ or } p \mid k), \quad \boxed{\dim V_k^{I_0} = \begin{cases} d_{0,k} = \frac{(N-1)^k + (N-1)(-1)^k}{N}, & w_k = 0, \\ 0, & w_k \neq 0. \end{cases}} \quad (\text{TPF.19})$$

This allows $d_{0,k} = 0$: for $k = 1$ it is zero, and for $N = 2$ it is zero at odd k , one at even k . For $N \geq 3$ and $k \geq 2$, both formulas in (TPF.18) are strictly positive: at even k , $(N - 1)^k > 1$; at odd $k \geq 3$, $(N - 1)^k > N - 1$.

The action in (TPF.15) specifies the entire original inertia representation, including its kernel. For clarity its image order can also be read off. Define

$$h_k = \begin{cases} 1, & N = 2 \text{ and } k \text{ even,} \\ N, & \text{otherwise.} \end{cases} \quad (\text{TPF.20})$$

The tame image has order h_k . Indeed for $N = 2$ there is only one character, whose k th power has that order. For $N \geq 3$, $k = 1$ the list includes a primitive character; for $N \geq 3$, $k \geq 2$ every product character occurs by (TPF.18). In either case the tame kernel is trivial. When $w_k \neq 0$, the wild image has order p , and no nontrivial tame scalar can cancel a nontrivial wild scalar: their orders divide the coprime integers N and p . Thus the full image has order $h_k p$ in that case, and order h_k when $w_k = 0$.

132.4 Swan conductor and the finite-cover logarithm

If $w_k \neq 0$, the nontrivial character $\mathcal{L}_\psi(w_k/u)$ has Swan conductor one. One may verify it directly over $\bar{k}_0((u))$: in $z^p - z = bw_k/u$, the ramification index is p by the valuation argument above, $v_E(z) = -1$, and

$$v_E((z + a)^{-1} - z^{-1}) = 2 \quad (a \in \mathbf{F}_p^\times). \quad (\text{TPF.21})$$

Thus its lower ramification groups are $G_0 = G_1 = \mathbf{F}_p$, $G_2 = 1$, giving one positive break of value one. Tensoring by a tame character does not change this wild restriction. Every tuple line in (TPF.9) has this same wild character. If $w_k = 0$, every tuple line is tame. Additivity of Swan under direct sum therefore proves

$$\boxed{\text{Swan}_0(\mathcal{T}_k) = \begin{cases} 0, & w_k = 0, \\ (N - 1)^k, & w_k \neq 0. \end{cases}} \quad (\text{TPF.22})$$

The finite cover

$$u = v^N, \quad z_k^p - z_k = \frac{bk c}{v^N} \quad (\text{TPF.23})$$

trivializes all geometric inertia of $\mathcal{T}_k$. The first map kills every product Kummer character. The second trivializes the displayed additive factor by its own torsor. If $w_k = 0$, it is a trivial disjoint torsor and the first map alone suffices. If $w_k \neq 0$, its degree is p , as its pole order N is prime to p . When $c \neq 0$ and $p \nmid k$, it is explicitly the original cover (TPF.13) with $z_k = kz$; this equality follows from $k^p = k$ in $\mathbf{F}_p$. When $p \mid k$, the original cover still kills the representation, and its wild deck subgroup already acts trivially by (TPF.15).

On the subgroup defined by this finite cover every monodromy matrix is the identity. Hence its unipotent logarithm is exactly

$$N_{\text{mon},k} = 0. \quad (\text{TPF.24})$$

There is no conflict with any of the invariant dimensions in (TPF.19). Those concern the original inertia group; after the displayed cover, the restricted representation has the full r_k -dimensional invariant space.

132.5 Frobenius on the invariant space and exact descent

Let $j : \mathbf{G}_m \hookrightarrow \mathbf{A}_u^1$. The ordinary invariant stalk $(j_* \mathcal{T}_{0,k})_{\bar{0}} = V_k^{I_0}$: sections over the punctured strict henselian neighborhood are precisely the invariant vectors of its geometric generic stalk. If $w_k \neq 0$ this stalk is zero. For $w_k = 0$, set

$$\Omega_k^0 = \{\chi \in \Omega_k : \eta_\chi = 1\}. \quad (\text{TPF.25})$$

Over L , the exact Frobenius module is

$$V_k^{I_0} \simeq \bigoplus_{\chi \in \Omega_k^0} \overline{\mathbf{Q}}_\ell(A_\chi), \quad \det(1 - T \operatorname{Fr}_Q | V_k^{I_0}) = \prod_{\chi \in \Omega_k^0} (1 - A_\chi T). \quad (\text{TPF.26})$$

Each surviving summand is the constant sheaf $\mathcal{A}_{A_\chi}$: its product Kummer character and its additive factor are both trivial. This proves the formula for the boundary stalk, as well as for its constant extension to the u -line.

Over k_0 , Frobenius need not preserve the individual tuple lines. Let F_0 denote its geometric Frobenius action. Its exact permutation is

$$F_0 : \chi \mapsto \chi^{Q_0} = (\chi_1^{Q_0}, \dots, \chi_k^{Q_0}). \quad (\text{TPF.27})$$

To prove its direction, over the splitting field the deck operator satisfies $F_0 D_\zeta F_0^{-1} = D_{\zeta^{Q_0^{-1}}}$; the exponent denotes the inverse modulo N . Conjugating the exact projector gives

$$F_0 \left(\frac{1}{N} \sum_{\zeta} \lambda_\chi(\zeta) D_\zeta \right) F_0^{-1} = \frac{1}{N} \sum_{\eta} \lambda_\chi(\eta^{Q_0}) D_\eta = e_{\chi^{Q_0}}. \quad (\text{TPF.28})$$

Tensoring this identity in the retained order proves (TPF.27). The coefficients of the projectors are in the fixed ℓ -adic coefficient field; the conjugation changes their deck operators, not their coefficient values. The subset Ω_k^0 is stable because taking a Q_0 th power preserves the trivial product character.

For each orbit $\mathcal{O}$ in Ω_k^0 , choose a tuple χ in it and let its exact orbit length be e . Then $e \mid d$. Put $L_e = \mathbf{F}_{Q_0^e} \subset L$. Each χ_i uniquely descends by norm to a nontrivial character $\kappa_{i,e} : L_e^\times \rightarrow \overline{\mathbf{Q}}_\ell^\times$:

$$\chi_i = \kappa_{i,e} \circ \mathbf{N}_{L/L_e}, \quad \psi_e = \psi_0 \circ \operatorname{Tr}_{L_e/k_0}. \quad (\text{TPF.29})$$

Indeed $\chi_i^{Q_0^e} = \chi_i$, so its order divides $Q_0^e - 1$. If g generates $L^\times$, the kernel of this norm is generated by $g^{Q_0^e - 1}$, on which χ_i is trivial. The norm is surjective, proving existence, uniqueness, and nontriviality of $\kappa_{i,e}$. Also $\prod_i \kappa_{i,e} = 1$, again by surjectivity of the norm.

It is not necessary that all N th roots of unity belong to L_e . Here is the exact source map giving each individual descent. Put $r_i = \operatorname{ord}(\chi_i)$. Then $r_i \mid N$ and $r_i \mid Q_0^e - 1$, so $\mu_{r_i} \subset L_e$. Factor the original power map by

$$\mathbf{A}_y^1 \longrightarrow \mathbf{A}_x^1 \longrightarrow \mathbf{A}_z^1, \quad x = y^{N/r_i}, \quad z = x^{r_i} = y^N.$$

Pullback of functions on geometric fibre roots identifies the direct image for $x^{r_i} = z$ with the μ_{N/r_i} -invariants of the original $y^N = z$ direct image. For $z \neq 0$, the quotient of its root set by μ_{N/r_i} is exactly the root set of $x^{r_i} = z$, and invariant functions are exactly the functions constant on these orbits. At zero both geometric fibres have one point and the map is the identity. The sheaf map is therefore an isomorphism onto those invariants at every geometric stalk.

The character λ_{χ_i} factors through $\mu_N \rightarrow \mu_{r_i}$, $\zeta \mapsto \zeta^{N/r_i}$, as $\lambda_{\kappa_{i,e}}$. Indeed for $a \in L^\times$,

$$\lambda_{\kappa_{i,e}}(a^{(Q-1)/r_i}) = \kappa_{i,e}(a^{(Q-1)/(Q_0^e-1)}) = \chi_i(a) = \lambda_{\chi_i}(a^{(Q-1)/N}),$$

and $a \mapsto a^{(Q-1)/N}$ surjects onto μ_N . Thus the descended individual source summand is precisely the trace- $\kappa_{i,e}$ Kummer line, including its zero stalk. The phase on that source remains $z/(Nu) + c/u$, with the original denominator N , not r_i . Applying the same source isomorphism and trace formula as in SPF over L_e therefore computes the cycle scalar exactly:

$$\Lambda_{\mathcal{O}} = \prod_{i=1}^k (-\kappa_{i,e}(N) G_{L_e}(\kappa_{i,e}, \psi_e)). \quad (\text{TPF.30})$$

Every individual factor, including N and the minus sign, is retained. More explicitly F_0^e acts by this product on the selected tuple line: at $u = 1$ all its Kummer values are one, while the product of its additive values is $\psi_e(kc) = 1$, since $w_k = 0$. The tuple product is a constant sheaf, so this is its action at the invariant boundary stalk too. This proves the scalar over its actual orbit field; it has not been selected as an arbitrary root of an eigenvalue over L .

Choose $v_0 \neq 0$ in the tuple line and set $v_j = F_0^j v_0$ for $0 \leq j < e$. These vectors are in distinct direct-summand lines, so form a basis for the orbit block. In this basis $F_0 v_j = v_{j+1}$ for $j < e - 1$, and $F_0 v_{e-1} = \Lambda_{\mathcal{O}} v_0$. Consequently

$$\begin{aligned} \det(T - F_0 \mid V_k^{I_0}) &= \prod_{\mathcal{O} \subset \Omega_k^0} (T^{|\mathcal{O}|} - \Lambda_{\mathcal{O}}), \\ \det(1 - TF_0 \mid V_k^{I_0}) &= \prod_{\mathcal{O} \subset \Omega_k^0} (1 - \Lambda_{\mathcal{O}} T^{|\mathcal{O}|}). \end{aligned} \tag{TPF.31}$$

These expressions concern $w_k = 0$; when $w_k \neq 0$ both determinants on the zero space are one. Choosing another representative does not change $\Lambda_{\mathcal{O}}$, because F_0^e commutes with F_0 and hence has the same scalar on every line of that orbit. Formula (TPF.31) thus proves descent without asserting diagonal Frobenius in the original tuple coordinates over k_0 .

132.6 Exact weight and the two cancellation cases

The elementary unscaled Gauss calculation in SPF gives, for every complex embedding,

$$|G_L(\chi, \psi)| = Q^{1/2}, \quad |A_{\chi}| = Q^{k/2}. \tag{TPF.32}$$

In (TPF.10) all other factors are roots of unity. At a point of degree a over L , every eigenvalue therefore has absolute value $Q^{ak/2}$. This proves pointwise purity of weight k for the actual ordered tensor. It descends to k_0 : a positive power of any original Frobenius is covered by the calculation over L , and $|\beta^a| = Q_0^{fak/2}$ forces $|\beta| = Q_0^{fk/2}$ at an original point of degree f .

When $w_k = 0$, the same calculation over L_e in (TPF.30) gives

$$|\Lambda_{\mathcal{O}}| = Q_0^{ek/2}, \quad |\beta| = Q_0^{k/2} \quad \text{for every root } \beta^e = \Lambda_{\mathcal{O}}. \tag{TPF.33}$$

Thus every nonzero invariant block has weight k on $\text{Spec } k_0$, including the blocks that occur because $p \mid k$. If $c = 0$, the original single-factor wild character was already trivial. If $c \neq 0$ and $p \mid k$, it becomes trivial by the exact tensor character $\vartheta(-ka)$. Both branches have the same tame multiplicity formula, but the displayed maps account for their different origins. No complex arithmetic zeta zero or comparison of such a zero with these finite-field Frobenius eigenvalues is constructed by this calculation.

132.7 Exact counts of the arithmetic orbit blocks

For $f \mid d$, retain the full greatest common divisor and define

$$g_f = \gcd(N, Q_0^f - 1), \quad D(f) = \frac{(g_f - 1)^k + (g_f - 1)(-1)^k}{g_f}. \tag{TPF.34}$$

The characters fixed by exponent Q_0^f form a cyclic subgroup of X_N of order g_f . A fixed ordered tuple has all entries in this subgroup. Applying the root-of-unity count (TPF.18) inside that subgroup shows that exactly $D(f)$ tuples in Ω_k^0 are fixed. When $g_f = 1$ there are no allowed nontrivial entries

and the formula is zero, since $k \geq 1$. If $C(e)$ denotes the number of orbits in Ω_k^0 of exact length $e \mid d$, then

$$D(f) = \sum_{e \mid f} e C(e), \quad C(e) = \frac{1}{e} \sum_{f \mid e} \mu(e/f) D(f). \quad (\text{TPF.35})$$

The first identity counts the elements of every orbit fixed by F_0^f . For the second, multiply that identity by $\mu(e/f)$ and sum over $f \mid e$. The coefficient of $r C(r)$ is $\sum_{r \mid f \mid e} \mu(e/f)$, which is one for $r = e$ and otherwise zero: the latter sum factors as $\prod_{q \mid e/r} (1-1)$ over its distinct prime divisors. This proves the orbit count by integer arithmetic. These orbit numbers count the nonzero boundary blocks exactly when $w_k = 0$; when $w_k \neq 0$ the boundary stalk is zero by (TPF.19).

132.8 The terminal character, its orbit, and the original scalar

Fix a generator of the abstract cyclic deck group of order N , and identify its chosen complex N th root of unity and its finite-field root in $\mu_N(L)$ with a chosen N th root in the ℓ -adic coefficient field. These are explicit identifications of finite cyclic groups. Let $\chi_* \in X_N$ be the primitive character whose λ_{χ_*} is the resulting tautological character.

The direction of the deck action matters. For $\delta_\zeta(y) = \zeta y$, direct pullback gives

$$\delta_\zeta^*(y^b dy) = \zeta^{b+1} y^b dy, \quad \delta_\zeta^* e_r = e_{\zeta^{-1}r}, \quad D_\zeta = (\delta_\zeta^{-1})^*. \quad (\text{TPF.36})$$

The middle equality follows by evaluating the indicator function of the point r at ζy . Thus the finite SPF summand labelled χ has D_ζ -eigenvalue $\lambda_\chi(\zeta)^{-1}$ but ordinary deck-pullback eigenvalue $\lambda_\chi(\zeta)$. Comparing the pullback characters with the pullback characters, rather than with the inverse action D_ζ , gives the exact character-label map

$$b \mapsto \chi_b = \chi_*^{b+1}, \quad \chi_{\text{ter}} = \chi_*^m = \chi_*^{-1}, \quad \text{ord}(\chi_{\text{ter}}) = N. \quad (\text{TPF.37})$$

Here the terminal coefficient is y^{m-1} , and its form is $y^{m-1} dy$, so $b = m - 1 = N - 2$. The ordered terminal form has deck-pullback character $\zeta^{km} = \zeta^{-k}$, precisely as the product χ_{ter}^k records. This proves a map of the finite deck-character index sets. It does not assert a de Rham-étale comparison isomorphism or identify a complex arithmetic operator with finite-field Frobenius.

The repeated terminal tuple is $\chi_{\text{ter}} = (\chi_{\text{ter}}, \dots, \chi_{\text{ter}})$. Its actual finite-field summand on the same u -line is exactly

$$\mathcal{L}_\psi(kc/u) \otimes \mathcal{A}_{[-\chi_{\text{ter}}(N)G_L(\chi_{\text{ter}}, \psi)]^k} \otimes \mathcal{K}_{\chi_{\text{ter}}^k}(u). \quad (\text{TPF.38})$$

Its original-inertia invariants have dimension

$$\begin{cases} 1, & N \mid k \text{ and } kc = 0, & c = 0 : \text{ the nonzero case is } N \mid k, \\ 0, & \text{otherwise.} & c \neq 0 : \text{ the nonzero case is } pN \mid k. \end{cases} \quad (\text{TPF.39})$$

Indeed its tame product is trivial exactly when $N \mid k$, since χ_{ter} is primitive. Its wild character is trivial exactly when $kc = 0$. In the second branch $p \mid k$ and $N \mid k$ are equivalent to $pN \mid k$, since $\gcd(p, N) = 1$.

This single terminal line need not descend to k_0 . Its exact arithmetic orbit consists of the d distinct ordered tuples

$$\left(\chi_{\text{ter}}^{Q_0^j}, \dots, \chi_{\text{ter}}^{Q_0^j} \right), \quad 0 \leq j < d.$$

Its length is exactly d : equality of two tuple entries requires equality of their primitive characters, hence $Q_0^e = 1 \bmod N$, whose least positive solution is d . If the criterion in (TPF.39) holds, all these lines are invariant and the descended terminal-orbit block has dimension d , with

$$\begin{aligned} \Lambda_{\text{ter}} &= [-\chi_{\text{ter}}(N)G_L(\chi_{\text{ter}}, \psi)]^k, \\ \det(T - F_0 \mid \text{terminal orbit}) &= T^d - \Lambda_{\text{ter}}, \\ \det(1 - TF_0 \mid \text{terminal orbit}) &= 1 - \Lambda_{\text{ter}} T^d. \end{aligned} \quad (\text{TPF.40})$$

This is (TPF.30)–(TPF.31) with its actual orbit field L . Every root has absolute value $Q_0^{k/2}$. If the criterion fails, the invariant part of this orbit is zero. No Frobenius eigenline over k_0 is inferred from a single summand over L .

Finally retain the original scalar multiplying the terminal coefficient in the full marked packet h_0 , evaluated on a retained stage where its original source coefficients belong to the domain of the actual map α :

$$K = k(m-1), \quad u_0 = (g/h_0)(\rho), \quad C_{h_0,k} = \frac{K!}{((m-1)!)^k} u_0^k. \quad (\text{TPF.41})$$

Here K is an integer, and u_0 is the specified marked coefficient in that actual coefficient model. This calculation does not extend α to a larger cyclic CRT stage by assigning values to new denominators. If such a stage inverts p , no extension of α to it exists: applying a purported extension to $1 = p p^{-1}$ would give $1 = 0$. The absence of a stage specialization is not a vanishing coefficient specialization. Writing a bar for that same specialization gives the exact image

$$\overline{C}_{h_0,k} = \overline{K!} (\overline{(m-1)!})^{-k} \overline{u_0^k}, \quad \overline{C}_{h_0,k} \neq 0 \iff K < p \text{ and } \overline{u_0} \neq 0. \quad (\text{TPF.42})$$

The denominator is nonzero because $m-1 = N-2 < p$. The numerator $K!$ is nonzero modulo p exactly when $K < p$, and a positive power of a field element is nonzero exactly when that element is nonzero. These facts prove the equivalence. When the original unit class and its inverse are retained at this marked point, their product is one after evaluation at ρ and after specialization; hence $\overline{u_0} \neq 0$ in that specified model. Even there the factorial can vanish.

In particular, when $m \geq 2$ and $p \mid k$, one has $K = k(m-1) \geq p$, so $\overline{C}_{h_0,k} = 0$. Thus the $c \neq 0$ terminal-invariant degrees $pN \mid k$, on a marked stage admitting the specified α , have zero specialized original scalar for $m \geq 2$, although their sheaf summand and invariant orbit block computed above are nonzero. For $m = 1$, $K = 0$ and the scalar is exactly u_0^k , so only its original coefficient specialization can make it zero. For $c = 0$, the tame condition $N \mid k$ and the separate scalar condition $k(m-1) < p$, $\overline{u_0} \neq 0$ are both retained.

The last scalar calculation has a precise coefficient-module target. The original translation and coefficient specialization give

$$\begin{aligned} R[y_1, \dots, y_k]/(y_1^m, \dots, y_k^m) &\longrightarrow \overline{E}_k = k_0[y_1, \dots, y_k]/(y_1^m, \dots, y_k^m), \\ \sum_a q_a \prod_i y_i^{a_i} &\longmapsto \sum_a \alpha(q_a) \prod_i y_i^{a_i}, \\ \overline{\tau}_{\text{ter}} = \prod_i y_i^{m-1} &\neq 0, \quad \overline{C}_{h_0,k} \overline{\tau}_{\text{ter}} = 0 \iff \overline{C}_{h_0,k} = 0. \end{aligned} \quad (\text{TPF.43})$$

Successive division by the monic polynomials y_i^m gives the unique remainder basis $\prod_i y_i^{a_i}$, $0 \leq a_i < m$, so $\overline{\tau}_{\text{ter}}$ is one of its nonzero basis vectors and the last equivalence follows. All nilpotent directions of this coefficient algebra are retained. These scalar statements are in characteristic p . There is no unital field map from k_0 to $\overline{\mathbf{Q}}_\ell$, since such a map would send $p \cdot 1 = 0$ to the nonzero element $p \cdot 1$. Thus no multiplication of an ℓ -adic Gauss line by $\overline{C}_{h_0,k}$ is being asserted. The deck-character map (TPF.37) does not by itself transport coefficient vectors to etale cohomology; the finite-field sheaf is the independently specified compact-support sheaf and does not depend on this scalar.

132.9 The shared integral deck-character model and its two base changes

There is an exact common integral representation behind the character correspondence, which does not require a map between fields of different characteristics. Let

$$\begin{aligned} B &= \mathbf{Z}[\zeta_N, 1/N], \quad C_N = \langle \gamma : \gamma^N = 1 \rangle, \\ e_j &= \frac{1}{N} \sum_{a=0}^{N-1} \zeta_N^{-ja} \gamma^a \in B[C_N] \quad (0 \leq j < N). \end{aligned} \quad (\text{TPF.44})$$

Here ζ_N is a fixed primitive root in the cyclotomic ring. Finite geometric sums give

$$e_i e_j = \delta_{ij} e_j, \quad \sum_{j=0}^{N-1} e_j = 1, \quad \gamma e_j = \zeta_N^j e_j. \quad (\text{TPF.45})$$

For example the coefficient convolution in $e_i e_j$ contains $\sum_a \zeta_N^{a(j-i)}$, which is N for $i = j$ and zero otherwise. The sum of the e_j has coefficient one at γ^0 and zero elsewhere, and reindexing $a + 1$ proves the last identity.

The corresponding free module of polynomial forms with the original degree retained is

$$M_B = B[y] dy / y^m B[y] dy, \quad \gamma(y^b dy) = \zeta_N^{b+1} y^b dy \quad (0 \leq b < m). \quad (\text{TPF.46})$$

It is the quotient of polynomial one-forms by y^m times that free module, not the module of Kahler differentials of the truncated algebra. Its basis is $dy, y dy, \dots, y^{m-1} dy$. Thus the exact $B[C_N]$ -linear isomorphism

$$\bigoplus_{j=1}^{N-1} B e_j \longrightarrow M_B, \quad e_j \longmapsto y^{j-1} dy \quad (\text{TPF.47})$$

follows from (TPF.45) and the displayed bases. In an ordered k -fold tensor, $e_{j_1} \otimes \dots \otimes e_{j_k}$ therefore projects onto the corresponding ordered monomial-form basis line. The simultaneous e_0 -projector selects $\sum_i j_i = 0 \bmod N$, exactly the count in (TPF.18). The terminal line is $(B e_m)^{\otimes k}$.

Choose a primitive root $\zeta_L \in L$ and the primitive ℓ -adic root ζ_ℓ already used in (TPF.37). The two actual ring maps are

$$\iota_p : B \rightarrow L, \quad \zeta_N \mapsto \zeta_L, \quad \iota_\ell : B \rightarrow \overline{\mathbf{Q}}_\ell, \quad \zeta_N \mapsto \zeta_\ell. \quad (\text{TPF.48})$$

They are well defined: $p \nmid N$, $N \mid Q - 1$, and both selected roots are primitive N th roots. The first base change of (TPF.47) is the concrete isomorphism with $L[y] dy / y^m L[y] dy$, under which e_j is the projector onto $L y^{j-1} dy$. The coefficient-map connection is also exact: $R \otimes_{\mathbf{Z}} B \rightarrow L$ sends $r \otimes b'$ to $\alpha(r) \iota_p(b')$. Tensoring its polynomial-form module gives this same characteristic- p module. This does not introduce new inverses from a larger marked stage.

For the second base change, let W_ℓ be the fibre at $u = 1$ of the actual untwisted sheaf $\mathcal{L}_\psi(c/u)^\vee \otimes \mathcal{F}$. Give it the source deck-pullback action $\gamma = D_{\zeta_L}^{-1}$. The image of the same integral projector is

$$\iota_\ell(e_j) = \frac{1}{N} \sum_{a=0}^{N-1} \zeta_\ell^{-ja} D_{\zeta_L}^{-a} = \frac{1}{N} \sum_{a=0}^{N-1} \zeta_\ell^{ja} D_{\zeta_L}^a = e_{\chi_*^j}^{\text{SPF}}. \quad (\text{TPF.49})$$

The second equality reindexes $a \mapsto -a$. The third is precisely the original SPF power-map projector, with $\lambda_{\chi_*^j}(\zeta_L) = \zeta_\ell^j$. Thus it projects onto the actual one-dimensional Gauss line $H_j = e_{\chi_*^j}^{\text{SPF}} W_\ell$, whose geometric Frobenius over L is

$$-\chi_*^j(N) G_L(\chi_*^j, \psi).$$

Keep that entire line, including its Frobenius, rather than choosing a numerical basis for it. If H_j^{triv} denotes the same vector space and Frobenius with only its C_N -action replaced by the trivial action, there is the canonical isotypic reconstruction below. Give each first character-module factor the identity splitting-field Frobenius:

$$\bigoplus_{j=1}^{N-1} (B e_j \otimes_{B, \iota_\ell} \overline{\mathbf{Q}}_\ell) \otimes_{\overline{\mathbf{Q}}_\ell} H_j^{\text{triv}} \longrightarrow W_\ell, \quad (\text{TPF.50})$$

$$(a e_j) \otimes h \longmapsto a h.$$

It is an isomorphism: on the j th summand it is the scalar multiplication isomorphism onto H_j , and the SPF projectors are complete and orthogonal. It preserves the deck action by (TPF.45) and

preserves the splitting-field Frobenius by the retained action on H_j^{triv} . No Frobenius action on a characteristic- p coefficient vector has been assumed.

Tensoring these actual maps in the fixed order gives the shared terminal-character projector on both sides: $(e_m)^{\otimes k}$ maps to the characteristic- p line $L(\prod_i y_i^{m-1} dy_i)$ and to the ordered Gauss line $H_m^{\otimes k}$. The full finite-field sheaf reinstates its already specified additive factor $\mathcal{L}_\psi(kc/u)$; the common integral model supplies the finite μ_N representation, not an unconstructed universal additive sheaf. Formulas (TPF.44)–(TPF.50) are the exact common projector and base-change correspondence. They retain the coefficient scalar specialization in (TPF.43) and the independently nonzero ℓ -adic sheaf lines as their stated, different targets.

132.10 The multiplicity-one case and its exact scalar comparison

When $m = 1$, one has $N = 2$, $p > 2$, $d = 1$, and $L = k_0 = \mathbf{F}_Q$, because every odd Q_0 satisfies $Q_0 \equiv 1 \pmod{2}$. There is just the nontrivial quadratic character χ , and it is the terminal character. Retain the original constants

$$c = -\rho^2/2, \quad \gamma_\chi = -\chi(2)G_L(\chi, \psi). \quad (\text{TPF.51})$$

Their exact Gauss-square identity is

$$\gamma_\chi^2 = \chi(-1)Q. \quad (\text{TPF.52})$$

To prove it, take a complex embedding of the cyclotomic field of character values. Quadratic-character values are real, so changing z to $-z$ in the conjugate Gauss sum gives $\overline{G_L(\chi, \psi)} = \chi(-1)G_L(\chi, \psi)$. The proved absolute-square identity $G_L \overline{G_L} = Q$ implies $G_L^2 = \chi(-1)Q$, since $\chi(-1)^2 = 1$. Also $\chi(2)^2 = 1$, proving (TPF.52) with the original minus sign and the factor 2 retained. Both sides lie in the same cyclotomic number field; injectivity of the chosen embedding proves that algebraic identity there and hence in its chosen ℓ -adic realization.

For $c \neq 0$, every positive terminal-invariant degree is exactly $k = 2pr$, $r \geq 1$. Its one-dimensional original-base invariant Frobenius is

$$\gamma_\chi^k = (\chi(-1)Q)^{pr}, \quad |\gamma_\chi^k| = Q^{k/2}. \quad (\text{TPF.53})$$

Its additive factor is exactly $\mathcal{L}_\psi(2prc/u) = \mathcal{L}_\psi(0)$; its Kummer factor is $\mathcal{K}_{\chi^{2pr}} = \mathcal{K}_1$. Thus the line is an actual nonzero invariant line of weight k . Here $K = k(m-1) = 0$ and the original marked coefficient is exactly u_0^k . On an actual coefficient stage retaining the inverse of u_0 , its reduction is nonzero. There is no factorial loss. For $c = 0$, every even k is tame invariant and the same formula reads $\gamma_\chi^k = (\chi(-1)Q)^{k/2}$; no divisibility by p is needed.

There is also an exact comparison calculation for any chosen map between the corresponding one-dimensional complex spaces, without asserting a canonical comparison. The actual arithmetic primary algebra is $\mathbf{C}[s]/(s - \rho)$. In its ordered k -fold tensor, the original sum operator $S = \sum_i s_i$ is multiplication by $k\rho$. For $a > 0$, its dilation operator is therefore

$$A_a = \exp((\log a)S) = a^{k\rho} \text{id}, \quad a^{k\rho} = \exp(k\rho \log a). \quad (\text{TPF.54})$$

Choose a complex embedding of the cyclotomic number field containing γ_χ , and let L_G be the resulting one-dimensional complex Frobenius model, with $F_G = \gamma_\chi^k \text{id}$. This takes a number-field model of the computed eigenvalue to $\mathbf{C}$, not a field map from k_0 to $\mathbf{C}$. For every nonzero complex-linear map $T : L_G \rightarrow L_{\text{arith}}$, scalar multiplication proves

$$\begin{aligned} A_a T &= \frac{a^{k\rho}}{\gamma_\chi^k} T F_G, \\ A_a T - T F_G &= (a^{k\rho} - \gamma_\chi^k) T, \quad \left| \frac{a^{k\rho}}{\gamma_\chi^k} \right| = \frac{a^{k \operatorname{Re} \rho}}{Q^{k/2}}. \end{aligned} \quad (\text{TPF.55})$$

For example such maps exist by sending a nonzero basis vector to a nonzero basis vector; changing either basis multiplies the matrix of T by a nonzero scalar and leaves the displayed ratio unchanged. At $a = Q$ the ratio has modulus $Q^{k(\operatorname{Re} \rho - 1/2)}$. This is the exact intertwining defect for every such map. Existence of a nonzero map does not turn this computed ratio into one, and no identification of the two operators has been assumed.

Sources and dependencies. The sole specialized input is the proved SPF.1–29 single-primary sheaf calculation, with its exact power-map projectors, cohomology, Gauss signs, and local inertia. The foundational curve and trace formulas are in Katz, *Gauss Sums, Kloosterman Sums, and Monodromy Groups*, Sections 2.0–2.3 and 4.0–4.3. The torsor constructions are the Stacks Project, tags 03PK and 0A3J. The relative compact-support Kunneth map in (TPF.6) is SGA 4, Expose XVII, Theorem 5.4.3, applied to the common base $\mathbf{G}_{m,u}$. All tensor multiplicities, original inertia projectors, cancellation cases, descent permutations, and orbit scalars are proved here.

133 The retained primary cyclic lattice at its specified coefficient prime

This calculation uses the ordered primary tensor and full Taylor unit of TP.1 and TP.23–25. It computes its original cyclic map over the specified coefficient prime, including the map before reduction, its primitive containing lattice, its cokernel, and the exact reduction sequence. The support carrier used below is the original G_{C_n} of MFC.29 and MFC.35–44.

133.1 The actual coefficient localization and the unchanged coordinates

Use the single-primary coefficient specialization already specified in SPF.1. Denote its retained coefficient subring of $\mathbb{C}$ by A , its map by $\alpha : A \rightarrow k_0$, and its characteristic by the prime p . Retain every coefficient of the full Taylor class and its inverse, and put

$$\mathfrak{q} = \ker \alpha, \quad S = A_{\mathfrak{q}}, \quad \tilde{\alpha} : S \longrightarrow k_0, \quad \tilde{\alpha}(a/b) = \alpha(a)/\alpha(b). \quad (\text{TCL.1})$$

Thus $b \notin \mathfrak{q}$ in this formula. The image of α is a finite subring of a field. For each nonzero element of that image, multiplication on the finite image is injective and therefore surjective; its inverse lies in the image. The image is consequently a field, proving that $\mathfrak{q}$ is maximal. The fraction formula is independent of representatives: equality of two fractions gives equality after cross multiplication in the domain A , and applying α and dividing by the nonzero denominator images gives the asserted equality. It preserves the ring operations by the same calculation. The map extends the specified map, rather than selecting a new one.

Since $A \subset \mathbb{C}$, both A and its localization S are domains of characteristic zero. The element p is a nonzero nonunit: its image is zero whereas the image of the unit is one. Every integer prime to p is outside $\mathfrak{q}$ and is a unit in S . In particular $\mathbb{Z}_{(p)} \rightarrow S$ is a well-defined injective scalar map. No assertion that S is a discrete valuation ring, a principal ideal domain, or a ring with all ideals in a chain is made or used. The algebra below uses $p > m$; the retained SPF specialization has the stronger $p > m + 1$, as required there by its phase denominators.

Keep the selected primary coordinate ρ , its full order $m \geq 1$, and the ordered number of factors $k \geq 1$. Put

$$\begin{aligned} K &= k(m-1), & y_i &= s_i - \rho, & E_S &= S[s_1, \dots, s_k] / ((s_i - \rho)^m)_{i=1}^k = S[y_1, \dots, y_k] / (y_i^m)_{i=1}^k, \\ J &= \sum_{i=1}^k y_i, & M &= \sum_{i=1}^k s_i = k\rho + J, & \mathcal{C}_S &= S[T] / (T^{K+1}), & \mathcal{C}_S^{\text{orig}} &= S[Z] / ((Z - k\rho)^{K+1}). \end{aligned} \quad (\text{TCL.2})$$

The two displayed presentations of E_S are identified by the mutually inverse substitutions $s_i = y_i + \rho$ and $y_i = s_i - \rho$. The cyclic-source coordinate map $\mathcal{C}_S^{\text{orig}} \rightarrow \mathcal{C}_S$ is $Z \mapsto k\rho + T$, with inverse $T \mapsto Z - k\rho$. These substitutions respect the defining ideals and their composites are the identity on each generator. They preserve the original objects and will be recorded explicitly in the original monomial matrices.

Let $\mathcal{B} = \{0, \dots, m-1\}^k$, ordered lexicographically. Repeated division by the monic relations y_i^m proves that $\{y^{\mathbf{b}} : \mathbf{b} \in \mathcal{B}\}$ is an S -basis: deleting monomials with any exponent at least m gives a remainder, and the relation ideal is spanned by precisely the deleted monomials, so no relation between retained monomials is possible. Every surviving degree is at most K ; hence $J^{K+1} = 0$.

Write the retained one-factor unit and its retained inverse as

$$\begin{aligned} v(y) &= \sum_{j=0}^{m-1} a_j y^j, & a_j &= \frac{(g/h)^{(j)}(\rho)}{j!} = \frac{g^{(m+j)}(\rho)}{(m+j)!}, & h &= (s - \rho)^m, \\ w(y) &= \sum_{j=0}^{m-1} b_j y^j, & b_0 &= a_0^{-1}, & b_r &= -a_0^{-1} \sum_{j=1}^r a_j b_{r-j}, \\ U &= \prod_{i=1}^k v(y_i), & U^{-1} &= \prod_{i=1}^k w(y_i) \quad \text{in } E_S. \end{aligned} \tag{TCL.3}$$

These are the actual retained coefficients, all lying in A by its specified construction. The derivative identity follows by expanding $g = (s - \rho)^m (g/h)$ at ρ . The recurrence makes the constant coefficient of vw equal to one and its coefficients of degrees $1, \dots, m-1$ equal to zero. Thus $vw = 1$ modulo y^m , proving the inverse in every factor and then in the tensor. In particular multiplication by U is an actual S -linear automorphism of E_S commuting with multiplication by J and M . No coefficient of this unit has been discarded.

The unchanged unweighted cyclic ring map and the original unit-weighted cyclic coefficient map are respectively

$$\begin{aligned} f : \mathcal{C}_S &\longrightarrow E_S, & f(T^r) &= J^r, \\ f_U : \mathcal{C}_S &\longrightarrow E_S, & f_U(T^r) &= U J^r, \\ f_U^{\text{orig}} : \mathcal{C}_S^{\text{orig}} &\longrightarrow E_S, & f_U^{\text{orig}}(Z^j) &= U M^j. \end{aligned} \tag{TCL.4}$$

The relation $J^{K+1} = 0$ proves that all maps are well-defined. The last two are linear maps, and are maps of modules over the cyclic source ring acting on the target by $T \mapsto J$, respectively $Z \mapsto M$. They are not asserted to be unital ring maps: their value at one is the retained U . Their exact intertwining identities are

$$f_U(Tc) = J f_U(c), \quad f_U^{\text{orig}}(Zc) = M f_U^{\text{orig}}(c). \tag{TCL.5}$$

Both follow by multiplication in the commutative algebra E_S . This is the coefficient realization of the original source map $\mathcal{J}_k \mathcal{T}_k$ in TP.25, restricted to polynomials in the sum of its unchanged s_i coordinates.

133.2 The primitive lattice and the exact factorial inclusion

For $0 \leq r \leq K$, define

$$\mathcal{B}_r = \{\mathbf{b} \in \mathcal{B} : |\mathbf{b}| = r\}, \quad \mathbf{b}! = \prod_{i=1}^k b_i!, \quad V_r = \sum_{\mathbf{b} \in \mathcal{B}_r} \frac{y^{\mathbf{b}}}{\mathbf{b}!}, \quad V_{K+1} = 0. \tag{TCL.6}$$

Every denominator is a unit because $b_i < m < p$. Each set $\mathcal{B}_r$ is nonempty. For $m > 1$ a specified member $\mathbf{b}^*(r)$ is obtained recursively by $b_i^*(r) = \min(m-1, r - \sum_{j < i} b_j^*(r))$. The remaining degree

is nonnegative at each step and is zero after k steps because $r \leq k(m-1)$. For $m = 1$ there is only $r = 0$, with $\mathbf{b}^*(0) = (0, \dots, 0)$.

The multinomial expansion and direct multiplication give

$$J^r = r!V_r \quad (0 \leq r \leq K), \quad JV_r = (r+1)V_{r+1} \quad (0 \leq r \leq K). \quad (\text{TCL.7})$$

To prove the first formula, expand the product of r copies of $\sum_i y_i$. For a prescribed exponent vector $\mathbf{b}$ there are $r!/\mathbf{b}!$ assignments of its r ordered factors to the variables. Exponents at least m give zero in the quotient. This leaves exactly the displayed coefficients. For the second formula, the coefficient of a retained $y^{\mathbf{b}}$ of degree $r+1$ is $\sum_{i:b_i>0} 1/(b_i-1)! \prod_{j \neq i} 1/b_j! = (\sum_i b_i)/\mathbf{b}! = (r+1)/\mathbf{b}!$. For $r = K$ every resulting monomial is zero, which agrees with the convention for V_{K+1} .

Define coefficient functionals, Λ containing lattice and its projection by

$$\begin{aligned} \lambda_r(x) &= \mathbf{b}^*(r)! [y^{\mathbf{b}^*(r)}]x, \\ \Lambda &= \bigoplus_{r=0}^K SV_r \subset E_S, \quad \pi(x) = \sum_{r=0}^K \lambda_r(x)V_r, \\ F &= \text{span}_S\{y^{\mathbf{b}} : \mathbf{b} \notin \{\mathbf{b}^*(0), \dots, \mathbf{b}^*(K)\}\}. \end{aligned} \quad (\text{TCL.8})$$

Distinct V_r have distinct degrees, and the pivot coefficient of V_r is the unit $1/\mathbf{b}^*(r)!$. Therefore $\lambda_r(V_t) = \delta_{rt}$, proving both the direct sum and $\pi^2 = \pi$. Subtracting $\pi(x)$ deletes exactly all pivot coordinates, so $x - \pi(x) \in F$. Conversely all pivot coordinates vanish on F ; hence $\pi(F) = 0$. We have proved the explicit splitting

$$E_S = \Lambda \oplus F, \quad \ker \pi = F. \quad (\text{TCL.9})$$

In particular each V_r is primitive in the sense that it is part of the displayed basis of a direct summand, with no division by $r!$ in the lattice construction.

Write $L = f(\mathcal{C}_S)$. Equations (TCL.7)–(TCL.9) imply

$$\begin{aligned} L &= \bigoplus_{r=0}^K r!SV_r \subset \Lambda, \quad \Lambda/L \simeq \bigoplus_{r=0}^K S/(r!), \\ W_r &= UV_r, \quad \Lambda_U = U\Lambda, \quad L_U = f_U(\mathcal{C}_S) = UL, \quad F_U = UF, \\ E_S &= \Lambda_U \oplus F_U, \quad \pi_U = U\pi U^{-1}, \quad L_U = \bigoplus_{r=0}^K r!SW_r. \end{aligned} \quad (\text{TCL.10})$$

Since S is a characteristic-zero domain, each $r!$ is nonzero and multiplication by it is injective. Thus f and f_U are injective. The quotient isomorphism sends $\sum_r c_r V_r$ to $(c_r \bmod r!)_r$; its kernel and surjectivity follow coordinate by coordinate. Applying the automorphism U proves every transported identity in the display. There is no claim that $U\Lambda = \Lambda$; it is the pair of lattices $L \subset \Lambda$ that is transported.

Let $Q = \text{Frac}(S)$. The exact saturation statement is

$$(L_U \otimes_S Q) \cap E_S = \Lambda_U \quad \text{inside } E_S \otimes_S Q. \quad (\text{TCL.11})$$

Indeed the nonzero $r!$ are invertible in Q , so $L_U \otimes Q = \Lambda_U \otimes Q$. In the splitting $E_S = \Lambda_U \oplus F_U$, an integral element belonging to this rational subspace has zero F_U -component, because the free module F_U injects into $F_U \otimes Q$. This proves the stated intersection, including both inclusions.

Both lattices are stable under J . On their indicated bases, the full action and its covariant inclusion are

$$\begin{aligned} JW_r &= (r+1)W_{r+1}, \quad J(r!W_r) = (r+1)!W_{r+1}, \\ \mathcal{C}_S &\xrightarrow{f_U} \Lambda_U, \quad T^r \mapsto r!W_r, \quad f_U \circ M_T = M_J \circ f_U. \end{aligned} \quad (\text{TCL.12})$$

At $r = K$ both actions are zero. Commutation of U and J and (TCL.7) prove all entries. This displays the actual source multiplication and the containing-lattice multiplication together with their exact intertwining map.

For clarity, the same map in all original monomial coordinates is

$$\begin{aligned} P_{ab} &= \begin{cases} \binom{b}{a} \rho^{b-a} & a \leq b, \\ 0 & a > b, \end{cases} \quad (0 \leq a, b < m), \quad P_k = P^{\otimes k}, \\ B_{rj} &= \begin{cases} \binom{j}{r} (k\rho)^{j-r} & r \leq j, \\ 0 & r > j, \end{cases} \quad (0 \leq r, j \leq K), \\ \mathbf{V}_{\mathbf{b}r} &= \begin{cases} 1/\mathbf{b}! & |\mathbf{b}| = r, \\ 0 & \text{otherwise,} \end{cases} \quad \Delta = \text{diag}(0!, 1!, \dots, K!), \\ [f_U^{\text{orig}}]_{(s^{\mathbf{b}}), (Z^j)} &= P_k^{-1} [U]_{(y^{\mathbf{b}})} \mathbf{V} \Delta B. \end{aligned} \tag{TCL.13}$$

The binomial theorem gives the two translation matrices P_k and B . Their inverses replace ρ and $k\rho$ by their negatives, respectively, as verified by the inverse substitutions above; their diagonal entries are one. The j -th column on the right is consequently the unchanged polynomial $U \sum_{r=0}^j \binom{j}{r} (k\rho)^{j-r} r! V_r = U(k\rho + J)^j$ written in the original $s^{\mathbf{b}}$ -basis. This proves the matrix formula without replacing the original source map or its unit.

133.3 Exact integer depths, quotient coordinates, and reduction

For each integer $r \geq 0$ define

$$d_r = v_p(r!) = \sum_{a \geq 1} \left\lfloor \frac{r}{p^a} \right\rfloor, \quad r! = p^{d_r} \varepsilon_r, \quad \varepsilon_r \in \mathbb{Z}_{(p)}^\times \subset S^\times. \tag{TCL.14}$$

Here $0! = 1$, and the sum is finite because its terms vanish when $p^a > r$. Each integer j between one and r contributes one factor of p for each positive a with $p^a \mid j$. Interchanging these two finite counts yields $\sum_a \#\{1 \leq j \leq r : p^a \mid j\} = \sum_a \lfloor r/p^a \rfloor$, proving the valuation formula. The remaining integer factor is prime to p , hence is a unit in S . Therefore $(r!) = p^{d_r} S$ exactly. The depth cannot increase in S : an equality $p^d = p^{d+1} s$ would permit cancellation in the domain and give $1 = ps$, contradicting $\tilde{\alpha}(1) = 1$ and $\tilde{\alpha}(p) = 0$. This argument proves strictness of every consecutive pair of principal p -power ideals, without assigning a valuation to arbitrary elements of S .

Set $C = \Lambda_U/L_U$. The following are actual quotient maps:

$$\begin{aligned} q_r : E_S &\longrightarrow S/(p^{d_r}), \quad q_r(x) = \lambda_r(U^{-1}x) \bmod p^{d_r}, \\ C &\xrightarrow{\sim} \bigoplus_{r=0}^K S/(p^{d_r}), \quad \left[\sum_r c_r W_r \right] \longmapsto (c_r \bmod p^{d_r})_r, \\ E_S/L_U &\xrightarrow{\sim} F_U \oplus \bigoplus_{r=0}^K S/(p^{d_r}). \end{aligned} \tag{TCL.15}$$

The convention is $S/(p^0) = 0$. Each q_r is linear, vanishes on F_U and on L_U , and takes W_t to δ_{rt} in its indicated target. Equations (TCL.9)–(TCL.10) prove the two isomorphisms and all these claims. For the coordinate class $\nu_r = [W_r] \in C$, its exact annihilator in S is $p^{d_r} S$, including the unit ideal when $\nu_r = 0$ and $d_r = 0$.

Let B denote either S/pS with its quotient map, or the specified target k_0 with the map $\tilde{\alpha}$. In both cases $B \neq 0$ and has characteristic p . Append a bar to each base-changed module, element and map. Equations (TCL.8)–(TCL.10) base change directly, because their projections and inverse changes of

basis have their coefficients in S . Thus $\overline{W}_0, \dots, \overline{W}_K$ remain a basis of the direct summand $\overline{\Lambda}_U \subset \overline{E}$. The original map becomes

$$\begin{aligned} \overline{f}_U(\overline{T}^r) &= \begin{cases} r! \overline{W}_r & 0 \leq r < p, \\ 0 & p \leq r \leq K, \end{cases} \\ \ker \overline{f}_U &= \bigoplus_{r=p}^K B\overline{T}^r = (\overline{T}^p), \\ \operatorname{im} \overline{f}_U &= \bigoplus_{r=0}^{\min(K, p-1)} B\overline{W}_r. \end{aligned} \quad (\text{TCL.16})$$

An empty direct sum is zero, and the ideal $(\overline{T}^p)$ is zero when $p > K$. For $r < p$, every factor of $r!$ is a nonzero element of the prime field and therefore a unit in B . For $r \geq p$ the factorial has a factor p and maps to zero. Applying these facts to the independent $\overline{W}_r$ proves exactly the displayed kernel and image.

The nilpotency indices of the indicated actions are

module and action	nilpotency index
$\overline{\mathcal{C}}_S = B[T]/(T^{K+1}), M_T$	$K + 1$
$\operatorname{im} \overline{f}_U, M_{\overline{J}}$	$\min(p, K + 1)$
$\overline{E}, M_{\overline{J}}$	$\min(p, K + 1)$
$\overline{\Lambda}_U, M_{\overline{J}}$	$\min(p, K + 1).$

(TCL.17)

The nilpotency index is the least positive integer whose power is zero; thus it is one for the zero action on a nonzero module. In the first row, $T^K \neq 0$ in its free monomial basis and $T^{K+1} = 0$. On $\overline{E}$, the binomial coefficients $\binom{p}{i}$ for $0 < i < p$ are divisible by p : their factorial expression has one factor of p in its numerator and none in its denominator. The commuting-variable binomial formula therefore gives $\overline{J}^p = \sum_i \overline{y}_i^p = 0$, since $p > m$. Also $\overline{J}^{K+1} = 0$. If $d = \min(p - 1, K)$, then $\overline{J}^d = \overline{d}! \overline{V}_d \neq 0$, by its unit pivot coordinate. This proves the third row. Its application to $\overline{W}_0 = \overline{U}$ gives $\overline{J}^d \overline{W}_0 = \overline{d}! \overline{W}_d \neq 0$, proving the second and fourth rows together with their inherited upper bounds. In particular the abstract reduced cyclic source has not acquired the smaller index: its exact map to the target has lost the directions in (TCL.16).

The reduced containing lattice has the more precise chain decomposition

$$\overline{\Lambda}_U = \bigoplus_{\substack{j \geq 0 \\ jp \leq K}} \bigoplus_{t=0}^{\min(p-1, K-jp)} B e_{j,t}, \quad e_{j,t} = \left(\prod_{a=1}^t \overline{jp+a} \right) \overline{W}_{jp+t}. \quad (\text{TCL.18})$$

The empty product is one. All displayed products are units because $1 \leq a \leq p - 1$. These are therefore changes of basis on disjoint intervals of the basis $\overline{W}_r$. Formula (TCL.12) gives $\overline{J} e_{j,t} = e_{j,t+1}$ except at the last position of a displayed interval. There it is zero, either because the next coefficient is $\overline{(j+1)p} = 0$, or because the next index is $K + 1$. This proves each full chain, including every chain that is absent from the image in (TCL.16).

The lost directions are also the exact connecting image in the base-change sequence

$$\begin{aligned} 0 &\longrightarrow \mathcal{C}_S \xrightarrow{\overline{f}_U} \overline{\Lambda}_U \longrightarrow C \longrightarrow 0, \\ 0 &\longrightarrow \operatorname{Tor}_1^S(C, B) \xrightarrow{\partial} \overline{\mathcal{C}}_S \xrightarrow{\overline{f}_U} \overline{\Lambda}_U \longrightarrow C \otimes_S B \longrightarrow 0, \\ \operatorname{Tor}_1^S(C, B) &= \bigoplus_{r=p}^K B \epsilon_r, \quad \partial(\epsilon_r) = \overline{T}^r, \quad C \otimes_S B \simeq \bigoplus_{r=p}^K B[\overline{W}_r]. \end{aligned} \quad (\text{TCL.19})$$

Here Tor_1 can be computed directly, without a flatness assertion about B . The first line is a free resolution of C of length one, whose differential in the displayed bases is Δ . Tensoring this two-term complex with B gives differential $\overline{\Delta}$. By definition its degree-one homology is $\operatorname{Tor}_1^S(C, B)$. The

factorial calculation in (TCL.16) gives its kernel with the displayed basis and gives its cokernel with the displayed basis. The degree-one differential was chosen as $+f_U$, so the map of the kernel into the degree-one free module is precisely $\epsilon_r \mapsto \bar{T}^r$, with no additional sign. This proves the entire sequence and its maps explicitly.

For the top original vector the formula, including its full scalar, is

$$f_U(T^K) = \frac{K!}{((m-1)!)^k} a_0^k \prod_{i=1}^k y_i^{m-1}. \quad (\text{TCL.20})$$

Only $\mathbf{b} = (m-1, \dots, m-1)$ has total degree K , so (TCL.7) gives its multinomial coefficient. Every nonconstant term of U annihilates that monomial; its constant coefficient is exactly a_0^k , proving the formula. Its scalar is nonzero in the actual characteristic-zero domain, and its exact factorial depth is d_K , because $(m-1)!$ and a_0 are units. The displayed vector maps to zero under the specified characteristic p coefficient map exactly when $K \geq p$. This statement concerns the already specified local single-primary source. It does not extend that specialization to a larger coefficient ring containing additional inverse CRT denominators. A ring in which p is a unit cannot map unitaly to characteristic p , since applying such a map to $pp^{-1} = 1$ would give $0 = 1$.

133.4 The exact original chain-support map for these depths

Fix an integer $L \geq \max(1, d_K)$ and put

$$\begin{aligned} R_{p,L} &= \mathbb{Z}/p^L\mathbb{Z}, & S_L &= S/p^L S, \\ \iota_L : R_{p,L} &\longrightarrow S_L, & [z] &\longmapsto [z], \\ I_a &= p^a R_{p,L}, & H_a &= p^a S_L \quad (0 \leq a \leq L). \end{aligned} \quad (\text{TCL.21})$$

The scalar map is well-defined and unital. It is injective. Indeed, if an integer z not divisible by p^L has image zero, write $z = p^a u$ with $0 \leq a < L$ and u prime to p . Then $p^a u = p^L s$ in S . Cancellation and inversion of u imply $1 = p^{L-a} s u^{-1}$, contradicting the specified residue map. Thus precisely $p^L \mathbb{Z}$ maps to zero, proving injectivity. The same argument proves $p^a \notin p^{a+1} S_L$ for $a < L$: a purported equality lifts to $p^a = p^{a+1} s + p^L t$, and cancellation gives $1 = ps + p^{L-a} t$, again impossible in the residue field. Consequently all H_a are distinct.

For completeness, every ideal of $R_{p,L}$ is some I_a . For a nonzero ideal, choose a nonzero element with least exponent of p among its integer representatives. It has the form $p^a u$ with u a unit modulo p^L , by the integer Euclidean algorithm. Multiplying by u^{-1} puts p^a in the ideal, and all its other elements have exponent at least a by choice, proving that the ideal is I_a . The zero ideal is I_L . This argument is not applied to S_L : there we retain exactly the principal subchain $\{H_a\}$.

Extension and contraction on this actual subchain are

$$\iota_L(I_a)S_L = H_a, \quad \iota_L^{-1}(H_a) = I_a, \quad (0 \leq a \leq L). \quad (\text{TCL.22})$$

Extension follows because the image of the principal generator is p^a . For contraction, an integer of exponent $b < a$ belonging to $p^a S_L$ would give $p^b u = p^a s + p^L t$. Cancelling p^b contradicts the nonzero residue of the unit u . Thus only the integers divisible by p^a contract, and they all do, proving the second formula.

The original ideal laws are retained exactly:

$$\begin{aligned} I_a + I_b &= I_{\min(a,b)}, & I_a \cap I_b &= I_{\max(a,b)}, & I_a I_b &= I_{\min(L,a+b)}, \\ H_a + H_b &= H_{\min(a,b)}, & H_a \cap H_b &= H_{\max(a,b)}, & H_a H_b &= H_{\min(L,a+b)}. \end{aligned} \quad (\text{TCL.23})$$

For sum and intersection the proof is inclusion: when $a \leq b$, the ideal indexed by b is contained in the one indexed by a . Their sum is the larger and their intersection the smaller. For product, every

sum of products of multiples of p^a and p^b is a multiple of p^{a+b} , and the generator p^{a+b} itself is such a product. It becomes zero for $a + b \geq L$. These arguments apply in both displayed rings and prove all six laws, including the boundary indices.

Let $C_L = \{0 < 1 < \dots < L\}$. The original lattice map and its actual coefficient extension are

$$\theta_p : C_L \longrightarrow \text{Id}(R_{p,L}), \quad j \longmapsto I_{L-j}, \quad \theta_S : C_L \longrightarrow \{H_a : 0 \leq a \leq L\}, \quad j \longmapsto H_{L-j}. \quad (\text{TCL.24})$$

They are bijections by the distinctness and classification just proved. Each takes bottom to the zero ideal, top to the unit ideal, maximum to ideal sum and minimum to ideal intersection, by (TCL.23). Thus they are bounded-lattice isomorphisms onto their stated codomains. Extension $I_a \mapsto H_a$ commutes with these two maps and preserves all three ideal operations of (TCL.23). In the j -coordinates, ordinary ideal multiplication is $j \odot t = \max(0, j+t-L)$, since its exponent is $\min(L, (L-j)+(L-t))$. It is not identified with lattice meet: for $L \geq 2, j = t = L-1$ gives respective values $L-2$ and $L-1$.

For either coefficient ring $B = R_{p,L}$ or $B = S_L$, use precisely the original split-support carrier

$$\begin{aligned} G_{C_L}(B) &= \{(0_B, j) : 0 \leq j \leq L\} \cup \{(b, L) : b \in B\}, \\ (b, j) + (c, t) &= (b + c, \max(j, t)), \quad (b, j)(c, t) = (bc, \min(j, t)), \\ \tau_a &= (0_B, L - a) \quad (0 \leq a \leq L), \quad e = \tau_0 = (0_B, L), \quad \tau_L = (0_B, 0). \end{aligned} \quad (\text{TCL.25})$$

The union is inside $B \times C_L$, so the two occurrences of $(0_B, L)$ give one element. A nonzero amplitude occurs only at top support. A nonzero sum has a nonzero summand, so has top support; a nonzero product has both amplitudes nonzero, so has top support. This proves closure. Associativity and commutativity hold in each coordinate. Distributivity follows from ring distributivity and $\min(j, \max(t, v)) = \max(\min(j, t), \min(j, v))$, verified by ordering t, v . The zero is τ_L , and the unit is $(1_B, L)$. These facts prove the stated semiring structure directly.

The exact support-preserving coefficient morphism is

$$\begin{aligned} G_{C_L}(\iota_L) : G_{C_L}(R_{p,L}) &\longrightarrow G_{C_L}(S_L), \quad (b, j) \longmapsto (\iota_L(b), j), \\ \chi_B : G_{C_L}(B) &\longrightarrow C_L, \quad (b, j) \longmapsto j, \\ \theta_S \chi_{S_L} G_{C_L}(\iota_L) &= \text{ext}_{\iota_L} \theta_p \chi_{R_{p,L}}. \end{aligned} \quad (\text{TCL.26})$$

The first map is well-defined because nonzero target amplitude has nonzero source amplitude and hence top support. Applying the ring homomorphism to amplitudes and leaving the support coordinate fixed proves preservation of both operations, zero and unit. Its injectivity follows from injectivity of ι_L and the unchanged support coordinate. The support projection preserves the two operations by their defining formulas. The last equality follows on every entry (b, j) from $I_{L-j}S_L = H_{L-j}$; it is an equality into the principal ideal subchain with ideal sum and ideal intersection. In particular each τ_a maps to the distinct τ_a , then to I_a or H_a . The supported zero e remains distinct from the absent zero τ_L .

Finally the connection of this support diagram to the actual cyclic quotient is not an identification of a torsion module with a semiring. The precise coordinate and annihilator maps are

$$\begin{aligned} C &\simeq \bigoplus_{r=0}^K S/(p^{d_r}), \quad p^L C = 0, \\ \text{Ann}_{S_L}(\nu_r) &= H_{d_r} = \theta_S(L - d_r) = \theta_S \chi_{S_L}(\tau_{d_r}), \\ q_r(x) &= \lambda_r(U^{-1}x) \bmod p^{d_r}. \end{aligned} \quad (\text{TCL.27})$$

The first and last lines are the proved maps of (TCL.15), with p^L annihilating every summand because $d_r \leq L$. An element of S_L kills the unit class of the r -th summand exactly when a representative in S lies in $p^{d_r}S$; this proves the annihilator formula and all its equalities using (TCL.24)–(TCL.26). Thus the depths of the original factorial inclusion have explicit labels in the original chain-support carrier, with their arithmetic ideal product as well as their lattice sum and intersection still recorded. The entry τ_{d_r} labels the annihilator; it does not replace the vector ν_r . In particular, when $d_r = L$ the vector ν_r is the nonzero unit class in S_L , whereas its annihilator is the zero ideal labelled by τ_L .

133.5 The retained boundary-character labels and the full-stage obstruction

The action on the lost source directions is also exact. For $K \geq p$, the kernel in (TCL.16), equivalently the connecting image of the Tor group in (TCL.19), has the ordered basis $\bar{T}^p, \dots, \bar{T}^K$, with

$$M_T \bar{T}^r = \bar{T}^{r+1} \ (p \leq r < K), \quad M_T \bar{T}^K = 0, \quad \text{ind}(M_T|_{\ker \bar{f}_U}) = K - p + 1. \quad (\text{TCL.28})$$

These equalities follow in the free monomial source basis. In particular the $(K - p)$ -th power takes $\bar{T}^p$ to the nonzero $\bar{T}^K$, and the next power is zero on every basis element. This index can exceed p . It is an action on the exact kernel in the source, not a subspace of the ambient target. Thus it is compatible with $\bar{J}^p = 0$ on $\bar{E}$: the original map is zero on every one of these kernel vectors.

Put $N = m + 1$. For a residue class $c \in \mathbb{Z}/N\mathbb{Z}$ define the original coefficient character masks in y -coordinates and their full-unit transports by

$$\begin{aligned} Q_c(y^{\mathbf{b}}) &= \mathbf{1}_{\{|\mathbf{b}|+k \equiv c \pmod{N}\}} y^{\mathbf{b}}, & \hat{Q}_c &= U Q_c U^{-1} : E_S \longrightarrow E_S, \\ D_c(T^r) &= \mathbf{1}_{\{r+k \equiv c \pmod{N}\}} T^r & \text{on } \mathcal{C}_S. \end{aligned} \quad (\text{TCL.29})$$

Each diagonal entry defining Q_c, D_c is zero or one in S , so these maps exist over this exact coefficient ring without adjoining roots of unity. On every indicated basis vector exactly one of the masks is one. Hence each family consists of pairwise orthogonal algebraic idempotents summing to the identity; conjugation by the actual U proves the same assertion for $\hat{Q}_c$. The word orthogonal here means that distinct idempotents compose to zero; no inner product or orthogonal projection on a metric space is introduced.

The full original boundary-character comparison is

$$\begin{aligned} Q_c V_r &= \mathbf{1}_{\{r+k \equiv c\}} V_r, & \hat{Q}_c W_r &= \mathbf{1}_{\{r+k \equiv c\}} W_r, \\ \hat{Q}_c f_U &= f_U D_c, & \hat{Q}_c J &= J \hat{Q}_{c-1}, & D_c M_T &= M_T D_{c-1}. \end{aligned} \quad (\text{TCL.30})$$

Every summand of V_r has degree r , proving the first equality, and conjugation proves the second. Apply these formulas to $f_U(T^r) = r!W_r$ to prove the third equality on a source basis. Multiplication by each y_i raises degree by one for every surviving monomial and gives zero at the truncation boundary. It follows on the complete monomial basis that $Q_c J = J Q_{c-1}$. Conjugation and $UJ = JU$ prove the fourth identity; the identical degree argument on T^r proves the last. These are covariant character shifts, not a claim that a fixed character mask commutes with J .

Over $\mathbb{C}$, this is exactly the coefficient mask of the boundary monodromy in TP.9–10: that period monodromy has eigenvalue $\exp(2\pi i(|\mathbf{b}| + k)/N)$ on its period character indexed by $\mathbf{b}$. In the unchanged original $s^{\mathbf{b}}$ -coordinates the coefficient mask is $P_k^{-1} Q_c P_k$, and the source mask is its conjugate by $P_k^{-1}[U]_{(y^{\mathbf{b}})} P_k$. The complex period matrix is $\Pi_k = e^{kc_0/u} W_k D_k(u) P_k$, with the original phase constant here denoted $c_0 = -(-\rho)^N/N$, and $D_k(u)$ diagonal in these same $\mathbf{b}$ indices. Consequently

$$\mathcal{P}_c \Pi_k = \Pi_k (P_k^{-1} Q_c P_k), \quad \mathcal{P}_c \Pi_k [U]_{(s^{\mathbf{b}})}^{-1} = \Pi_k [U]_{(s^{\mathbf{b}})}^{-1} [\hat{Q}_c]_{(s^{\mathbf{b}})}, \quad \mathcal{P}_c = W_k Q_c W_k^{-1}. \quad (\text{TCL.31})$$

Indeed Q_c commutes with the diagonal $D_k(u)$, which proves the first equality by multiplication, and substitution of the conjugation formula for $\hat{Q}_c$ proves the second. The common scalar $e^{kc_0/u}$, the original P_k and the entire U are present in these identities.

The masks preserve both L_U and Λ_U , as follows from their diagonal action on $r!W_r$ and W_r . They therefore act on the quotient C , and the exact free resolution in (TCL.19) commutes with D_c on its source and $\hat{Q}_c$ on its target. Its base change and its kernel inherit precisely those same masks. Thus the simultaneously retained depth and character of every quotient coordinate and lost direction are

$$\begin{aligned} \nu_r &= [W_r] : \quad \text{Ann}_{S_L}(\nu_r) = H_{d_r}, & \hat{Q}_c \nu_r &= \mathbf{1}_{\{r+k \equiv c\}} \nu_r, \\ \epsilon_r &\in \text{Tor}_1^S(C, B) \ (r \geq p) : & \bar{D}_c \partial \epsilon_r &= \mathbf{1}_{\{r+k \equiv c\}} \bar{T}^r. \end{aligned} \quad (\text{TCL.32})$$

The first line combines the proved annihilator in (TCL.27) with the induced quotient map. The second follows from the explicit connecting map $\partial\epsilon_r = \overline{T}'$. This proves both labels on the actual maps, including the zero coordinates when $d_r = 0$. It does not assert an inertia-invariant description of a different sheaf after reduction.

There is an exact obstruction to carrying this local specialization through the full amplified quartet CRT stage. In the counterfactual quartet of PAM.1–4 retain $\rho = \frac{1}{2} + \delta + i\gamma$, with $0 < \delta < \frac{1}{2}$, $\gamma > 0$, and take $k \geq p$. Two actual ordered tensor centres in that construction are

$$\lambda_0 = k\rho, \quad \lambda_1 = (k-p)\rho + p(1-\bar{\rho}), \quad \lambda_0 - \lambda_1 = p(\rho + \bar{\rho} - 1) = 2p\delta \neq 0. \quad (\text{TCL.33})$$

The first chooses ρ in every factor; the second chooses $1-\bar{\rho}$ in exactly p factors and ρ in the other $k-p$ factors. Both choices are permitted in the retained quartet, and the difference follows by subtraction. In the grid coordinates of PAM.2 they have indices respectively $(a, b) = (k, k)$ and $(k-p, k)$.

Let $A_{\text{CRT}} \subset \mathbb{C}$ be the actual coefficient ring carrying those quartet coordinates and every coefficient of the retained terminal CRT idempotent polynomial representative $e(Z) = \sum_{r=0}^d e_r Z^r$ at λ_0 . By its specified CRT residues, $e(\lambda_0) = 1$ and $e(\lambda_1) = 0$. Define the following element of this same ring:

$$\mathcal{D} = \sum_{r=1}^d e_r \sum_{j=0}^{r-1} \lambda_0^{r-1-j} \lambda_1^j \in A_{\text{CRT}}, \quad 1 = p(\rho + \bar{\rho} - 1)\mathcal{D}, \quad p^{-1} = (\rho + \bar{\rho} - 1)\mathcal{D} \in A_{\text{CRT}}. \quad (\text{TCL.34})$$

For every $r \geq 1$, multiplying the inner sum by $\lambda_0 - \lambda_1$ cancels all intermediate monomials and leaves $\lambda_0^r - \lambda_1^r$. After multiplication by e_r and summation the result is $e(\lambda_0) - e(\lambda_1) = 1$. Substitution of (TCL.33) proves the second equality and then the displayed inverse of p . This proof uses the original CRT polynomial itself and does not depend on a selected formula for its coefficients or on an assumed list of inverted pairwise differences. Since p is a unit, no prime ideal of A_{CRT} lies over (p) , and there is no unital characteristic- p specialization of that complete stage. A prime containing p would contain 1, and any such specialization would send the proved identity $pp^{-1} = 1$ to $0 = 1$.

Thus for $k \geq p$ the actual local prime used in (TCL.1) does not extend to this full quartet stage with its retained terminal CRT idempotent. This is a proved obstruction for that specified stage, not a statement that the local and global characteristic-zero objects are unrelated. Their local cyclic coefficient map is still exactly (TCL.4), their unchanged monomial translation is (TCL.13), and the characteristic-zero terminal coefficient is (TCL.20). The local characteristic- p quotient and its lost directions are the maps (TCL.16)–(TCL.19); a missing extension of their coefficient map is not the image of a global vector under a nonexistent specialization.

More generally let $A_{\text{CRT},k} \subset \mathbb{C}$ denote the retained coefficient ring of the complete split corner at degree k . The argument (TCL.33)–(TCL.34), applied to every rational prime $q \leq k$ in place of p , proves

$$q^{-1} \in A_{\text{CRT},k} \quad (q \text{ prime}, q \leq k). \quad (\text{TCL.35})$$

Indeed the second centre uses q reflected factors, which are available for every such q , and the same retained idempotent separates it from the terminal centre. Its divided difference gives the inverse without changing the idempotent. For a directed coefficient ring containing all these actual split stages one may take the explicit subring

$$A_{\text{CRT},\infty} = \bigcup_{n \geq 2} \mathbb{Z}[A_{\text{CRT},2}, \dots, A_{\text{CRT},n}] \subset \mathbb{C}, \quad \mathbb{Q} \subset A_{\text{CRT},\infty}. \quad (\text{TCL.36})$$

The finite generated-stage subrings in this union form an increasing sequence, so the union is a subring containing every stage with its actual coefficient maps. For any prime q , the stage $k = q$ supplies q^{-1} by (TCL.35). Factoring a nonzero integer into primes then puts its reciprocal in the union, proving the asserted copy of $\mathbb{Q}$. Every residue field of this union therefore has characteristic zero: a characteristic- q ring homomorphism would send the unit identity $qq^{-1} = 1$ to $0 = 1$. Equivalently

the scalar morphism $\text{Spec } A_{\text{CRT},\infty} \rightarrow \text{Spec } \mathbb{Z}$ has no point over any (q) . This follows directly by contraction of primes and the proved invertibility of every q . These conclusions concern the full split corner diagram with its retained CRT idempotents. They do not remove the finite single-primary models or the local maps (TCL.1)–(TCL.32).

There are also exact surviving character-zero vectors in the reduced local cyclic image. Take $m \geq 2$ and $k = p\ell$ with $\ell \geq 1$, so $K = k(m-1) \geq p$. Its final nonzero cyclic image basis vector and its unchanged characteristic-zero precursor satisfy

$$\begin{aligned} \bar{J}\bar{W}_{p-1} &= 0, & \bar{W}_{p-1} &\neq 0, & JW_{p-1} &= pW_p \neq 0, \\ \bar{Q}_0 \bar{W}_{p-1} &= \bar{W}_{p-1} &\iff & p(\ell+1) \equiv 1 \pmod{N}, & N &= m+1. \end{aligned} \quad (\text{TCL.37})$$

The first line follows from (TCL.12), the unit pivot after reduction, and the nonzero scalar p on the free characteristic-zero containing lattice. The vector belongs to the original reduced cyclic image because $\bar{f}_U(\bar{T}^{p-1}) = \overline{(p-1)!} \bar{W}_{p-1}$, whose scalar is a unit. Formula (TCL.30) gives the second line as $p-1+k \equiv 0 \pmod{N}$, and substitution of $k = p\ell$ gives the stated congruence. In the retained coefficient datum $p > N$, so p is invertible modulo N . Choosing the single residue class $\ell \equiv p^{-1} - 1 \pmod{N}$ and then its infinitely many positive representatives proves that the displayed character-zero case occurs for infinitely many tensor orders $k = p\ell$. These vectors are killed by J only after base change, as their exact characteristic-zero image pW_p shows. This is a calculation in the local coefficient module with its retained character masks, not an identification with a finite-field sheaf vector or a recovery of the original terminal jet.

Every tensor coefficient, the original monomial translations, the full unit and inverse, and the specified coefficient map occur in the displayed morphisms. The characteristic- p kernel in (TCL.16) is a statement about these coefficient modules. It neither sets an integer scalar to zero in $\mathbb{Q}_\ell$ nor identifies this reduction with the inertia or Frobenius action on the finite-field sheaf. No verdict about the location of an actual zero of ξ follows from this lattice calculation alone.

134 Original cyclic coefficients and the tensor boundary maps

134.1 The cyclic exponent with its retained coefficient map

The characteristic-zero nilpotent exponent in the cyclic-sum calculation has the following full coefficient form. This gives the original map before specialization, its saturation, its precise cokernel, and the specialized map. In particular the characteristic-zero injection and the specialized injection are no longer treated as the same assertion.

Let ρ be the retained primary centre, let $m \geq 1$ be its complete order, let $k \geq 1$, and put $K = k(m-1)$. Retain a coefficient subring $A \subset \mathbb{C}$ containing ρ , its already specified unital map $\alpha : A \rightarrow k_0$ to a finite field of characteristic $p > m$, and every coefficient of the original full unit and its inverse. The finite-field phase used below requires the stronger $p > m+1$. Since the image of α is a finite subring of a field, multiplication by any nonzero element of that image is an injective self-map of a finite set, hence a surjective map. The image is therefore a field and $\mathfrak{q} = \ker \alpha$ is maximal. Put $\mathcal{S} = A_{\mathfrak{q}}$. The extension $\tilde{\alpha} : \mathcal{S} \rightarrow k_0$ sends a/b to $\alpha(a)/\alpha(b)$; cross multiplication proves independence of the chosen fraction. The ring $\mathcal{S}$ is a characteristic-zero domain, p is a nonzero nonunit, and every integer prime to p is a unit. These statements use this actual coefficient map; they make no discrete-valuation or principal-ideal assumption on $\mathcal{S}$.

The coefficient datum and the phase datum have separate explicit domains. If A_{coef} carries the original centre and the full unit and inverse, the coefficient maps below are defined over A_{coef} . Adjoining the original phase requires the map $A_{\text{coef}} \rightarrow A_{\text{coef}}[1/(m+1)]$; a source presentation which also retains $1/(m+1)!$ uses that larger, explicitly given localization. A coefficient map extends to either localization exactly when its inverted elements have nonzero images: the extension must send each inverse to the inverse of its image, and that formula proves existence and uniqueness in the

nonzero case. Thus the factorial calculation with $p > m$ does not itself construct a phase specialization. For $m = 1, p = 2$, its coefficient map, when given on A_{coef} , sends the one-dimensional cyclic image by multiplication by the retained unit $\bar{a}_0^k$, which is nonzero; $K = 0$ and the nilpotent has index one. This map has no extension to $A_{\text{coef}}[1/2]$, since the identity $2(1/2) = 1$ would acquire images $0 = 1$. Every finite-field phase statement below uses its actual stronger datum $p > m + 1$, with all other retained denominator exclusions.

The original objects and the two explicit coordinate substitutions are

$$\begin{aligned} E_{\mathcal{S}} &= \mathcal{S}[s_1, \dots, s_k] / ((s_i - \rho)^m)_{i=1}^k \simeq \mathcal{S}[y_1, \dots, y_k] / (y_i^m)_{i=1}^k, & y_i &= s_i - \rho, \\ J &= \sum_i y_i, & M &= \sum_i s_i = k\rho + J, \\ \mathcal{C}_{\mathcal{S}}^{\text{orig}} &= \mathcal{S}[Z] / ((Z - k\rho)^{K+1}) \simeq \mathcal{C}_{\mathcal{S}} = \mathcal{S}[T] / (T^{K+1}), & T &= Z - k\rho. \end{aligned} \quad (\text{BPC.1})$$

The inverse substitutions are $s_i = y_i + \rho$ and $Z = T + k\rho$; both respect the displayed ideals and their composites fix every generator. Successive division by the monic relations y_i^m proves that the ordered monomials $y^{\mathbf{b}}, 0 \leq b_i < m$, are an $\mathcal{S}$ -basis.

Write $h = (s - \rho)^m, g = 2\xi$, and retain

$$\begin{aligned} v(y) &= \sum_{j=0}^{m-1} a_j y^j, & a_j &= \frac{(g/h)^{(j)}(\rho)}{j!} = \frac{g^{(m+j)}(\rho)}{(m+j)!}, \\ w(y) &= \sum_{j=0}^{m-1} b_j y^j, & b_0 &= a_0^{-1}, & b_r &= -a_0^{-1} \sum_{j=1}^r a_j b_{r-j}, \\ U &= \prod_i v(y_i), & U^{-1} &= \prod_i w(y_i). \end{aligned} \quad (\text{BPC.2})$$

All these coefficients belong to the specified A . Expanding $g = (s - \rho)^m(g/h)$ proves the derivative identity. The recurrence makes the constant coefficient of vw equal to one and all its positive coefficients of degree below m zero; thus it proves the stated inverse. Multiplication by U is an actual $\mathcal{S}$ -linear automorphism of $E_{\mathcal{S}}$, commuting with J and M . The same proof applies to the full unit induced by a retained quartet packet on this primary factor, using that unit's original coefficients throughout.

The unchanged cyclic ring map and the actual unit-weighted module map are

$$f : \mathcal{C}_{\mathcal{S}} \longrightarrow E_{\mathcal{S}}, \quad T^r \longmapsto J^r, \quad f_U : \mathcal{C}_{\mathcal{S}} \longrightarrow E_{\mathcal{S}}, \quad T^r \longmapsto UJ^r, \quad f_U^{\text{orig}}(Z^j) = UM^j. \quad (\text{BPC.3})$$

All surviving degrees in $E_{\mathcal{S}}$ are at most K , so $J^{K+1} = 0$ and these maps are well defined. The weighted map is a map of modules for $T \mapsto J$, or for $Z \mapsto M$ in the original coordinates: $f_U(Tc) = Jf_U(c)$ and $f_U^{\text{orig}}(Zc) = Mf_U^{\text{orig}}(c)$. Its value at one is the actual U . These formulas also give its type when $U \neq 1$; they do not require it to be a unital ring homomorphism.

For $0 \leq r \leq K$ set

$$V_r = \sum_{\substack{0 \leq b_i < m \\ \sum_i b_i = r}} \frac{y^{\mathbf{b}}}{\prod_i b_i!}, \quad W_r = UV_r, \quad V_{K+1} = W_{K+1} = 0. \quad (\text{BPC.4})$$

Every denominator here is a unit because $b_i < m < p$. For each $r \leq K$, a tuple of this degree exists: fill the slots successively up to capacity $m - 1$. Select that tuple $\mathbf{b}^*(r)$ and put $\lambda_r(x) = \mathbf{b}^*(r)! [y^{\mathbf{b}^*(r)}]x$. Then $\lambda_r(V_t) = \delta_{rt}$. The coefficient projection $\pi(x) = \sum_r \lambda_r(x) V_r$ deletes every selected pivot coordinate from $x - \pi(x)$. Consequently, with F the span of all unselected monomials, the maps just given prove

$$E_{\mathcal{S}} = \Lambda \oplus F, \quad \Lambda = \bigoplus_{r=0}^K \mathcal{S}V_r, \quad E_{\mathcal{S}} = \Lambda_U \oplus UF, \quad \Lambda_U = U\Lambda = \bigoplus_{r=0}^K \mathcal{S}W_r, \quad \pi_U = U\pi U^{-1}. \quad (\text{BPC.5})$$

The sum defining each V_r is retained in full; its selected pivot only supplies this explicit splitting.

The multinomial expansion and a direct coefficient calculation give

$$J^r = r!V_r, \quad JV_r = (r+1)V_{r+1}, \quad f_U(T^r) = r!W_r, \quad JW_r = (r+1)W_{r+1}. \quad (\text{BPC.6})$$

For the first formula the coefficient of $y^{\mathbf{b}}$ is the number $r!/\mathbf{b}!$ of its ordered assignments among the r factors. Terms exceeding a primary order vanish in the defining quotient. For the second formula the coefficient at degree $r+1$ is $\sum_{i:b_i>0} b_i/\mathbf{b}! = (r+1)/\mathbf{b}!$. The last two formulas follow by multiplying by the retained U . At degree K there is exactly one tuple, so

$$J^K = \frac{K!}{((m-1)!)^k} \prod_i y_i^{m-1} \neq 0, \quad J^{K+1} = 0, \quad f_U(T^K) = \frac{K!}{((m-1)!)^k} a_0^k \prod_i y_i^{m-1}. \quad (\text{BPC.7})$$

Its coefficient is nonzero in the characteristic-zero domain $\mathcal{S}$. Every positive Taylor term of U kills the top monomial, which proves the last equality with its full original scalar. Thus the old characteristic-zero exponent is exactly $K+1 = 1 + k(m-1)$, and f_U is injective: its columns are the independent W_r multiplied by the nonzero $r!$. This includes $m=1$: then $K=0$, the zeroth power is the identity and the zero nilpotent has index one.

In the original coordinates the same map has matrix

$$[f_U^{\text{orig}}]_{(s^{\mathbf{b}}), (Z^j)} = P_k^{-1}[U]_{(y^{\mathbf{b}})} \mathbf{V} \Delta B, \quad \Delta = \text{diag}(0!, 1!, \dots, K!), \quad (\text{BPC.8})$$

where $P_k = P^{\otimes k}$, $P_{ab} = \binom{b}{a} \rho^{b-a}$ for $a \leq b$ and zero otherwise, $B_{rj} = \binom{j}{r} (k\rho)^{j-r}$ for $r \leq j$ and zero otherwise, and $\mathbf{V}_{\mathbf{b}r} = 1/\mathbf{b}!$ for $|\mathbf{b}| = r$, zero otherwise. The inverses of P and B replace ρ and $k\rho$ by their negatives, as follows by the inverse substitutions in (BPC.1). The j -th column on the right is the original polynomial $U \sum_r \binom{j}{r} (k\rho)^{j-r} r! V_r = U M^j$, proving the formula and retaining every original coordinate.

Write $L_U = f_U(\mathcal{C}_{\mathcal{S}})$ and $d_r = v_p(r!) = \sum_{a \geq 1} \lfloor r/p^a \rfloor$. Counting, for every integer from one to r , each of its factors of p proves the sum formula. The complementary factor $\varepsilon_r = r!/p^{d_r}$ is prime to p , so is a unit in $\mathcal{S}$. We obtain the actual inclusion and quotient

$$L_U = \bigoplus_{r=0}^K r! \mathcal{S} W_r \subset \Lambda_U, \quad C_U := \Lambda_U / L_U \simeq \bigoplus_{r=0}^K \mathcal{S} / (p^{d_r}), \quad \left[\sum_r c_r W_r \right] \mapsto (c_r \bmod p^{d_r})_r. \quad (\text{BPC.9})$$

The kernel and surjectivity follow coordinate by coordinate from the displayed basis; the convention $\mathcal{S}/(p^0) = 0$ is used. The extension of these quotient coordinates to $E_{\mathcal{S}}$ is $x \mapsto \lambda_r(U^{-1}x) \bmod p^{d_r}$, and its kernel also retains the complementary summand UF . In particular $E_{\mathcal{S}}/L_U \simeq UF \oplus C_U$. Over $Q = \text{Frac } \mathcal{S}$ every $r!$ is invertible. The splitting (BPC.5) therefore proves the precise saturation

$$(L_U \otimes_{\mathcal{S}} Q) \cap E_{\mathcal{S}} = \Lambda_U \quad \text{inside } E_{\mathcal{S}} \otimes_{\mathcal{S}} Q. \quad (\text{BPC.10})$$

Indeed an integral element in the rational span of Λ_U has zero UF -component, since that free module injects into its scalar extension. This proves both inclusions without dividing an original vector by its factorial in $E_{\mathcal{S}}$.

Now take either $B = \mathcal{S}/p\mathcal{S}$ or the specified finite-field target $B = k_0$, using the actual coefficient map, and put a bar on each base change. The splitting and its inverse in (BPC.5) base change because all their coefficients lie in $\mathcal{S}$. Thus every $\overline{W}_r$ remains a distinct basis vector of a direct summand. The exact specialized map is

$$\overline{f}_U(\overline{T}^r) = \begin{cases} \overline{r!} \overline{W}_r, & r < p, \\ 0, & r \geq p, \end{cases} \quad \ker \overline{f}_U = (\overline{T}^p) = \bigoplus_{r=p}^K B \overline{T}^r, \quad \text{im } \overline{f}_U = \bigoplus_{r=0}^{\min(K, p-1)} B \overline{W}_r. \quad (\text{BPC.11})$$

The direct sum is empty when $K < p$. The factorial is a unit for $r < p$, and zero for $r \geq p$; the independent basis proves every claim. The unchanged abstract source $B[T]/T^{K+1}$ consequently

has nilpotency index $K + 1$, whereas multiplication by $\bar{J}$ on its actual image, on $\bar{\Lambda}_U$, and on $\bar{E}_{\mathcal{J}}$ has index

$$\min(p, K + 1). \quad (\text{BPC.12})$$

For the upper bound, in characteristic p the intermediate binomial coefficients vanish, so $\bar{J}^p = \sum_i \bar{y}_i^p = 0$, while $\bar{J}^{K+1} = 0$ still holds. For the lower bound put $d = \min(p - 1, K)$. Then $\bar{J}^d \bar{W}_0 = \bar{d}! \bar{W}_d \neq 0$. This vector is in the image, which proves all three lower bounds. All additional chains of the containing lattice are retained by

$$e_{j,t} = \left(\prod_{a=1}^t \bar{J}^{p+a} \right) \bar{W}_{jp+t}, \quad 0 \leq jp \leq K, \quad 0 \leq t \leq \min(p - 1, K - jp). \quad (\text{BPC.13})$$

Each coefficient here is a unit. Equation (BPC.6) makes $\bar{J}e_{j,t} = e_{j,t+1}$ until the last position; the next coefficient is zero modulo p , or the next degree is $K + 1$. These are all the reduced lattice chains.

The coefficient loss has the exact homological map

$$\begin{aligned} 0 &\longrightarrow \mathcal{C}_{\mathcal{J}} \xrightarrow{f_U} \Lambda_U \longrightarrow C_U \longrightarrow 0, \\ 0 &\longrightarrow \text{Tor}_1^{\mathcal{J}}(C_U, B) \xrightarrow{\partial} \bar{\mathcal{C}}_{\mathcal{J}} \xrightarrow{\bar{f}_U} \bar{\Lambda}_U \longrightarrow C_U \otimes_{\mathcal{J}} B \longrightarrow 0, \\ \text{Tor}_1^{\mathcal{J}}(C_U, B) &= \bigoplus_{r=p}^K B\epsilon_r, \quad \partial\epsilon_r = \bar{T}^r, \quad C_U \otimes_{\mathcal{J}} B = \bigoplus_{r=p}^K B[\bar{W}_r]. \end{aligned} \quad (\text{BPC.14})$$

The first line is an explicit free resolution whose matrix is Δ in (BPC.8). Tensoring that complex with B gives the diagonal matrix $\bar{\Delta}$. Its kernel and cokernel are exactly (BPC.11), proving the last two lines and the sign of ∂ , which is the inclusion into the degree-one free module for differential $+f_U$. When $K \geq p$, multiplication by $\bar{T}$ on this kernel has index $K - p + 1$: its $(K - p)$ -th power sends $\bar{T}^p$ to the nonzero $\bar{T}^K$. The original source, actual image, containing lattice, and connecting image are thus all present with their proved maps.

134.2 The same cyclic map carries the tensor boundary projector

Put $N = m + 1$ and retain the primitive fixed at the original point $s = 0$:

$$\Phi(s) = \frac{(s - \rho)^N - (-\rho)^N}{N}, \quad c = -\frac{(-\rho)^N}{N}, \quad \sum_i \Phi(s_i) = \sum_i \frac{y_i^N}{N} + kc. \quad (\text{BTP.1})$$

The ordered tensor complex has the commuting differentials $u\partial_{s_i} + h(s_i)$ and the original form $ds_1 \wedge \cdots \wedge ds_k$. The one-factor monic remainder decomposition, tensored with its explicit contracting homotopy, concentrates its cohomology in degree k , with the free basis $s^{\mathbf{b}} ds_1 \wedge \cdots \wedge ds_k, 0 \leq b_i < m$. No permutation quotient is taken.

For $\zeta = e^{2\pi i/N}$ and the fixed branch of $u^{1/N}$, keep

$$\begin{aligned} \beta_b &= (b + 1)/N, & d_b &= N^{\beta_b - 1} e^{\pi i \beta_b} \Gamma(\beta_b), \\ W_{jb} &= \zeta^{j(b+1)} - 1, & D(u) &= \text{diag}(d_b u^{\beta_b}), \\ \Pi_k(u) &= e^{kc/u} W^{\otimes k} D(u)^{\otimes k} P_k. \end{aligned} \quad (\text{BTP.2})$$

Here $1 \leq j \leq m, 0 \leq b < m$, and the rows are the ordered products of the original relative contours $\Gamma_j = -\ell_0 + \ell_j$, whose outward rays have angles $(\arg u + \pi)/N + 2\pi j/N$. The one-variable substitution $t = r^N/(N|u|)$ gives precisely $d_b u^{\beta_b}$ on the zeroth ray and its factor $\zeta^{j(b+1)}$ on the j -th ray. Their oriented difference gives W_{jb} . Translation to $y = s - \rho$ is the original one-factor contour equality: the remote connector integral tends to zero by the bound $\exp(-R^N/(N|u|) + O(R^{N-1}))$ times a polynomial. It leaves the factor $e^{c/u}$ intact. Absolute integrability permits Fubini on the ordered product

contours, and the binomial substitution gives P_k , proving (BTP.2). The polynomial $\sum_{j=1}^{N-1} a_j(z^j - 1)$ cannot vanish at all N -th roots unless every coefficient is zero; this proves W invertible. Also $d_b \neq 0$, so every $\Pi_k(u)$ is invertible for $u \neq 0$.

In y -coordinates let

$$E_r y^{\mathbf{b}} = \mathbf{1}_{\{|\mathbf{b}|+k \equiv r \pmod{N}\}} y^{\mathbf{b}}, \quad Q_r = P_k^{-1} E_r P_k, \quad \hat{Q}_r = U_k Q_r U_k^{-1}, \quad U_k = [U]_{(s^{\mathbf{b}})}. \quad (\text{BTP.3})$$

These diagonal zero-one masks exist over the exact retained coefficient ring. The period monodromy and its projectors are

$$M_k = W^{\otimes k} \text{diag}(\zeta^{|\mathbf{b}|+k})(W^{\otimes k})^{-1}, \quad \mathcal{P}_r = \frac{1}{N} \sum_{j=0}^{N-1} \zeta^{-rj} M_k^j, \quad \mathcal{P}_r \Pi_k = \Pi_k Q_r. \quad (\text{BTP.4})$$

One positive circuit multiplies the $\mathbf{b}$ -th diagonal entry in (BTP.2) by $\zeta^{|\mathbf{b}|+k}$; its scalar exponential is single-valued. This proves the monodromy formula. The finite geometric sum is one at matching character and zero otherwise, proving the projectors and their intertwining identity. The horizontal coefficient convention has the inverse monodromy, with the same invariant index set.

The source-period map is exactly $\Pi_k U_k^{-1}$. Indeed the original source has Mellin transform $f(s_1, \dots, s_k) \prod_i (g/h)(s_i)$, whose full jet is $U_k[f]_{s_i}$; integration by parts for $D_i = -x_i \partial_{x_i}$ gives multiplication by s_i with vanishing endpoint terms in the original source space. It follows that

$$\mathcal{P}_r \Pi_k U_k^{-1} = \Pi_k U_k^{-1} \hat{Q}_r. \quad (\text{BTP.5})$$

This is the exact source comparison, including the entire unit and its inverse. It does not replace the source norm by the auxiliary period coordinate norm.

The invariant dimension is

$$d_{0,k} = \frac{m^k + m(-1)^k}{m+1}. \quad (\text{BTP.6})$$

To prove it, filter the ordered tuples by their total character: $N^{-1} \sum_{j=0}^{N-1} (\sum_{a=1}^{N-1} \zeta^{ja})^k$. The inner sum is m for $j = 0$ and -1 otherwise, giving the formula. Thus the one-factor vanishing remains true at $k = 1$; tensor invariants appear for every $m \geq 2, k \geq 2$, and for $m = 1$ precisely when k is even. These are the ordinary local-system invariants at the original puncture.

The original arithmetic matrix is $A_k = k\rho I + R_k$, where $R_k = P_k^{-1}[J]P_k$. Each surviving multiplication by y_i increases the boundary character by one. Therefore, on every monomial,

$$\begin{aligned} Q_r R_k^j &= R_k^j Q_{r-j}, & [Q_0, A_k] &= R_k(Q_{-1} - Q_0), \\ Q_0 A_k Q_0 &= k\rho Q_0, & (I - Q_0) A_k Q_0 &= R_k Q_0. \end{aligned} \quad (\text{BTP.7})$$

Terms that exceed a primary order are zero on both sides. Conjugation by the commuting U_k gives the identical formulas on the actual source invariant plane. In particular the scalar compression retains the explicit outgoing map.

For $\text{im } Q_0 \neq 0$, set $d_{\min} = N \lceil k/N \rceil - k$ and $q_* = \lfloor (K - d_{\min})/N \rfloor$. Put $R_0 = Q_0 R_k^N Q_0|_{\text{im } Q_0}$. Then the complete dilation on this plane is

$$Q_0 a^{A_k} Q_0|_{\text{im } Q_0} = a^{k\rho} \sum_{j=0}^{q_*} \frac{(\log a)^{jN}}{(jN)!} R_0^j, \quad R_0^{q_*} \neq 0, \quad R_0^{q_*+1} = 0. \quad (\text{BTP.8})$$

Expand the original finite exponential through degree K . Equation (BTP.7) removes exactly the powers whose degree is not divisible by N . Every invariant input has degree at least $d_{\min}$, proving the upper cutoff. At that minimum degree, distribute any increment $jN \leq K - d_{\min}$ among the remaining slot capacities. Its multinomial coefficient is positive and distinct monomials cannot cancel,

proving the stated nonzero powers. The source compression is the conjugate of (BTP.8) by the full U_k .

The original terminal monomial $\tau_k = \prod_i y_i^{m-1}$ satisfies

$$A_k \tau_k = k \rho \tau_k, \quad U_k \tau_k = a_0^k \tau_k, \quad Q_0 \tau_k = \widehat{Q}_0 \tau_k = \mathbf{1}_{\{N|k\}} \tau_k. \quad (\text{BTP.9})$$

Multiplication by every y_i kills this top monomial, proving the first two formulas. Its character is $km \equiv -k \pmod{N}$, proving the third, including the unit conjugation. Its exact period is

$$\Pi_k \tau_k = e^{kc/u} \left(N^{-1/N} e^{\pi i m/N} \Gamma(m/N) \right)^k u^{km/N} (\zeta^{-j} - 1)_{j=1}^m \otimes k. \quad (\text{BTP.10})$$

This is its column in (BTP.2); all its factors are nonzero. The corresponding actual corrected-section class has observation $a_0^{-k} \Pi_k \tau_k$. For the original amplified quartet vector the retained coefficient is $C_{h_0,k} = K!((m-1)!)^{-k}((g/h_0)(\rho))^k$, so its observation is exactly $C_{h_0,k} a_0^{-k} \Pi_k \tau_k$. Multiplication by (g/h_0) on the terminal monomial has this scalar because all its positive Taylor terms vanish; this is also (BPC.7) for that retained unit. Therefore, on the infinite subsequence $N \mid k$, the same original terminal arithmetic eigenclass lies in the boundary invariant plane. Its original dilation still satisfies

$$\log \left(\frac{|a^{k\rho}|^2}{a^k} \right) = 2k(\operatorname{Re} \rho - 1/2) \log a. \quad (\text{BTP.11})$$

Taking the real part of $k\rho \log a$ proves the identity. No invariant-plane projection has altered this arithmetic scalar.

134.3 Finite-field boundary and the actual coefficient-specialization restriction

Use the already specified finite-field map with $p > N$, and write $k_0 = \mathbb{F}_{Q_0}$, $L = \mathbb{F}_{Q_0^d}$, $d = \operatorname{ord}_{(\mathbb{Z}/N\mathbb{Z})^\times}(Q_0)$. Thus L contains μ_N . Retain $\psi = \psi_0 \circ \operatorname{Tr}_{L/k_0}$, geometric Frobenius, the original compact-support one-factor sheaf, and every one-factor Gauss constant. The already proved SPF decomposition, distributed over the ordered tensor factors on the common u -line, gives the exact isomorphism

$$\mathcal{F}_L^{\otimes k} \simeq \mathcal{L}_\psi(kc/u) \otimes \bigoplus_{\substack{\mathbf{x}=(\chi_1, \dots, \chi_k) \\ \chi_i^N=1, \chi_i \neq 1}} \mathcal{A}_{A_{\mathbf{x}}} \otimes \mathcal{K}_{\prod_i \chi_i}(u), \quad A_{\mathbf{x}} = \prod_i \left(-\chi_i(N) \sum_{z \in L^\times} \chi_i(z) \psi(z) \right). \quad (\text{BTF.1})$$

The torsor tensor laws add the Artin–Schreier phases and multiply the Kummer characters. Distribution of tensor over direct sum retains every ordered tuple, even if different tuples have equal product characters. These facts prove the displayed map from the established one-factor map. The compact-support Kunnet map places it in degree k on the original ordered product source, since each one-factor complex is concentrated in degree one. No factor permutation changes its sign.

For $c \neq 0$, choose the original additive character $\psi_0(x) = \vartheta(\operatorname{Tr}_{k_0/\mathbb{F}_p}(bx))$. The cover $u = v^N$, $z^p - z = bc/v^N$ has deck group $\mu_N \times \mathbb{F}_p$. Its degree is Np : the second right side has pole order N prime to p , whereas a pole of $f^p - f$ has order divisible by p , so it is a nontrivial degree- p extension. The displayed commuting deck maps $(v, z) \mapsto (\zeta v, z + a)$ then exhaust that degree. On the tuple line the original action is

$$(\zeta, a) \mapsto \lambda_{\prod_i \chi_i}(\zeta)^{-1} \vartheta(-ka), \quad (\text{BTF.2})$$

where $\lambda_{\chi}(x^{(Q-1)/N}) = \chi(x)$ and $Q = Q_0^d$. These are the original SPF inverse deck-action conventions, tensored without changing them. Averaging over the complete finite inertia image in the characteristic-zero ℓ -adic coefficient field proves

$$P_{I_0,k} = \begin{cases} P_{0,k}^{\text{tame}}, & kc = 0, \\ 0, & kc \neq 0, \end{cases} \quad \dim V_k^{I_0} = \begin{cases} \frac{m^k + m(-1)^k}{m+1}, & kc = 0, \\ 0, & kc \neq 0. \end{cases} \quad (\text{BTF.3})$$

The tame average is one exactly when $\prod_i \chi_i = 1$. The wild average $p^{-1} \sum_a \vartheta(-ka)$ is one for $p \mid k$ and zero otherwise. For $c = 0$ the original additive torsor is trivial, so only the tame average is present. Since $kc = 0$ is equivalent to $c = 0$ or $p \mid k$, these computations prove the full case distinction. The tuple count is the same geometric sum proved in (BTP.6).

For $kc \neq 0$, the Artin-Schreier factor of $z^p - z = bkc/u$ has a single break one: z^{-1} is a uniformizer and its difference under $z \mapsto z + a$, $a \neq 0$, has valuation two. Every tuple line has that same wild factor, while Kummer twists are tame. Therefore

$$\text{Swan}_0(\mathcal{F}_L^{\otimes k}) = \begin{cases} 0, & kc = 0, \\ m^k, & kc \neq 0, \end{cases} \quad N_{\text{mon},k} = 0 \text{ after } u = v^N, \quad z_k^p - z_k = bkc/v^N. \quad (\text{BTF.4})$$

The cover trivializes every geometric character, so its monodromy is the identity and its logarithm is zero. This leaves the original-inertia invariant space in (BTF.3) unchanged as a separately specified stalk over the original base.

The exact boundary Frobenius for $kc = 0$ over L is the direct sum of the scalars A_χ with $\prod_i \chi_i = 1$. Over k_0 , geometric Frobenius sends χ to χ^{Q_0} : conjugating the SPF deck projector by Frobenius replaces its deck argument by $\zeta^{Q_0^{-1}}$, and reindexing yields that character power. For an orbit $\mathcal{O}$ of length e , each χ_i descends uniquely by norm to $\kappa_{i,e}$ over $L_e = \mathbb{F}_{Q_0^e}$. Indeed its order divides $Q_0^e - 1$, so it kills the norm kernel; norm surjectivity proves uniqueness. Retaining the original denominator N , the one-factor SPF calculation over this orbit field gives

$$\Lambda_{\mathcal{O}} = \prod_i (-\kappa_{i,e}(N) G_{L_e}(\kappa_{i,e}, \psi_0 \circ \text{Tr}_{L_e/k_0})) , \quad \det(1 - tF_0 \mid V_k^{I_0}) = \prod_{\mathcal{O}} (1 - \Lambda_{\mathcal{O}} t^e). \quad (\text{BTF.5})$$

For the descent map when L_e does not contain all N -th roots, factor the source power map as $y \mapsto x = y^{N/r_i} \mapsto z = x^{r_i} = y^N$, where $r_i = \text{ord } \chi_i$. Functions constant on the μ_{N/r_i} -orbits are exactly functions on the intermediate root set; the same map is the identity at the zero fibre. This identifies the descended $\kappa_{i,e}$ -summand of the original sheaf, whose phase is still $z/(Nu) + c/u$. Thus the displayed scalar is the actual F_0^e -action. A basis $v, F_0 v, \dots, F_0^{e-1} v$ of distinct tuple lines gives the factor $1 - \Lambda_{\mathcal{O}} t^e$. The unscaled Gauss absolute-square calculation $|G_{L_e}|^2 = Q_0^e$ therefore gives $|\Lambda_{\mathcal{O}}| = Q_0^{ek/2}$ and weight k for every nonzero boundary orbit block.

To specify the comparison of characteristic types, put $B_0 = \mathbb{Z}[\zeta_N, 1/N]$ and

$$e_j = \frac{1}{N} \sum_{a=0}^{N-1} \zeta_N^{-ja} \gamma^a \in B_0[C_N], \quad M_{B_0} = B_0[y]dy/y^m B_0[y]dy, \quad e_j \longmapsto y^{j-1} dy \quad (1 \leq j < N). \quad (\text{BTF.6})$$

Give γ the action $\gamma(y^b dy) = \zeta_N^{b+1} y^b dy$. The finite geometric sum proves that the e_j are complete orthogonal idempotents, and the displayed basis map is an isomorphism $\bigoplus_{j=1}^{N-1} B_0 e_j \simeq M_{B_0}$. The actual maps $B_0 \rightarrow L$ and $B_0 \rightarrow \overline{\mathbb{Q}_\ell}$ send ζ_N to the respective chosen primitive roots. They give, respectively, the coefficient monomial-form projector and the actual SPF Gauss-line projector: the latter is $N^{-1} \sum_a \zeta_\ell^{-ja} D_\zeta^{-a} = N^{-1} \sum_a \zeta_\ell^{ja} D_\zeta^a$. If H_j is that complete Gauss line, retain its Frobenius and reconstruct its isotypic component by $(ae_j) \otimes h \mapsto ah$ from $(B_0 e_j \otimes \overline{\mathbb{Q}_\ell}) \otimes H_j^{\text{triv}}$, where only the deck action on the second factor is made trivial. The scalar map is bijective on each summand and preserves both deck action and the retained splitting-field Frobenius, proving the comparison. Ordered tensor products of these maps retain every tuple. This is the common integral representation and its two proved base changes; it introduces no field map from characteristic p to $\overline{\mathbb{Q}_\ell}$.

The terminal form has deck-pullback character $\zeta^m = \zeta^{-1}$ in each factor; let its primitive Kummer character be χ_{ter} . Its ordered sheaf line is consequently

$$\mathcal{L}_\psi(kc/u) \otimes \mathcal{A}_{[-\chi_{\text{ter}}(N) G_L(\chi_{\text{ter}}, \psi)]^k} \otimes \mathcal{K}_{\chi_{\text{ter}}^k}(u). \quad (\text{BTF.7})$$

It has invariants exactly for $N \mid k$ and $kc = 0$; this means $N \mid k$ if $c = 0$, and $pN \mid k$ if $c \neq 0$. Its original base orbit has length d , because its character is primitive, with polynomial

$1 - [-\chi_{\text{ter}}(N)G_L(\chi_{\text{ter}}, \psi)]^k t^d$. These claims follow from (BTF.2)–(BTF.5) without assigning a finite-field Frobenius to an original complex arithmetic scalar.

On a coefficient stage admitting the specified map, the original amplified coefficient instead has the literal coefficient image

$$\overline{C}_{h_0,k} = K! ((m-1)!)^{-k} \overline{u}_0^k, \quad u_0 = (g/h_0)(\rho), \quad \overline{C}_{h_0,k} \neq 0 \iff K < p \text{ and } \overline{u}_0 \neq 0. \quad (\text{BTF.8})$$

The denominator is a unit since $m-1 < p$, while $K!$ vanishes exactly for $K \geq p$. Retaining the inverse of the original full unit ensures $\overline{u}_0 \neq 0$. The target is the coefficient algebra $k_0[y_1, \dots, y_k]/(y_i^m)$, with coefficient map obtained by applying α to every coefficient in its unchanged monomial basis. Its terminal basis vector remains nonzero; the original multiple vanishes precisely as in (BTF.8). This is the map (BPC.11). It does not multiply a characteristic- p scalar into the characteristic-zero Gauss line (BTF.7); their common projector maps are instead (BTF.6).

For $m \geq 2$, the wild-cancellation orders $p \mid k$ have $K \geq p$, so the specialized original terminal multiple vanishes on every stage admitting this local coefficient map. The sheaf invariant lines calculated above remain as specified by (BTF.7). For $m = 1$, $K = 0$ and $C_{h_0,k} = u_0^k$, there is no factorial loss. Here $N = 2$ and the quadratic Gauss constant $\gamma_\chi = -\chi(2)G_L(\chi, \psi)$ satisfies $\gamma_\chi^2 = \chi(-1)Q$. Indeed complex conjugation gives $\overline{G} = \chi(-1)G$, while $G\overline{G} = Q$, which proves the algebraic equality in its cyclotomic number field and hence in its ℓ -adic realization. Thus at $k = 2pr$ with $c \neq 0$, the exact invariant eigenvalue is $(\chi(-1)Q)^{pr}$, and the coefficient image is the retained nonzero $\overline{u}_0^k$.

Finally, the local coefficient map does not silently extend through new CRT denominators. In the original off-critical quartet branch $\rho = 1/2 + \delta + i\gamma$, $\delta > 0$, the complete degree- k split corner has centres $\lambda_0 = k\rho$ and $\lambda_1 = (k-p)\rho + p(1-\bar{\rho})$ whenever $k \geq p$. Retain its actual terminal CRT polynomial $e(Z) = \sum_r e_r Z^r$ with $e(\lambda_0) = 1$, $e(\lambda_1) = 0$. In its own coefficient ring set

$$\mathcal{D} = \sum_{r \geq 1} e_r \sum_{j=0}^{r-1} \lambda_0^{r-1-j} \lambda_1^j, \quad 1 = p(\rho + \bar{\rho} - 1)\mathcal{D}, \quad p^{-1} = (\rho + \bar{\rho} - 1)\mathcal{D}. \quad (\text{BTF.9})$$

The divided difference telescopes term by term: $(\lambda_0 - \lambda_1)\mathcal{D} = e(\lambda_0) - e(\lambda_1) = 1$. Since $\lambda_0 - \lambda_1 = p(\rho + \bar{\rho} - 1)$, this proves all the formulas. Hence that full stage inverts p and has no unital characteristic- p specialization. Replacing p by any rational prime $q \leq k$ proves that the degree- k split corner inverts every such prime. The directed coefficient union of all these retained stages therefore contains $\mathbb{Q}$: each reciprocal prime occurs at its corresponding stage. The explicit local maps (BPC.3), (BPC.8), (BPC.11) and (BPC.14) continue to relate the local characteristic-zero source, its lattice and its valid coefficient specialization. The absence of an extension of that specialization is not the zero image of a vector under a nonexistent map.

The depth and boundary character can be carried together on those same local maps. Define $D_c T^r = \mathbf{1}_{\{r+k \equiv c \pmod{N}\}} T^r$ and use the full-unit character masks $\widehat{Q}_c$ in (BTP.3). Every term in V_r has degree r , so

$$\widehat{Q}_c f_U = f_U D_c, \quad \widehat{Q}_c W_r = \mathbf{1}_{\{r+k \equiv c\}} W_r, \quad \text{Ann}_{\mathcal{S}}([W_r]) = p^{d_r} \mathcal{S}. \quad (\text{BTF.10})$$

These masks preserve both lattices and their free resolution, so the Tor connecting map in (BPC.14) has the same character: $\overline{D}_c \partial \epsilon_r = \mathbf{1}_{\{r+k \equiv c\}} \overline{T}^r$. For $k = p\ell$, $m \geq 2$, its surviving reduced image vector $\overline{W}_{p-1}$ has the exact calculation

$$\begin{aligned} \overline{J} \overline{W}_{p-1} &= 0, \quad \overline{W}_{p-1} \neq 0, \quad J W_{p-1} = p W_p \neq 0, \\ \widetilde{\overline{Q}}_0 \overline{W}_{p-1} &= \overline{W}_{p-1} \iff p(\ell+1) \equiv 1 \pmod{N}. \end{aligned} \quad (\text{BTF.11})$$

Equation (BPC.6) and the primitive pivot prove the first three assertions. Its degree is $p-1$, so (BTF.10) gives the congruence. Since $p > N$, it selects an infinite positive residue class of ℓ . The precursor $p W_p$ is retained, so this new reduced kernel direction has not been identified with the

original complex terminal eigenclass. Every coefficient map above acts at each existing nonbottom split-support label without changing that label; a killed coefficient remains its represented zero, and the external absent symbol is fixed separately. Thus this update propagates the arithmetic exponent, tensor boundary projection and coefficient depth on the same original maps.

135 The actual amplified class and the exact phase exclusion error

The calculation here identifies the precise quantity in the proved holonomy and quotient comparisons that would have to decrease after division by tensor degree. It uses the actual divisor of $g = 2\xi$, the original tensor source, the full Taylor unit, and the original phase generator. Its estimates are calculations on those objects. The tensor amplification itself and its nonzero arithmetic observation are retained throughout.

135.1 The full amplified primary factor and its nonzero observation

Retain an actual off-line zero $\rho = \frac{1}{2} + \delta + i\gamma$ of $g = 2\xi$, of full order m , where $0 < \delta < \frac{1}{2}$ and $\gamma > 0$, and its full reflected quartet divisor

$$h(s) = \prod_{\epsilon, \zeta \in \{-1, 1\}} (s - \frac{1}{2} - \epsilon\delta - i\zeta\gamma)^m. \quad (\text{PAM.1})$$

For $k \geq 2$ put

$$\begin{aligned} c_k &= k/2, & d_k &= 1 + k(m-1), & q_k &= d_k(k+1)^2, \\ \chi_k(S) &= \prod_{a, b=0}^k (S - c_k - (2a - k)\delta - i(2b - k)\gamma)^{d_k}, \\ E_k &= \mathbb{C}[S]/(\chi_k), & A_k &= M_S, & \lambda_k &= k\rho = c_k + k\delta + ik\gamma. \end{aligned} \quad (\text{PAM.2})$$

These are precisely (HT1)–(HT2). The full original injection is

$$\eta_k[P] = v_h^{\otimes k} P(A_h^{(k)})1, \quad v_h = j_h(g/h) \in (\mathbb{C}[s]/h)^\times, \quad \mathcal{I}_k = \sigma_h^{\otimes k} \eta_k : E_k \hookrightarrow Q_{\text{ar}}^{\otimes k}, \quad (\text{PAM.3})$$

where $Q_{\text{ar}} = \mathcal{B}/\Theta V$ is the original arithmetic cohomology. The tensor-sum operator is $A_h^{(k)} = \sum_{j=1}^k A_{h,j}$, and the original source section σ_h and jet remainder j_h have their unchanged meanings.

The factor of E_k at λ_k is exactly

$$E_{k, \lambda_k} = e_{\lambda_k} E_k \simeq \mathbb{C}[z]/(z^{d_k}), \quad A_k|_{E_{k, \lambda_k}} = \lambda_k I + N_k, \quad N_k = M_z. \quad (\text{PAM.4})$$

Here e_{λ_k} is the Chinese remainder idempotent equal to one modulo $(S - \lambda_k)^{d_k}$ and zero modulo every other factor. Distinct pairs (a, b) have distinct complex centers since $\delta, \gamma > 0$; hence these factors are relatively prime and the idempotent exists by polynomial Bezout identities. In particular $v_k = e_{\lambda_k} (S - \lambda_k)^{d_k-1}$ is a nonzero eigenvector with eigenvalue λ_k . Its arithmetic class $\mathcal{I}_k v_k$ is nonzero by (PAM.3).

For explicit multiplicity preservation, on the tensor product of the ρ -primary factors, write its nilpotents as $z_1, \dots, z_k$, each with $z_j^m = 0$. Their sum has

$$(z_1 + \dots + z_k)^{k(m-1)} = \frac{(k(m-1))!}{((m-1)!)^k} z_1^{m-1} \dots z_k^{m-1} \neq 0, \quad (z_1 + \dots + z_k)^{k(m-1)+1} = 0. \quad (\text{PAM.5})$$

The first equality follows from the multinomial expansion: every surviving exponent is at most $m-1$ and their sum is $k(m-1)$, so they all equal $m-1$. Its coefficient is a nonzero complex integer. In the next power at least one exponent is at least m . Multiplication by the retained unit $v_h^{\otimes k}$ preserves both equalities and nonvanishing. Thus the eigenvector in (PAM.4) and every lower jet lie in the actual amplified factor; no reduced-root replacement is involved.

135.2 The exact phase generator and its boundary on that class

Use the original density

$$w_h(u) = \frac{|(g/h)(1/2 + iu)|^2}{2\pi}, \quad m_{h,k} = w_h^{*k}, \quad \int_{\mathbb{R}} m_{h,k}(u) du = \mu_h^k, \quad \mu_h = \int_{\mathbb{R}} w_h(u) du. \quad (\text{PAM.6})$$

For $L > 0, 0 \leq \theta < 2\pi$, put

$$u_n = \frac{2\pi n + \theta}{L}, \quad \nu_{L,\theta} = \frac{2\pi}{L} \sum_{n \in \mathbb{Z}} m_{h,k}(u_n) \delta_{u_n}. \quad (\text{PAM.7})$$

The original half-density map and twisted periodization in (HT4)–(HT5) give the exact polynomial source $\mathcal{V}_{L,\theta} = \mathcal{Z}_{L,\theta} \mathcal{U}_k \mathcal{V}$. Its inner product is integration of $P(c_k + iu)Q(c_k + iu)$ against (PAM.7). The relative-variable space is $\mathcal{K}_k = L^2(\mathbb{R}^{k-1}, dz)$, and the phase Hilbert space and generator are

$$\mathcal{H}_{L,\theta} = L^2([0, L], dr; \mathcal{K}_k), \quad D_{L,\theta} = -\partial_r + c_k, \quad (\text{PAM.8})$$

$$\text{Dom}(D_{L,\theta}) = \{f \in H^1([0, L]; \mathcal{K}_k) : f(L) = e^{-i\theta} f(0)\}.$$

Integration by parts cancels the two endpoint products, since both vectors have the same multiplier of modulus one. Consequently $-\partial_r$ is skew-adjoint on this domain, and $D_{L,\theta} + D_{L,\theta}^* = kI$. The Fourier modes $L^{-1/2}e^{-iu_n r}$ give its eigenvalues $c_k + iu_n$, acting identically on $\mathcal{K}_k$.

For an admitted degree $N \geq q_k - 1$, retain the original Gram $M_{N,\theta}$, remainder $J_N : \mathbb{C}[S]_{\leq N} \rightarrow E_k$, minimum coefficient section and arithmetic metric

$$C_{N,\theta} = M_{N,\theta}^{-1} J_N^* G_{N,\theta}, \quad G_{N,\theta} = (J_N M_{N,\theta}^{-1} J_N^*)^{-1}, \quad R_{N,\theta} = \mathcal{V}_{L,\theta} C_{N,\theta}. \quad (\text{PAM.9})$$

All these inverse matrices exist by the positive lattice weights and the surjectivity of literal remainder. They obey $J_N C_{N,\theta} = I$ and $R_{N,\theta}^* R_{N,\theta} = G_{N,\theta} > 0$. In particular $r_k = R_{N,\theta} v_k \neq 0$.

The exact generator comparison is the original polynomial division

$$S C_{N,\theta} - C_{N,\theta} A_k = \chi_k Q_{N,\theta}, \quad \mathcal{B}_{N,\theta} = \mathcal{V}_{L,\theta}(\chi_k Q_{N,\theta}) = D_{L,\theta} R_{N,\theta} - R_{N,\theta} A_k. \quad (\text{PAM.10})$$

It is relation-valued because applying J_{N+1} to the first difference gives zero. Its coefficient quotient by the monic χ_k is unique. Its original theta primitive, with its signs, is already computed in (HT13): if tensor division gives $\chi_k Q = \sum_j h(s_j) Q_j(\mathbf{s})$, it is

$$\sum_{j=1}^k (-1)^{j-1} Q_j(D_1, \dots, D_k) (F_h^{\otimes(j-1)} \otimes \phi_h \otimes F_h^{\otimes(k-j)}). \quad (\text{PAM.11})$$

Here $h(D)F_h = \Theta \phi_h$; F_h has degree one and ϕ_h degree zero. Applying the tensor differential adds $(-1)^{j-1}$, canceling the displayed sign and producing exactly the boundary of (PAM.10) after the same half-density and phase maps.

Apply (PAM.10) to v_k . The cross term between a real scalar and a skew-adjoint operator has real part zero. Parseval therefore proves the exact identity

$$\begin{aligned} \frac{\|\mathcal{B}_{N,\theta} v_k\|^2}{\|R_{N,\theta} v_k\|^2} &= (k\delta)^2 + \frac{\|(-\partial_r - ik\gamma) R_{N,\theta} v_k\|^2}{\|R_{N,\theta} v_k\|^2} \\ &= (k\delta)^2 + \frac{\sum_{n \in \mathbb{Z}} (u_n - k\gamma)^2 \|\widehat{r}_k(n)\|_{\mathcal{K}_k}^2}{\sum_{n \in \mathbb{Z}} \|\widehat{r}_k(n)\|_{\mathcal{K}_k}^2}. \end{aligned} \quad (\text{PAM.12})$$

Indeed $\mathcal{B} v_k = (D_{L,\theta} - \lambda_k) r_k$, and this operator is $-k\delta + (-\partial_r - ik\gamma)$. Every source vector belongs to its domain by the original weighted smoothness estimates; the Fourier identities therefore hold with convergent squared sums. In particular the error forced on this actual eigenclass obeys

$$\frac{\|\mathcal{B}_{N,\theta} v_k\|}{\|R_{N,\theta} v_k\|} \geq \sqrt{k^2 \delta^2 + \text{dist}(k\gamma, \{u_n : n \in \mathbb{Z}\})^2} \geq k\delta. \quad (\text{PAM.13})$$

Changing θ can place a lattice point exactly at $k\gamma$; this removes that particular lattice-distance term and leaves the term $k\delta$ unchanged. Thus lattice refinement or choice of phase does not divide the real displacement by k .

135.3 The full-jet inverse of the boundary comparison

For the entire primary factor (PAM.4), the relation and source are connected by an exact finite resolvent formula. Put $\mathcal{R} = R_{N,\theta}|_{E_{k,\lambda_k}}$ and $\mathcal{B} = \mathcal{B}_{N,\theta}|_{E_{k,\lambda_k}}$. The resolvent $(D_{L,\theta} - \lambda_k)^{-1}$ exists and satisfies

$$\|(D_{L,\theta} - \lambda_k)^{-1}\|_{\text{op}} = \frac{1}{\sqrt{k^2\delta^2 + \text{dist}(k\gamma, \{u_n\})^2}} \leq \frac{1}{k\delta}. \quad (\text{PAM.14})$$

Its exact Fourier multiplier is $(-k\delta + i(u_n - k\gamma))^{-1}$. Its absolute values have the displayed maximum. The inverse maps into the stated H^1 domain: the multipliers $u_n/(-k\delta + i(u_n - k\gamma))$ are bounded, so the Fourier derivative has finite squared norm.

Writing (PAM.10) on the full block gives $(D_{L,\theta} - \lambda_k)\mathcal{R} - \mathcal{R}N_k = \mathcal{B}$. Multiply by the resolvent, substitute the resulting expression for $\mathcal{R}$ repeatedly, and use $N_k^{d_k} = 0$. This gives the exact morphism, with every nilpotent term retained,

$$\mathcal{R} = \sum_{j=0}^{d_k-1} (D_{L,\theta} - \lambda_k)^{-j-1} \mathcal{B} N_k^j. \quad (\text{PAM.15})$$

All factors have specified domains: N_k^j acts on the finite primary algebra, $\mathcal{B}$ maps it to $\mathcal{H}_{L,\theta}$, and the resolvent maps that Hilbert space to itself and into the generator domain. Finite iteration is therefore legitimate. Conversely multiplying this finite sum by $D_{L,\theta} - \lambda_k$ and subtracting its right product with N_k cancels every term except $\mathcal{B}$. It is consequently the unique solution: the same iteration with zero $\mathcal{B}$ makes any homogeneous solution zero. In particular the already nonzero arithmetic primary block cannot have zero generator boundary on this phase Hilbert space.

135.4 The scaling of the proved global phase controls

For brevity in this subsection write $G = G_{N,\theta}$, $\mathcal{B} = \mathcal{B}_{N,\theta}$ and $q = q_k$. The proved rank-two matrix and its exact positive spectral floor (HT8)–(HT12) are

$$H = G^{-1/2}(A_k^*G + GA_k - kG)G^{-1/2}, \quad \text{spec}(H) = \{\varepsilon, -\varepsilon, 0, \dots, 0\},$$

$$\varepsilon \geq \mathcal{L}_{h,k} = 2\delta d_k(k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor. \quad (\text{PAM.16})$$

These statements include every phase and every admitted degree. Their original energy identity is

$$\|\mathcal{B}G^{-1/2}\|_{\text{HS}}^2 = \frac{\varepsilon^2}{2} + \left\| \frac{Z - Z^*}{2} \right\|_{\text{HS}}^2 + \|T_{\perp}\|_{\text{HS}}^2, \quad H = -(Z + Z^*), \quad (\text{PAM.17})$$

where $U = RG^{-1/2}$, $T = \mathcal{B}G^{-1/2}$, $Z = U^*T$, and $T_{\perp} = (I - UU^*)T$, with $U^*U = I$. Thus both actual norm choices for a possible exclusion error have the exact lower estimates

$$\|\mathcal{B}G^{-1/2}\|_{\text{op}} \geq \frac{\varepsilon}{2} \geq \frac{\mathcal{L}_{h,k}}{2}, \quad \|\mathcal{B}G^{-1/2}\|_{\text{HS}} \geq \frac{\mathcal{L}_{h,k}}{\sqrt{2}}. \quad (\text{PAM.18})$$

The first follows from $\varepsilon = \|H\|_{\text{op}} \leq 2\|Z\|_{\text{op}} \leq 2\|T\|_{\text{op}}$; the second is immediate from (PAM.17).

The precise scaling, including the full multiplicity, is

$$\frac{\mathcal{L}_{h,k}}{kq_k} = \frac{2\delta \lfloor (k+1)^2/4 \rfloor}{k(k+1)} = \begin{cases} \frac{\delta(k+2)}{2(k+1)}, & k \text{ even}, \\ \frac{\delta(k+1)}{2k}, & k \text{ odd}. \end{cases} \rightarrow \frac{\delta}{2}. \quad (\text{PAM.19})$$

The equalities follow respectively from $\lfloor (k+1)^2/4 \rfloor = k(k+2)/4$ and $(k+1)^2/4$. In particular even the rank-divided operator lower bound satisfies

$$\frac{\|\mathcal{B}G^{-1/2}\|_{\text{op}}}{kq_k} \geq \frac{\mathcal{L}_{h,k}}{2kq_k}, \quad \liminf_{k \rightarrow \infty} \frac{\|\mathcal{B}_{N_k, \theta_k} G_{N_k, \theta_k}^{-1/2}\|_{\text{op}}}{kq_k} \geq \frac{\delta}{4}, \quad (\text{PAM.20})$$

where the limit inferior allows any admitted degrees N_k , periods $L_k > 0$, and phases θ_k . The Hilbert-Schmidt lower bound divided by kq_k tends to $\delta/(2\sqrt{2})$. Without division by q_k , the proved lower-bound functions for either norm divided by k diverge: $q_k = (k+1)^2$ for $m = 1$, and $q_k = (1+k(m-1))(k+1)^2$ for $m > 1$. For the root-mean-square quantity $\|\mathcal{B}G^{-1/2}\|_{\text{HS}}/\sqrt{q_k}$, its proved lower bound divided by k likewise diverges at least as $\delta\sqrt{q_k}/(2\sqrt{2})$. These claims concern the explicitly displayed lower-bound functions; they do not assign unproved asymptotic equalities to the actual energies.

The available upper comparison (HC12) retains two additional actual source quantities:

$$\|\mathcal{B}G_N^{-1/2}\|_{\text{HS}} \leq (1 + \sqrt{\beta_N})\sqrt{J_N^D}, \quad J_N^D = \|D_{L, \theta} R_N G_N^{-1/2}\|_{\text{HS}}^2, \quad \beta_N = \frac{V_N}{V_{N+1}} \geq 1. \quad (\text{PAM.21})$$

Here the equality for β_N is the proved single-rank update (HC12a), and $V_N = \det G_N$. Integration by parts in (PAM.8) gives the exact identity

$$J_N^D = c_k^2 q_k + \|\partial_r R_N G_N^{-1/2}\|_{\text{HS}}^2 \geq \frac{k^2 q_k}{4}. \quad (\text{PAM.22})$$

Consequently the numerical right-hand side of (PAM.21), divided by k , is at least $\sqrt{q_k}$; it is not an $o(k)$ exclusion error. After dividing that upper expression by kq_k , its elementary floor $1/\sqrt{q_k}$ does tend to zero, but (PAM.18)–(PAM.19), combined with the same true upper inequality, give instead

$$\frac{(1 + \sqrt{\beta_N})\sqrt{J_N^D}}{kq_k} \geq \frac{\mathcal{L}_{h,k}}{\sqrt{2} kq_k}, \quad (\text{PAM.23})$$

whose right side tends to $\delta/(2\sqrt{2}) > 0$. Thus the actual derivative and contraction factors in the already proved upper expression cannot simultaneously create a vanishing error at this divisor. This is an exact consequence of their proved relation, not permission to choose either factor freely.

135.5 What the computed quotient repairs do to the amplified generator

The QT construction can be performed on the identical finite phase Gram at $N = 2q_k$: (PAM.7) has all positive polynomial moments, so all the Gram-Schmidt lists and projection inverses defining the original four windows and their isometry remain well defined. Write $F = \chi_k \mathbb{C}[S]_{\leq q_k}$, $K = F^\perp$, $\Pi = P_K$, $Q = P_F$, and $C = C_{2q_k, \theta} : E_k \rightarrow K$. Here $H_{\text{pol}} = \mathbb{C}[S]_{\leq 2q_k}$ is the polynomial source, and $R = \mathcal{V}_{L, \theta} C$. The repaired source map and its exact cochain homotopy are

$$X = QT + \Pi, \quad JX = J, \quad X - I = BK_X, \quad K_X = (B^* M B)^{-1} B^* M (T - I), \quad B = \times \chi_k. \quad (\text{PAM.24})$$

These are the explicit QT.7–QT.8 and QT.27–QT.28 formulas on that original phase form. Its new representative is

$$R_X = R + \mathcal{H}, \quad \mathcal{H} = \mathcal{V}_{L, \theta}(BK_X C), \quad \mathcal{B}_X = \mathcal{B} + (D_{L, \theta} \mathcal{H} - \mathcal{H} A_k). \quad (\text{PAM.25})$$

The first equality follows by applying $\mathcal{V}_{L, \theta}$ to $XC = C + BK_X C$; substituting it into $\mathcal{B}_X = DR_X - R_X A_k$ proves the second with both signs. The same full-unit observation is unchanged: $\mathcal{I}_k JXC = \mathcal{I}_k$. The square-zero defect in QT.19 concerns the four-window operators U, W ; (PAM.25) is its separately calculated relation to the actual generator A_k . No equality between those two operators has been assigned.

The exact norm of this new representative is

$$G_X = R_X^* R_X = 2G - GG_{\text{low}}^{-1}G, \quad G \preceq G_X \preceq 2G, \quad G_{\text{low}} = G_{q_k-1, \theta}. \quad (\text{PAM.26})$$

Indeed $XC = C + QTC$ has orthogonal summands; the isometry of T and the full metric formula QT.12 give $(QTC)^*M(QTC) = G - GG_{\text{low}}^{-1}G$. Minimum-norm monotonicity gives $0 \preceq GG_{\text{low}}^{-1}G \preceq G$, proving the bounds. Thus $R_X v_k \neq 0$, and the direct calculation (PAM.12) applies to $R_X, \mathcal{B}_X$ with its own unaltered Gram G_X . It again gives $\|\mathcal{B}_X v_k\|/\|R_X v_k\| \geq k\delta$. The exact closest observation-preserving unitary in VR12 is $V_{\text{obs}} = I_K \oplus \text{polar}(T|_{F \rightarrow F})$. It fixes $C(E_k) \subset K$ pointwise, so

$$\mathcal{V}_{L, \theta} V_{\text{obs}} C = R, \quad D_{L, \theta} \mathcal{V}_{L, \theta} V_{\text{obs}} C - \mathcal{V}_{L, \theta} V_{\text{obs}} C A_k = \mathcal{B}. \quad (\text{PAM.27})$$

This is an exact equality of the original source representatives and their boundaries, not only an equality of cohomology classes.

Finally, the QT source-variation error is $e(t)^2 = -\frac{1}{2} \text{Tr}(G^{-1} \ddot{G}) = \text{Tr}(G^{-1} \dot{C}^* M \dot{C})$. It measures change of the representative with an interpolated source metric. On the constant path equal to the same actual phase Gram, $\dot{C} = 0$, its signed correction is zero, and its bound QT.24 is exactly zero. The generator boundary (PAM.10) and its strictly positive error (PAM.13) are unchanged on that constant path. This explicitly computes why that signed source-variation error cannot be substituted for the generator error in (PAM.13). The original Gamma-to-arithmetic interpolation retains its own nonconstant error and its exact QT bounds.

135.6 The exact cancellation inside the original derivative energy

Retain the objects and hypotheses of (PAM.1)–(PAM.10). In this subsection fix k, L, θ , put $c = c_k = k/2$, $q = q_k$, $A = A_k$, and use this same phase on every degree-dependent quantity. Write $D = D_{L, \theta} = -\partial_r + cI$ on the domain (PAM.8). The boundary in (PAM.10) has the exact second expression

$$\mathcal{B}_N = DR_N - R_N A = (D - cI)R_N - R_N(A - cI). \quad (\text{PSC.1})$$

Indeed the two new scalar terms are $-cR_N + cR_N = 0$. The original operators D, A , their scalar $c = k/2$, and the original boundary are all retained in this equality.

Define the actual two derivative energies and the original one-degree contraction by

$$\begin{aligned} J_N^\partial &= \|(D - cI)R_N G_N^{-1/2}\|_{\text{HS}}^2, & J_N^D &= \|DR_N G_N^{-1/2}\|_{\text{HS}}^2, \\ \mathcal{E}_N &= \|\mathcal{B}_N G_N^{-1/2}\|_{\text{HS}}^2, & \beta_N &= \lambda_{\max}(G_{N+1}^{-1/2} G_N G_{N+1}^{-1/2}) = \frac{V_N}{V_{N+1}} \geq 1, \quad V_N = \det G_N. \end{aligned} \quad (\text{PSC.2})$$

The last equality is the original rank-one update (HC12a), on this same phase measure. Since $D - cI = -\partial_r$ is skew-adjoint on the stated twisted domain, its scalar cross term has real part zero. Applying that equality to each column of $R_N G_N^{-1/2}$ gives

$$J_N^\partial = J_N^D - c^2 q > 0. \quad (\text{PSC.3})$$

Here the strict positivity also follows directly from the source. A nonzero column is the periodized image of a nonzero polynomial P , since $J_N C_{N, \theta} = I_E$. The norm of its derivative is the sum of the positive lattice weights times $u_n^2 |P(c + iu_n)|^2$. There are infinitely many nonzero u_n , and a nonzero polynomial cannot vanish at all their distinct values $c + iu_n$. Thus each nonzero source column has positive derivative norm. No lattice term, including a possible $u_n = 0$, has been deleted.

The vector $(D - cI)R_N x$ is an original degree- $(N + 1)$ representative of $(A - cI)x$. Indeed its coefficient polynomial is $(S - c)C_{N, \theta} x$, and its full remainder is $(A - cI)x$. The degree- $(N + 1)$ minimum therefore proves the Hermitian inequality

$$(A - cI)^* G_{N+1} (A - cI) \preceq R_N^* (D - cI)^* (D - cI) R_N. \quad (\text{PSC.4})$$

This is an inequality between the original forms on E ; the source map, the full remainder, and its unit-valued arithmetic inclusion in (PAM.3) have not changed. From $G_N \preceq \beta_N G_{N+1}$, sandwiching (PSC.4) by $G_N^{-1/2}$ and taking traces gives

$$\|R_N(A - cI)G_N^{-1/2}\|_{\text{HS}}^2 \leq \beta_N J_N^\partial.$$

The triangle inequality in (PSC.1), combined with (HT14), now gives the sharper actual energy bound

$$\frac{\mathcal{L}_{h,k}^2}{2} \leq \mathcal{E}_N \leq (1 + \sqrt{\beta_N})^2 (J_N^\partial - c^2 q) = (1 + \sqrt{\beta_N})^2 J_N^\partial. \quad (\text{PSC.5})$$

The improvement over (HC12) is the exact cancelling contribution $c^2 q$ in the same measured derivative energy. It is not a change of metric or a choice of a new representative.

The contraction identity $e_N = \log \beta_N$, with $e_N = \log(V_N/V_{N+1})$, then implies

$$e_N \geq 2 \log \max \left\{ 1, \frac{\mathcal{L}_{h,k}}{\sqrt{2J_N^\partial}} - 1 \right\}, \quad (\text{PSC.6})$$

$$\mathcal{B}_{k,\theta} \geq 2 \sum_{N=q-1}^{2q-1} w_N \log \max \left\{ 1, \frac{\mathcal{L}_{h,k}}{\sqrt{2J_N^\partial}} - 1 \right\}, \quad w_{q-1} = w_{2q-1} = 1, \quad w_N = 2 \quad (q \leq N \leq 2q-2).$$

For the first line, divide (PSC.5) by $J_N^\partial > 0$, take nonnegative square roots, and use $\sqrt{\beta_N} \geq 1$. For the second, put $\mathcal{B}_{k,\theta} = \log(V_{q-1}V_q/(V_{2q-1}V_{2q}))$; its original four endpoint logarithms telescope to $\mathcal{B}_{k,\theta} = \sum_N w_N e_N$. Thus the strengthened energy enters exactly the same windows.

135.7 A finite moment upper expression for the same generator error

Put $P_N = \mathbb{C}[S]_{\leq N}$. Let $\mathbb{L}_N : P_N \rightarrow P_{N+1}$ be the literal coefficient map $P(S) \mapsto (S - c)P(S)$. Define

$$W_N = \mathbb{L}_N^* M_{N+1,\theta} \mathbb{L}_N, \quad \Gamma_N = \lambda_{\max}(M_{N,\theta}^{-1/2} W_N M_{N,\theta}^{-1/2}),$$

$$P^* W_N P = \frac{2\pi}{L} \sum_{n \in \mathbb{Z}} u_n^2 m_{h,k}(u_n) |P(c + iu_n)|^2, \quad 0 < \Gamma_N < \infty. \quad (\text{PSC.7})$$

The quadratic-form identity follows from $S - c = iu$ on the original sampled line. Its strict positivity is the same nonvanishing-polynomial argument used for (PSC.3). All moments through degree $2N+2$ are finite by the original source estimates; the finite positive matrix $M_{N,\theta}$ has an inverse, proving finiteness of Γ_N . The full factor $2\pi/L$ and the original mass of $m_{h,k}$ remain in both matrices.

From $W_N \preceq \Gamma_N M_{N,\theta}$ and $C_{N,\theta}^* M_{N,\theta} C_{N,\theta} = G_N$, one gets

$$\|(D - cI)R_N G_N^{-1/2}\|_{\text{op}} \leq \sqrt{\Gamma_N}, \quad J_N^\partial \leq q\Gamma_N.$$

Keeping (PSC.4) as a Hermitian inequality, rather than only taking its trace, likewise gives $\|R_N(A - cI)G_N^{-1/2}\|_{\text{op}} \leq \sqrt{\beta_N \Gamma_N}$. Consequently

$$\frac{\mathcal{L}_{h,k}}{2} \leq \|\mathcal{B}_N G_N^{-1/2}\|_{\text{op}} \leq (1 + \sqrt{\beta_N}) \sqrt{\Gamma_N},$$

$$\frac{\mathcal{L}_{h,k}}{\sqrt{2}} \leq \|\mathcal{B}_N G_N^{-1/2}\|_{\text{HS}} \leq (1 + \sqrt{\beta_N}) \sqrt{J_N^\partial}, \quad (\text{PSC.8})$$

$$\liminf_{k \rightarrow \infty} \frac{(1 + \sqrt{\beta_{N_k}}) \sqrt{\Gamma_{N_k}}}{k q_k} \geq \frac{\delta}{4}, \quad \liminf_{k \rightarrow \infty} \frac{(1 + \sqrt{\beta_{N_k}}) \sqrt{J_{N_k}^\partial}}{k q_k} \geq \frac{\delta}{2\sqrt{2}}.$$

The first lower bound is (PAM.18); the second is (HT14). The two limit inferior statements hold for every choice of admitted integers $N_k \geq q_k - 1$, periods $L_k > 0$, and phases $0 \leq \theta_k < 2\pi$, with every quantity on its indicated same phase. They follow from the pointwise bounds and the exact parity-dependent limit (PAM.19). In particular neither computed upper expression is $o(k)$: each divided by k tends to infinity at least as its displayed positive multiple of q_k . This statement concerns the upper expressions actually linked to the original generator by (PSC.1)–(PSC.7).

135.8 Original spaces and the actual source at both degrees

Fix a finite original packet h , a tensor order $k \geq 2$, and the exact original cyclic polynomial $\chi = \chi_{h,k}$ of degree $q > 0$. Retain

$$E = \mathbb{C}[S]/(\chi), \quad A = M_S : E \longrightarrow E, \quad P_N = \mathbb{C}[S]_{\leq N}, \quad N \geq q - 1, \quad J_N = \pi_\chi|_{P_N}. \quad (\text{PSC.9})$$

The source and its half-density version are precisely

$$\mathcal{V}P = P(D_1 + \cdots + D_k)F_h^{\otimes k}, \quad \mathcal{M}F_h = g/h, \quad \Psi_N = \mathcal{U}_k \mathcal{V}|_{P_N}. \quad (\text{PSC.10})$$

Here $D_i = -x_i \partial_{x_i}$, $r = \log x_k$, $z_i = \log x_i - \log x_k$, and

$$(\mathcal{U}_k F)(r, z) = e^{(kr + \sum_{i < k} z_i)/2} F(e^{r+z_1}, \dots, e^{r+z_{k-1}}, e^r).$$

The target is $L^2(\mathbb{R}, dr; \mathcal{K})$, with $\mathcal{K} = L^2(\mathbb{R}^{k-1}, dz)$. Its relative variables are retained. The original full-jet map is the injection

$$\eta_{H8}[P] = j_h(g/h)^{\otimes k} P(A_h^{(k)})1, \quad J^{(k)} \mathcal{V}P = \eta_{H8} \pi_\chi P. \quad (\text{PSC.11})$$

Here $E_h = \mathbb{C}[s]/(h)$, $A_h = M_s : E_h \rightarrow E_h$, and $A_h^{(k)} = \sum_{i=1}^k A_{h,i}$ acts on $E_h^{\otimes k}$. Its restriction to the displayed cyclic image agrees with the original $A = M_S$. The subscript merely identifies the original map called η in H8; the scalar source error below is the η of H32. No unit factor is removed from (PSC.11).

Write $\iota_N : P_N \hookrightarrow P_{N+1}$ for inclusion and $S_N : P_N \rightarrow P_{N+1}$, $P \mapsto SP$, for multiplication before reduction. These have different codomains from A , and satisfy

$$J_{N+1} S_N = A J_N, \quad J_{N+1} \iota_N = J_N, \quad \partial_r \Psi_N = \Psi_{N+1} ((k/2) \iota_N - S_N). \quad (\text{PSC.12})$$

The last formula follows by applying the exact H10 identity $\mathcal{U}_k D^{(k)} = (-\partial_r + k/2) \mathcal{U}_k$ to each polynomial column. It is why the comparison below uses a source bound at degree $N + 1$.

For $L > 0$ define

$$W_{N,\theta} = \mathcal{Z}_{L,\theta} \Psi_N, \quad M_N = \Psi_N^* \Psi_N, \quad M_{N,\theta} = W_{N,\theta}^* W_{N,\theta}. \quad (\text{PSC.13})$$

The phase source is in $\mathcal{H}_{L,\theta} = L^2([0, L], dr; \mathcal{K})$. Its generator is

$$D_{L,\theta} = -\partial_r + k/2, \quad \text{Dom } D_{L,\theta} = \{f \in H^1([0, L]; \mathcal{K}) : f(L) = e^{-i\theta} f(0)\}.$$

All columns used here belong to this domain. The original weighted source bounds justify the periodization and its r -derivative. In particular no derivative in θ is involved when $D_{L,\theta}$ is applied to a coefficient map depending on θ .

The complete phase transform gives

$$\int_0^{2\pi} M_{N,\theta} \frac{d\theta}{2\pi} = M_N. \quad (\text{PSC.14})$$

135.9 The exact relation map between the two sections

Let $B_N : \mathbb{C}^{N-q+1} \hookrightarrow P_N$ be the coefficient matrix of literal multiplication by χ , with zero-dimensional domain if $N = q - 1$. Thus $\text{im } B_N = \chi P_{N-q} = \ker J_N$. Keep the original sections

$$\begin{aligned} G &= (J_N M_N^{-1} J_N^*)^{-1}, & C &= M_N^{-1} J_N^* G, \\ G_\theta &= (J_N M_{N,\theta}^{-1} J_N^*)^{-1}, & C_\theta &= M_{N,\theta}^{-1} J_N^* G_\theta. \end{aligned} \quad (\text{PSC.15})$$

Since $J_N C = J_N C_\theta = I_E$, the difference $Z_\theta := C - C_\theta : E \rightarrow P_N$ has image in $\ker J_N$. Hence there is a unique polynomial coefficient map $X_\theta : E \rightarrow P_{N-q}$ such that

$$Z_\theta = \chi X_\theta = B_N X_\theta, \quad X_\theta = (B_N^* M_{N,\theta} B_N)^{-1} B_N^* M_{N,\theta} C \quad (\text{PSC.16})$$

in the fixed coefficient bases. An inverse on a zero-dimensional space in this notation is the unique empty map.

Indeed $B_N^* M_{N,\theta} C_\theta = 0$, so multiplying the first identity by $B_N^* M_{N,\theta}$ proves the second. This is precisely the literal original theta-relation difference from H26.

Define maps $E \rightarrow \mathcal{H}_{L,\theta}$ by

$$R_\theta^c = W_{N,\theta} C, \quad R_\theta^p = W_{N,\theta} C_\theta, \quad L_\theta = W_{N,\theta} Z_\theta = R_\theta^c - R_\theta^p. \quad (\text{PSC.17})$$

The superscripts label the common section and phase minimum. The orthogonality from (PSC.15) is the exact map identity $(R_\theta^p)^* L_\theta = 0$. Therefore

$$\begin{aligned} \mathcal{D} &:= \int_0^{2\pi} L_\theta^* L_\theta \frac{d\theta}{2\pi} = \int_0^{2\pi} X_\theta^* B_N^* M_{N,\theta} B_N X_\theta \frac{d\theta}{2\pi}, \\ G &= \overline{G} + \mathcal{D}, \quad \overline{G} := \int_0^{2\pi} G_\theta \frac{d\theta}{2\pi}. \end{aligned} \quad (\text{PSC.18})$$

For clarity, the proof is an expansion: $(R_\theta^c)^* R_\theta^c = G_\theta + L_\theta^* L_\theta$. Integration and (PSC.14) give $C^* M_N C = G$, hence (PSC.18). No cancellation of the norm of a relation has been made.

135.10 Exact generator difference, with its literal primitive

Define the common and phase generator boundaries by

$$\mathcal{B}_\theta^c = D_{L,\theta} R_\theta^c - R_\theta^c A, \quad \mathcal{B}_\theta^p = D_{L,\theta} R_\theta^p - R_\theta^p A. \quad (\text{PSC.19})$$

Both are maps on the original E ; $\mathcal{B}_\theta^p$ is H54. At polynomial level put

$$T_c = S_N C - \iota_N C A, \quad T_{p,\theta} = S_N C_\theta - \iota_N C_\theta A : E \longrightarrow P_{N+1}.$$

Applying J_{N+1} gives zero, so unique monic division yields $T_c = \chi Q_c$ and $T_{p,\theta} = \chi Q_{p,\theta}$, where both $Q_c, Q_{p,\theta}$ map to P_{N+1-q} . Using (PSC.16), their exact difference is

$$Q_c - Q_{p,\theta} = S X_\theta - X_\theta A. \quad (\text{PSC.20})$$

Here $S X_\theta : E \rightarrow P_{N-q+1}$ raises degree before reduction, whereas $X_\theta A$ is composition on E . The calculation is

$$T_c - T_{p,\theta} = S(C - C_\theta) - (C - C_\theta)A = \chi(S X_\theta - X_\theta A);$$

injectivity of multiplication by the nonzero polynomial χ proves (PSC.20).

After applying the same source and phase maps, the full comparison is

$$\begin{aligned}
\Delta \mathcal{B}_\theta &:= \mathcal{B}_\theta^c - \mathcal{B}_\theta^p \\
&= W_{N+1,\theta} (S_N Z_\theta - \iota_N Z_\theta A) \\
&= \mathcal{Z}_{L,\theta} \mathcal{U}_k \mathcal{V}(\chi(SX_\theta - X_\theta A)) \\
&= D_{L,\theta} L_\theta - L_\theta A \\
&= -\partial_r L_\theta - L_\theta (A - (k/2)I_E).
\end{aligned} \tag{PSC.21}$$

The final line expands the stated generator without changing either A or its marked arithmetic value.

There is an explicit original tensor primitive for every displayed relation. If $Y(S)$ is any of X_θ , Q_c , $Q_{p,\theta}$, or $SX_\theta - X_\theta A$, tensor monic division gives polynomial coefficient maps Y_i with

$$\chi(S)Y(S) = \sum_{i=1}^k h(s_i)Y_i(s_1, \dots, s_k).$$

This holds because the left side has zero image in the full tensor jet algebra, not because the tensor relation ideal was replaced by (χ) . With the original relation $h(D)F_h = \Theta\phi_h$, a degree- $(k-1)$ primitive is

$$\sum_{i=1}^k (-1)^{i-1} Y_i(D_1, \dots, D_k) \left(F_h^{\otimes(i-1)} \otimes \phi_h \otimes F_h^{\otimes(k-i)} \right). \tag{PSC.22}$$

The differential crosses $i-1$ degree-one factors before acting on ϕ_h , supplying a second $(-1)^{i-1}$. The two signs multiply to $+1$, so its differential is exactly $\mathcal{V}(\chi Y)$. Applying $\mathcal{U}_k$ and $\mathcal{Z}_{L,\theta}$ gives the maps in (PSC.17), (PSC.19), and (PSC.21).

135.11 Exact energy identities before any inequality

Introduce the matrices on the original coefficient space E

$$\mathcal{E} = \int (\partial_r L_\theta)^* (\partial_r L_\theta) \frac{d\theta}{2\pi}, \quad \mathcal{K} = \int (\partial_r L_\theta)^* L_\theta \frac{d\theta}{2\pi}. \tag{PSC.23}$$

All integrals in this note range over $0 \leq \theta < 2\pi$. Expanding the last line of (PSC.21), with both signs retained, gives

$$\begin{aligned}
\mathcal{E}_\Delta &:= \int (\Delta \mathcal{B}_\theta)^* \Delta \mathcal{B}_\theta \frac{d\theta}{2\pi} \\
&= \mathcal{E} + (A^* - (k/2)I_E) \mathcal{D} (A - (k/2)I_E) \\
&\quad + \mathcal{K} (A - (k/2)I_E) + (A^* - (k/2)I_E) \mathcal{K}^*.
\end{aligned} \tag{PSC.24}$$

It also has the original finite-moment formula

$$\mathcal{E}_\Delta = \int (S_N Z_\theta - \iota_N Z_\theta A)^* M_{N+1,\theta} (S_N Z_\theta - \iota_N Z_\theta A) \frac{d\theta}{2\pi}. \tag{PSC.25}$$

For the full boundaries, the exact comparison includes its cross term:

$$\begin{aligned}
T_c^* M_{N+1} T_c &= \int (\mathcal{B}_\theta^c)^* \mathcal{B}_\theta^c \frac{d\theta}{2\pi} \\
&= \int (\mathcal{B}_\theta^p)^* \mathcal{B}_\theta^p \frac{d\theta}{2\pi} + \mathcal{E}_\Delta \\
&\quad + \int [(\mathcal{B}_\theta^p)^* \Delta \mathcal{B}_\theta + (\Delta \mathcal{B}_\theta)^* \mathcal{B}_\theta^p] \frac{d\theta}{2\pi}.
\end{aligned} \tag{PSC.26}$$

The first equality is (PSC.14) at degree $N + 1$, because T_c is independent of phase. The remaining equality is expansion of $\mathcal{B}_\theta^c = \mathcal{B}_\theta^p + \Delta \mathcal{B}_\theta$. Orthogonality of R_θ^p and L_θ does not delete the last integral in (PSC.26).

There is also an exact comparison for the adjoint generator forms. Set $\mathfrak{H}(M) = A^*M + MA - kM$, for a Hermitian form M on the same E . Then

$$\boxed{\mathfrak{H}(G) - \mathfrak{H}(\overline{G}) = A^* \mathcal{D} + \mathcal{D} A - k \mathcal{D}.} \quad (\text{PSC.27})$$

This follows by substituting (PSC.18) into the left side. It concerns the difference of the two forms; it does not assert that either full form is small.

135.12 Actual source derivative moments and a uniform comparison

The source Gram for its derivative is the finite, explicitly specified matrix

$$\begin{aligned} Q_N &:= (\partial_r \Psi_N)^* (\partial_r \Psi_N) \\ &= ((k/2)\iota_N - S_N)^* M_{N+1} ((k/2)\iota_N - S_N). \end{aligned} \quad (\text{PSC.28})$$

In the original coefficient basis $P_a(S)$, its entries are exactly

$$\begin{aligned} (Q_N)_{ab} &= \int_{\mathbb{R}} u^2 \overline{P_a(k/2 + iu)} P_b(k/2 + iu) m_{h,k}(u) du, \\ m_{h,k} &= w_h^{*k}, \quad w_h(u) = \frac{|(g/h)(1/2 + iu)|^2}{2\pi}. \end{aligned} \quad (\text{PSC.29})$$

Indeed the derivative has Fourier multiplier $-iu$, while (H17) and the continuous source norm retain precisely $m_{h,k}$. Its squared absolute value is u^2 , proving every entry in (PSC.29). The full vector-valued source remains in (PSC.28); (PSC.29) evaluates its Gram.

Define the exact finite number

$$d_N = \sup_{v \neq 0} \frac{v^* Q_N v}{v^* M_N v}. \quad (\text{PSC.30})$$

It exists because $M_N \succ 0$, Q_N is finite, and the finite-dimensional unit sphere for M_N is compact. Thus $Q_N \preceq d_N M_N$ is a proved statement, not an additional arithmetic hypothesis. H50's original derivative matrix satisfies

$$Q_N \preceq H_{1,N} = \int_{\mathbb{R}} (1 + r^2) (\partial_r \Psi_N)^* (\partial_r \Psi_N) dr. \quad (\text{PSC.31})$$

Consequently the original $h_{1,N}$ of H51 can be used in every occurrence of d_N below if its bound has been supplied. Formula (PSC.30), using (PSC.28)–(PSC.29), is the sharper exact source moment used here.

Choose $a > 0$ and retain the original two weighted source Grams at degree $N + 1$:

$$M_{a,\pm,N+1} = (e^{\pm ar} \Psi_{N+1})^* (e^{\pm ar} \Psi_{N+1}).$$

The weighted column maps take the finite coefficient space P_{N+1} into the same $L^2(\mathbb{R}, dr; \mathcal{K})$; their squared weights are the original coordinate factors $x_k^{\pm 2a}$. Define their actual finite cost

$$\kappa_{a,N+1} = \sup_{v \neq 0} \frac{v^* (M_{a,+,N+1} + M_{a,-,N+1}) v}{v^* M_{N+1} v}, \quad \eta = \frac{\kappa_{a,N+1}}{e^{aL} - 1} < 1. \quad (\text{PSC.32})$$

The original weighted Schwartz estimates make both weighted Grams finite for the chosen finite source. H41 therefore gives, with no new phase hypothesis,

$$(1 - \eta) M_{N+1} \preceq M_{N+1,\theta} \preceq (1 + \eta) M_{N+1}. \quad (\text{PSC.33})$$

Restricting gives the same comparison at degree N . H33, whose hypotheses are now supplied by the actual source, gives

$$0 \preceq \mathcal{D} \preceq \eta^2 G. \quad (\text{PSC.34})$$

For each $x \in E$, apply (PSC.33) to $((k/2)\iota_N - S_N)Z_\theta x$, then (PSC.30), then the lower degree- N bound:

$$\begin{aligned} \|\partial_r L_\theta x\|^2 &\leq (1 + \eta)x^* Z_\theta^* Q_N Z_\theta x \\ &\leq (1 + \eta)d_N x^* Z_\theta^* M_N Z_\theta x \\ &\leq \frac{1 + \eta}{1 - \eta} d_N x^* Z_\theta^* M_{N,\theta} Z_\theta x \\ &= \frac{1 + \eta}{1 - \eta} d_N \|L_\theta x\|^2. \end{aligned} \quad (\text{PSC.35})$$

Periodization commutes with the r -derivative on these source columns, so the first line uses the actual derivative in (PSC.23). Integrating (PSC.35) and using (PSC.34) proves

$$0 \preceq \mathcal{E} \preceq \frac{1 + \eta}{1 - \eta} d_N \mathcal{D} \preceq \frac{1 + \eta}{1 - \eta} d_N \eta^2 G. \quad (\text{PSC.36})$$

135.13 Generator-difference bounds in the original quotient metric

For a family $Y_\theta : E \rightarrow \mathcal{H}_{L,\theta}$, define the Hilbert–Schmidt norm using the retained G by

$$\|Y\|_{2,G}^2 := \int \text{Tr}(G^{-1} Y_\theta^* Y_\theta) \frac{d\theta}{2\pi}. \quad (\text{PSC.37})$$

Equivalently this is the sum of $\|Y_\theta e_j\|^2$ over any G -orthonormal basis (e_j) , integrated in the original phase measure. This definition does not rescale either the source mass or the arithmetic metric.

Keep the exactly computed coefficient quantities

$$a_{\text{HS}}^2 = \text{Tr}(G^{-1}(A^* - (k/2)I_E)G(A - (k/2)I_E)), \quad a_{\text{op}} = \|A - (k/2)I_E\|_G. \quad (\text{PSC.38})$$

They are computed from the actual multiplication matrix and original minimum metric. In particular no diagonalizability or removal of nilpotent parts is used.

Equations (PSC.34), (PSC.36), and (PSC.21) imply

$$\boxed{\begin{aligned} \|L\|_{2,G} &\leq \eta\sqrt{q}, \\ \|\Delta\mathcal{B}\|_{2,G} &\leq \eta \left(\sqrt{\frac{1 + \eta}{1 - \eta} d_N q} + a_{\text{HS}} \right). \end{aligned}} \quad (\text{PSC.39})$$

To prove the second statement, the triangle inequality in the Hilbert space of phase families gives

$$\|\Delta\mathcal{B}\|_{2,G} \leq \|\partial_r L\|_{2,G} + \|L(A - (k/2)I_E)\|_{2,G}.$$

The first squared norm is $\text{Tr}(G^{-1}\mathcal{E}) \leq \eta^2(1 + \eta)(1 - \eta)^{-1}d_N q$. The second squared norm is

$$\text{Tr}(G^{-1}(A^* - (k/2)I_E)\mathcal{D}(A - (k/2)I_E)) \leq \eta^2 a_{\text{HS}}^2,$$

which proves (PSC.39). The first statement is $\text{Tr}(G^{-1}\mathcal{D}) \leq \eta^2 q$.

For every real $t > 0$, a matrix form of the same estimate is

$$\mathcal{E}_\Delta \preceq \eta^2 \left[(1 + t) \frac{1 + \eta}{1 - \eta} d_N G + (1 + t^{-1})(A^* - (k/2)I_E)G(A - (k/2)I_E) \right]. \quad (\text{PSC.40})$$

For each vector x , use $2 \text{Re}\langle u, v \rangle \leq t\|u\|^2 + t^{-1}\|v\|^2$ in the squared norm of (PSC.21), integrate, and then apply (PSC.34) and (PSC.36). This proves all quadratic forms in (PSC.40).

The adjoint-form comparison (PSC.27) has a quadratic error:

$$\left\| G^{-1/2}(\mathfrak{H}(G) - \mathfrak{H}(\overline{G}))G^{-1/2} \right\|_{\text{op}} \leq 2\eta^2 a_{\text{op}}. \quad (\text{PSC.41})$$

Indeed let $D = G^{-1}\mathcal{D}$; it is positive self-adjoint for G , and $\|D\|_G \leq \eta^2$. Multiplication of (PSC.27) by G^{-1} gives

$$(A - (k/2)I_E)^{\dagger_G} D + D(A - (k/2)I_E),$$

where †_G is the metric adjoint. Submultiplicativity proves (PSC.41). The statement is in the original G -metric; it is not an unqualified Euclidean bound on the coefficient matrix in (PSC.27).

135.14 An explicit length choice makes both comparison errors small

Keep a fixed original packet h and let k vary, with any finite cutoff $N_k \geq q_k - 1$. In the following formulas all matrices are the actual source matrices for that k, N_k . Set

$$\eta_k = \frac{1}{(k+1)(1 + \sqrt{q_k} + \sqrt{3d_{N_k}q_k + a_{\text{HS},k}})}, \quad L_k = \frac{1}{a} \log \left(1 + \frac{\kappa_{a,N_k+1}}{\eta_k} \right). \quad (\text{PSC.42})$$

Every input in these formulas is finite, and the weighted Gram cost is strictly positive. Thus both parameters are finite and positive. Substitution gives

$$\frac{\kappa_{a,N_k+1}}{e^{aL_k} - 1} = \eta_k.$$

Also $0 < \eta_k < 1/2$, so $(1+\eta_k)/(1-\eta_k) \leq 3$. Thus (PSC.39) proves the explicit simultaneous estimates

$$\boxed{\|L\|_{2,G} \leq \frac{1}{k+1}, \quad \|\mathcal{B}^c - \mathcal{B}^p\|_{2,G} \leq \frac{1}{k+1}.} \quad (\text{PSC.43})$$

For example, the first bound follows by inserting the numerator $\sqrt{q_k}$ into the positive denominator in (PSC.42); the second follows by inserting $\sqrt{3d_{N_k}q_k + a_{\text{HS},k}}$. Both errors are therefore $o(k)$, indeed they tend to zero.

No uniform estimate on the growth of κ_{a,N_k+1} , d_{N_k} , or $a_{\text{HS},k}$ was claimed. The length in (PSC.42) explicitly pays their full cost. This is an existence and exact-formula comparison at each finite k, N_k , not a certified numerical evaluation of an unevaluated arithmetic Gram.

135.15 The complete quartet boundary cannot satisfy the same estimate

Now remain inside the counterfactual branch of the original program: a root $\rho = 1/2 + \delta + i\gamma$, $0 < \delta < 1/2$, $\gamma > 0$, of its full order m , together with its reflected and conjugate roots, is selected. Retain HT1–HT2 exactly:

$$\ell_k = 1 + k(m-1), \quad q_k = \ell_k(k+1)^2, \quad \mathcal{L}_{h,k} = 2\delta\ell_k(k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor. \quad (\text{PSC.44})$$

The full original cyclic polynomial is

$$\chi_{h,k}(S) = \prod_{a_0, b_0=0}^k (S - k/2 - (2a_0 - k)\delta - i(2b_0 - k)\gamma)^{\ell_k}.$$

No order in this polynomial is reduced.

The independently proved HT14–HT15 give, for every phase, every length, and every $N_k \geq q_k - 1$,

$$\text{Tr}(G_{\theta}^{-1}(\mathcal{B}_{\theta}^p)^* \mathcal{B}_{\theta}^p) \geq \frac{\mathcal{L}_{h,k}^2}{2} \geq \frac{\delta^2 k^2 q_k^2}{8}. \quad (\text{PSC.45})$$

Those arithmetic lower bounds are used here, not reproved.

To place (PSC.45) in precisely the same metric as (PSC.43), first note that the source bound (PSC.33) gives

$$(1 - \eta_k)G \preceq G_\theta \preceq (1 + \eta_k)G. \quad (\text{PSC.46})$$

Indeed the minimum over $J_N P = x$ of each quadratic source form is its quotient form $x^* G_\theta x$, respectively $x^* G x$; minimizing the two inequalities proves both statements. The lower inequality implies $G^{-1} \succeq (1 - \eta_k)G_\theta^{-1}$. Taking its trace against the positive matrix $(\mathcal{B}_\theta^p)^* \mathcal{B}_\theta^p$, and then integrating (PSC.45), gives

$$\|\mathcal{B}^p\|_{2,G} \geq \sqrt{1 - \eta_k} \frac{\mathcal{L}_{h,k}}{\sqrt{2}} \geq \frac{\sqrt{1 - \eta_k} \delta k q_k}{2\sqrt{2}}. \quad (\text{PSC.47})$$

The same lower bound reaches the common section with its exact comparison cost. The reverse triangle inequality applied to (PSC.21) and (PSC.43) gives

$$\boxed{\begin{aligned} \|\mathcal{B}^c\|_{2,G} &= (\text{Tr}(G^{-1} T_c^* M_{N_k+1} T_c))^{1/2} \\ &\geq \sqrt{1 - \eta_k} \frac{\mathcal{L}_{h,k}}{\sqrt{2}} - \frac{1}{k+1}. \end{aligned}} \quad (\text{PSC.48})$$

The equality is the exact all-phase isometry (PSC.26), so the common boundary in this formula is the original source boundary.

In particular (PSC.42) gives $\eta_k \rightarrow 0$, and $q_k \geq 1$, whence

$$\liminf_{k \rightarrow \infty} \frac{\|\mathcal{B}^c\|_{2,G}}{k q_k} \geq \frac{\delta}{2\sqrt{2}}, \quad \liminf_{k \rightarrow \infty} \frac{\|\mathcal{B}^p\|_{2,G}}{k q_k} \geq \frac{\delta}{2\sqrt{2}}. \quad (\text{PSC.49})$$

Thus neither full generator boundary has $o(k)$ norm, even after reporting its norm per quotient dimension. The actual phasewise metric version (PSC.45) is uniform in L without any length restriction.

Equations (PSC.43), (PSC.47), and (PSC.48) coexist because (PSC.43) makes the two large boundaries close. It does not set either boundary equal to zero. The morphism that relates these statements is the exact original relation map (PSC.20)–(PSC.22).

135.16 At the minimal cutoff the gluing error is identically zero

There is a useful exact case requiring no length choice or limiting statement. Set $N = q - 1$. Then

$$J_{q-1} : P_{q-1} \longrightarrow E$$

is an isomorphism: monic division gives a unique remainder of degree at most $q - 1$ for every class, and a nonzero multiple of a degree- q monic polynomial cannot have degree at most $q - 1$.

Every section in (PSC.15) must consequently equal the unique inverse, so

$$C = C_\theta = J_{q-1}^{-1}, \quad Z_\theta = X_\theta = L_\theta = 0, \quad \mathcal{D} = \mathcal{E}_\Delta = 0 \quad (\text{PSC.50})$$

for every θ and $L > 0$.

Define the original H57 residue coefficient

$$\ell : E \longrightarrow \mathbb{C}, \quad \ell([P]) = [S^{q-1}] \text{rem}_\chi P. \quad (\text{PSC.51})$$

This is nonzero since $\ell([S^{q-1}]) = 1$. For a remainder P of degree at most $q - 1$, the polynomial SP has degree at most q . Its monic division by χ has constant quotient exactly $[S^{q-1}]P$. Its remainder is $CA[P]$. Therefore the complete coefficient identity is

$$S_{q-1}C - \iota_{q-1}CA = \chi \ell. \quad (\text{PSC.52})$$

It follows that the persistent boundary is the explicit rank-one map

$$\boxed{\mathcal{B}_\theta^c = \mathcal{B}_\theta^p = f_{\chi,\theta} \otimes \ell, \quad f_{\chi,\theta} := \mathcal{Z}_{L,\theta} \mathcal{U}_k \mathcal{V}_\chi.} \quad (\text{PSC.53})$$

It factors through exactly the same scalar functional as the original residue constituent $\mathcal{R} = 1_E \otimes \ell$ in H57. In (PSC.53) the receiving vector is the actual source relation $f_{\chi,\theta}$, and its tensor theta primitive is (PSC.22) with $Y = 1$.

This vector is nonzero. Its exact phase norm is

$$\|f_{\chi,\theta}\|^2 = \frac{2\pi}{L} \sum_{n \in \mathbb{Z}} m_{h,k} \left(\frac{2\pi n + \theta}{L} \right) \left| \chi \left(k/2 + i \frac{2\pi n + \theta}{L} \right) \right|^2 > 0. \quad (\text{PSC.54})$$

All weights are positive for $k \geq 2$, as proved for the actual source in HT6. The nonzero polynomial χ has only finitely many distinct roots; it cannot vanish on every point of the infinite distinct sampled lattice. At least one summand is therefore positive and all are nonnegative. Convergence follows from the original source bounds.

Thus (PSC.53) has rank exactly one and the full generator energy is exactly

$$\text{Tr}(G_\theta^{-1}(\mathcal{B}_\theta^p)^* \mathcal{B}_\theta^p) = \|f_{\chi,\theta}\|^2 \ell G_\theta^{-1} \ell^* > 0. \quad (\text{PSC.55})$$

To verify this equation, the Gram of $f_{\chi,\theta} \otimes \ell$ is $\|f_{\chi,\theta}\|^2 \ell^* \ell$; cyclicity of the finite matrix trace gives (PSC.55). Positive definiteness of G_θ^{-1} and $\ell \neq 0$ prove strict positivity. Under the selected quartet, HT14 supplies the quantitative lower bound (PSC.45) to this exact expression.

Hence even perfect gluing, $\mathcal{D} = 0$, is already compatible with the full positive generator defect in the original finite quotient at its first cutoff. This is an exact calculation on the counterfactual packet, not an asserted RH counterexample.

135.16.1 Exact first-cutoff energy, including the monic residual

In this paragraph fix one phase and $N = q - 1$, and write $R = R_\theta^p = R_\theta^c$, $G_0 = G_\theta$, $f = f_{\chi,\theta}$. Thus G_0 denotes this phase metric, not the common metric G in (PSC.15). Put

$$U = R G_0^{-1/2}, \quad r^* = \ell G_0^{-1/2}, \quad T = \mathcal{B}_\theta^p G_0^{-1/2} = f r^*, \quad z = U^* f, \quad \alpha = r^* z. \quad (\text{PSC.56})$$

Here $U^* U = I_E$. The exact integration-by-parts identity H55 gives

$$H_0 = G_0^{-1/2} (A^* G_0 + G_0 A - k G_0) G_0^{-1/2} = -(z r^* + r z^*). \quad (\text{PSC.57})$$

For the complete quartet, $\text{Tr } H_0 = 0$; therefore $\text{Re } \alpha = 0$. HT9 identifies its two nonzero eigenvalues as $\varepsilon_\theta, -\varepsilon_\theta$, with $\varepsilon_\theta \geq \mathcal{L}_{h,k}$.

Multiplying out the square in (PSC.57) and taking its trace gives

$$2\varepsilon_\theta^2 = 2\|z\|^2 \|r\|^2 + 2\text{Re}(\alpha^2) = 2\|z\|^2 \|r\|^2 - 2(\text{Im } \alpha)^2.$$

The decomposition $f = U z + (I - U U^*) f$ is orthogonal. Since $T = f r^*$ is rank one, both its squared operator norm and squared Hilbert–Schmidt norm equal $\|f\|^2 \|r\|^2$. Consequently

$$\boxed{\|T\|_{\text{op}}^2 = \|T\|_{\text{HS}}^2 = \varepsilon_\theta^2 + (\text{Im } \alpha)^2 + \|r\|^2 \|(I - U U^*) f\|^2.} \quad (\text{PSC.58})$$

In particular the projection term is present.

Let p_j be the actual monic orthogonal polynomials for the same original phase measure

$$d\nu_{L,\theta}(u) = \frac{2\pi}{L} \sum_{n \in \mathbb{Z}} m_{h,k}(u_n) \delta_{u_n}, \quad u_n = (2\pi n + \theta)/L, \quad S = k/2 + iu,$$

and let $\omega_j = \int |p_j(k/2 + iu)|^2 d\nu_{L,\theta}(u) > 0$. The range of U is precisely $W_{q-1,\theta}P_{q-1}$, since $C = J_{q-1}^{-1}$ is an isomorphism. Both χ and p_q are monic of degree q , so $\chi - p_q \in P_{q-1}$, while $W_{q,\theta}p_q$ is orthogonal to that range. It follows that

$$(I - UU^*)f = W_{q,\theta}p_q, \quad \|(I - UU^*)f\|^2 = \omega_q. \quad (\text{PSC.59})$$

On the orthogonal basis $p_0, \dots, p_{q-1}$ of P_{q-1} , the functional ℓ is zero on p_j for $j < q-1$ and equals one on p_{q-1} . Its squared dual norm is therefore exactly $1/\omega_{q-1}$. The identification with the phase quotient is the isometry $C : (E, G_0) \rightarrow (P_{q-1}, M_{q-1,\theta})$. Thus

$$\|r\|^2 = \ell G_0^{-1} \ell^* = \frac{1}{\omega_{q-1}}, \quad \|T\|_{\text{op}}^2 = \|T\|_{\text{HS}}^2 = \varepsilon_\theta^2 + (\text{Im } \alpha)^2 + \frac{\omega_q}{\omega_{q-1}} > \varepsilon_\theta^2 \geq \mathcal{L}_{h,k}^2. \quad (\text{PSC.60})$$

This is a strictly stronger first-cutoff floor, using the original monic source moments and preserving their mass.

135.16.2 A full-jet eigenvector and its exact arithmetic boundary ratio

Let λ be any root of χ of its complete order d_λ , and write

$$\psi_\lambda(S) = \frac{\chi(S)}{(S - \lambda)^{d_\lambda}}, \quad \psi_\lambda(\lambda) \neq 0, \quad v_\lambda = \left[\frac{\chi(S)}{(S - \lambda)\psi_\lambda(\lambda)} \right] \in E. \quad (\text{PSC.61})$$

The displayed representative has degree $q-1$. It satisfies $(A - \lambda I_E)v_\lambda = 0$, since multiplication by $S - \lambda$ produces the multiple $\chi/\psi_\lambda(\lambda)$. At the full local factor $\mathbb{C}[\epsilon]/(\epsilon^{d_\lambda})$, its value is

$$\epsilon^{d_\lambda-1} \frac{\psi_\lambda(\lambda + \epsilon)}{\psi_\lambda(\lambda)} = \epsilon^{d_\lambda-1}.$$

At every other full primary factor its value is zero. Thus this is a specified nonzero vector in the full original jet algebra, with every local order retained. Its leading coefficient is

$$\ell(v_\lambda) = \frac{1}{\psi_\lambda(\lambda)}. \quad (\text{PSC.62})$$

The exact two squared norms before any cancellation of a coefficient are

$$\begin{aligned} \|\mathcal{B}_\theta^p v_\lambda\|^2 &= \frac{1}{|\psi_\lambda(\lambda)|^2} \int |\chi(k/2 + iu)|^2 d\nu_{L,\theta}(u), \\ \|Rv_\lambda\|^2 &= \frac{1}{|\psi_\lambda(\lambda)|^2} \int \left| \frac{\chi(k/2 + iu)}{k/2 + iu - \lambda} \right|^2 d\nu_{L,\theta}(u). \end{aligned} \quad (\text{PSC.63})$$

The quotient inside the second integral is the polynomial $\chi(S)/(S - \lambda)$, including at any sampled root. In particular no singular point is omitted. The denominator is strictly positive by the infinite positive lattice argument used in (PSC.54).

For the extreme complete primary factor $\lambda = k/2 + k\delta + ik\gamma$, with $d_\lambda = \ell_k$, division of the two equations in (PSC.63) gives the exact identity

$$\frac{\|\mathcal{B}_\theta^p v_\lambda\|^2}{\|Rv_\lambda\|^2} = k^2 \delta^2 + \frac{\int (u - k\gamma)^2 \left| \frac{\chi(k/2 + iu)}{k/2 + iu - \lambda} \right|^2 d\nu_{L,\theta}(u)}{\int \left| \frac{\chi(k/2 + iu)}{k/2 + iu - \lambda} \right|^2 d\nu_{L,\theta}(u)} > k^2 \delta^2. \quad (\text{PSC.64})$$

Indeed on the original sampled line, $|k/2 + iu - \lambda|^2 = k^2 \delta^2 + (u - k\gamma)^2$. Multiplying this equality by $|\chi(k/2 + iu)/(k/2 + iu - \lambda)|^2$, integrating, and using (PSC.63) proves the formula. The last numerator is positive: at most one lattice point has $u = k\gamma$, and the nonzero polynomial in the integrand cannot vanish at all remaining infinitely many points. Both the nonzero factor $\psi_\lambda(\lambda)$ and the full arithmetic unit in (PSC.11) were retained in the actual vector and observation maps before the equality of ratios was calculated.

135.17 Split-base typing, provenance, and independent check

Each displayed linear coefficient map acts on a fixed original support label by

$$(\lambda, v) \mapsto (\lambda, fv), \quad \tau \mapsto \tau.$$

If $fv = 0$, the target is the represented zero at that label. For instance the full-jet observation of $\mathcal{V}(\chi Y)$ is zero by (PSC.11), although its source representative and norm remain in (PSC.22), (PSC.26), and (PSC.55). This is the original map to the receiving coefficient zero; it does not send represented data to external absence. Arithmetic scalars remain under $G(\mathbb{Z}) \rightarrow G(\mathbb{C})$, the marked $a = 0$ coefficient remains fixed, and neither the phase θ nor the length L translates A , g , or χ .

135.18 The actual match to the amplification calculation

The amplified nonzero arithmetic class is supplied by (PAM.3)–(PAM.5), with eigenvalue $k\rho$. The phase Hilbert space supplies a precisely critical-line generator, by (PAM.8). The exact map between them is (PAM.9)–(PAM.11), and on the amplified primary factor its full inverse relation is (PAM.15). The real displacement is $k\delta$; the actual comparison error on its eigenvector is the explicitly computed norm (PAM.12), at least $k\delta$. The available canonical global controls grow at least as the functions in (PAM.18)–(PAM.23), and the class-preserving repairs preserve this generator obstruction by (PAM.25)–(PAM.27). Consequently none of these proved holonomy or repaired-source estimates is an exclusion of the amplified class with error $o(k)$. They give the explicit positive boundary energies and exact maps displayed above. These calculations do not assert that a new opposing estimate is impossible, or that an off-line zeta packet exists.

136 The actual arithmetic amplification and its proved error scales

This calculation uses one fixed original counterfactual anchor $\rho = 1/2 + \delta + i\gamma$, of full order m in $g = 2\xi$, with $0 < \delta < 1/2$ and $\gamma > 0$. Its entire quotient and full Taylor unit are retained throughout:

$$h(s) = \prod_{\epsilon, \eta \in \{-1, 1\}} (s - 1/2 - \epsilon\delta - i\eta\gamma)^m, \quad v_h = g/h, \quad v_h = j_h(v_h), \quad w_h(u) = \frac{|v_h(1/2 + iu)|^2}{2\pi}. \quad (\text{AAM.1})$$

The original tensor source, its arithmetic injection and the finite source degrees provide the following simultaneous data for every integer $k \geq 3$:

$$\begin{aligned} c &= k/2, \quad \ell_k = 1 + k(m-1), \quad q_k = \ell_k(k+1)^2, \quad f_k = \left\lfloor \frac{(k+1)^2}{4} \right\rfloor, \\ \lambda_{a,b} &= c + (2a-k)\delta + i(2b-k)\gamma \quad (0 \leq a, b \leq k), \\ \chi_k(S) &= \prod_{a,b=0}^k (S - \lambda_{a,b})^{\ell_k}, \quad E_k = \mathbb{C}[S]/(\chi_k), \quad A_k^{\text{cyc}} = M_S, \\ m_{h,k} &= w_h^{*k}, \quad \mathcal{I}_k = \sigma_h^{\otimes k} \eta_{h,k} : E_k \hookrightarrow Q^{\otimes k}, \quad \eta_{h,k}[P] = v_h^{\otimes k} P(A_h^{(k)})1. \end{aligned} \quad (\text{AAM.2})$$

The superscript on A_k^{cyc} distinguishes this operator from the scalar upper-envelope constant A_k used in (TW8). No coordinate or operator has been multiplied by this scalar. The full local nilpotent sum has exact index ℓ_k : its power $k(m-1)$ has coefficient $(k(m-1))!/((m-1)!)^k \neq 0$ on the product of the k top local monomials, whereas the next power is zero. Every real and imaginary sign count occurs in the ordered tensor product, and $\delta\gamma \neq 0$ makes the displayed sums distinct. Thus the stated complete cyclic annihilator and its dimension are exactly those in (HT2), with no local directions omitted.

For $N \geq q_k - 1$, the original exact sequence is

$$0 \longrightarrow \mathcal{P}_{N-q_k} \xrightarrow{\times \chi_k} \mathcal{P}_N \xrightarrow{J_{k,N}} E_k \longrightarrow 0, \quad \mathcal{P}_N = \mathbb{C}[S]_{\leq N}. \quad (\text{AAM.3})$$

The source norm is the integral of $|P(c + iu)|^2 m_{h,k}(u)$. The relation source is zero when $N = q_k - 1$. The unique canonical minimum lift $R_{k,N} : E_k \rightarrow \mathcal{P}_N$ satisfies $J_{k,N} R_{k,N} = I$ and $R_{k,N}^* H_{k,N} R_{k,N} = G_{k,N} > 0$, in the original remainder frame, and $V_{k,N} = \det G_{k,N}$. These facts follow by orthogonal projection onto the kernel in the finite positive-definite source form, as proved in (CA6).

136.1 The invariant that the tensor construction amplifies

A nonzero eigenvector v of A_h at ρ has nonzero ordered tensor power: a linear functional taking v to one takes $v^{\otimes k}$ to one. The sum generator acts on that tensor by $k\rho$, whose real displacement from c is exactly $k\delta$. The complete positive-half-plane trace uses all primary spaces, not only this vector. Its original value is

$$\mathcal{L}_k = 2\delta \ell_k(k+1)f_k = 2 \sum_{a > k/2} \sum_{b=0}^k \ell_k(2a-k)\delta. \quad (\text{AAM.4})$$

To evaluate the sum, for $k = 2r$ its positive real coefficients sum to $2(1 + \dots + r) = r(r+1)$; for $k = 2r-1$ they sum to $1 + 3 + \dots + (2r-1) = r^2$. These are exactly f_k . In particular the following are exact finite equalities:

$$\frac{\mathcal{L}_k}{kq_k} = \begin{cases} \frac{\delta}{2}(1 + 1/k), & k \text{ odd}, \\ \frac{\delta}{2}(1 + 1/(k+1)), & k \text{ even}, \end{cases} \quad \mathcal{L}_k \geq \frac{\delta k q_k}{2}, \quad \frac{\mathcal{L}_k}{kq_k} \longrightarrow \frac{\delta}{2}. \quad (\text{AAM.5})$$

Here is the exact finite control to which that trace applies. Suppress k in the subscripts while keeping it fixed, and put $A = A_k^{\text{cyc}}$. The Hermitian matrix in the original quotient metric is

$$\mathbf{H}_N = G_N^{-1/2} (A^* G_N + G_N A - k G_N) G_N^{-1/2}. \quad (\text{AAM.6})$$

Write p_n for the original monic orthogonal polynomials and ω_n for their squared norms, and $b_n = [p_n]_{\chi_k}$. The monic recurrence in the exact sum coordinate is $S p_n = p_{n+1} + (c + i\beta_n)p_n - (\omega_n/\omega_{n-1})p_{n-1}$ with real β_n . Inserting it in $K_N = \sum_{n=0}^N b_n b_n^*/\omega_n$ cancels every internal adjacent term and gives

$$A K_N + K_N A^* - k K_N = \frac{b_{N+1} b_N^* + b_N b_{N+1}^*}{\omega_N}, \quad K_N = G_N^{-1}. \quad (\text{AAM.7})$$

Congruence by $G_N^{1/2}$ identifies its left side with (AAM.6). It has rank at most two. Its trace is $2\Re \text{Tr } A - kq_k = 0$ by the complete root grid. It therefore has eigenvalues $\varepsilon_{k,N}$, $-\varepsilon_{k,N}$ and zeros, with $\varepsilon_{k,N} \geq 0$.

Let E_+ be the direct sum of the complete primary spaces with $a > k/2$, and let P_+ be the orthogonal projection onto $G_N^{1/2} E_+$ in the displayed Euclidean coordinates. This subspace is invariant under $G_N^{1/2} A G_N^{-1/2}$. Taking the trace in an orthonormal basis of that invariant subspace gives $\text{Tr}(P_+ \mathbf{H}_N) = \mathcal{L}_k$. For a Hermitian matrix with spectrum $\varepsilon, -\varepsilon, 0, \dots, 0$, any orthogonal projection has trace pairing at most ε : its diagonal coefficients in an eigenbasis lie between zero and one. Thus

$$\boxed{\varepsilon_{k,N} = \|\mathbf{H}_N\| \geq \mathcal{L}_k, \quad \frac{\varepsilon_{k,N}}{kq_k} \geq \frac{\mathcal{L}_k}{kq_k} \geq \frac{\delta}{2}.} \quad (\text{AAM.8})$$

This is the common normalized invariant at every admitted source degree. It is also the phasewise invariant in (HT9), with the phase metric retained there. Neither a source norm nor an unnormalized matrix can be substituted into the numerator of (AAM.8).

136.2 The exact original window map into that control

In this subsection $q = q_k$, and every measure is the unperiodized original $m_{h,k}$. Define the original four-volume and norm term

$$\mathcal{B}_k = \log \frac{V_{q-1}V_q}{V_{2q-1}V_{2q}}, \quad \Omega_k = \log \frac{\omega_{2q-1}\omega_{2q}}{\omega_{q-1}\omega_q}. \quad (\text{AAM.9})$$

Retain $d_j = V_j/V_{j-1}$ and the complete contraction penalties

$$P_- = -\log(1 - d_{2q-1}) - 2 \sum_{j=q}^{2q-2} \log(1 - d_j), \quad (\text{AAM.10})$$

$$P_+ = -\log(1 - d_q) - \log(1 - d_{2q}) - 2 \sum_{j=q+1}^{2q-1} \log(1 - d_j), \quad P_k = P_- + P_+.$$

Here $0 < d_j < 1$ on these degrees by the original consecutive identities and the positive trace floor. The phase is the original real number ϕ_N specified by $b_N^* G_N b_{N+1} = i\omega_N \phi_N$. Let $w_{q-1} = w_{2q-1} = 1$ and $w_N = 2$ for the intervening degrees; their sum is $2q$. The original first-step and regular products (CJ.9)–(CJ.13) prove exactly

$$\mathcal{B}_k = \sum_{N=q-1}^{2q-1} w_N \log(\varepsilon_{k,N}^2 + \phi_N^2) - \Omega_k + P_k. \quad (\text{AAM.11})$$

There is no inverse at degree $q - 2$: the first product has one terminal contraction and the squared interior contractions displayed in P_- .

The following quantities extract the same control from that identity, retaining its entire phase and contraction data:

$$\Phi_k = \sum_N w_N \log(1 + \phi_N^2/\varepsilon_{k,N}^2) \geq 0, \quad \bar{\varepsilon}_k = \prod_N \varepsilon_{k,N}^{w_N/(2q)}, \quad (\text{AAM.12})$$

$$\mathbf{n}_k = e^{\Omega_k/(4q)}, \quad \mathbf{c}_k = e^{(\mathcal{B}_k - P_k - \Phi_k)/(4q)}.$$

Every denominator is positive by (AAM.8). Splitting each logarithm in (AAM.11) proves the exact multiplicative correspondence

$$\boxed{\bar{\varepsilon}_k = \mathbf{n}_k \mathbf{c}_k, \quad \mathcal{L}_k \leq \min_{q-1 \leq N \leq 2q-1} \varepsilon_{k,N} \leq \bar{\varepsilon}_k.} \quad (\text{AAM.13})$$

In particular the exact scalar exclusion threshold for the given window is

$$\mathcal{B}_k^{\text{crit}} = 4q \log \mathcal{L}_k - \Omega_k, \quad \mathcal{B}_k - \mathcal{B}_k^{\text{crit}} = P_k + \sum_N w_N \log \frac{\varepsilon_{k,N}^2 + \phi_N^2}{\mathcal{L}_k^2} \geq 0. \quad (\text{AAM.14})$$

More precisely, $\mathcal{B}_k - P_k - \Phi_k \geq \mathcal{B}_k^{\text{crit}}$. This follows from (AAM.13), so it retains rather than deletes the actual phases.

136.3 Uniform norm errors and their precise amplified rates

We use the literal constants already proved in (TW2), (TW7)–(TW8):

$$\alpha = \pi/2, \quad p = 8m - 9/2, \quad B = 42 + 8m, \quad M = B/2,$$

$$\vartheta_h = \int_{-1}^1 w_h(u) du, \quad M_\alpha = \int_{\mathbb{R}} e^{\alpha u} w_h(u) du,$$

$$a_k = \frac{c_h \vartheta_h^{k-3} e^{-\alpha(k-3)} (k-2)^{-B}}{C_\Gamma 2^M}, \quad A_k = \frac{C_h}{c_\Gamma} k^{p+1} M_\alpha^{k-1}, \quad (\text{AAM.15})$$

$$D_N = [1 + 4(N + M)^2]^M, \quad c_\Gamma = \sqrt{2}e^{-7/6}, \quad C_\Gamma = \sqrt{2\sqrt{5}}e^{2/3}.$$

Here C_h is the full boundary-tilt constant of (BT12), and c_h is the original positive convolution lower-envelope constant of (AU.10). Their original constructions, compact contributions and full masses remain in the retained chapters. No new zeta bound is assumed in using them. The proved all-polynomial estimate is $a_k H_N^\sigma / D_N \preceq H_{k,N} \preceq A_k H_N^\sigma$, where $\sigma(u) = |\Gamma(1/4 + iu/2)|^2 / (2\pi)$ has its original mass $\sqrt{2\pi}$. Minimizing on monic affine fibres gives $a_k \gamma_n / D_n \leq \omega_n \leq A_k \gamma_n$, with $\gamma_n = \sqrt{2\pi}(2n)!/4^n$.

Define the exact nonnegative norm-window error and common-source comparison error by

$$\mathcal{E}_k = 2 \log(A_k/a_k) + \log D_{q-1} + \log D_q, \quad \Lambda_k = \log(A_k/a_k) + \log D_{2q}. \quad (\text{AAM.16})$$

The symbol $\mathcal{E}_k$ here denotes exactly E_k in (TW20), and is distinct from the quotient vector space E_k in (AAM.2). The two original norm windows (TW16)–(TW19) imply

$$\mathfrak{n}_k/q \longrightarrow 4/e, \quad \Omega_k \leq 4q \log(4q/e) + \mathcal{E}_k, \quad \mathcal{E}_k/q \longrightarrow 0. \quad (\text{AAM.17})$$

For completeness the first claim uses the separate limits $q^{-1}(\omega_{2q}/\omega_q)^{1/(2q)} \rightarrow 4/e$ and $q^{-1}(\omega_{2q-1}/\omega_{q-1})^{1/(2q)} \rightarrow 4/e$; their positive geometric mean is exactly $\mathfrak{n}_k/q$. The upper logarithmic estimate is the sum of the two original upper norm comparisons and the exact factorial inequality (TW18).

The exponential dependence of the scalar constants can be calculated more precisely than a big-O estimate. Put

$$d_h = \alpha + \log(M_\alpha/\vartheta_h). \quad (\text{AAM.18})$$

The actual w_h is even and positive almost everywhere, so $M_\alpha = \int \cosh(\alpha u) w_h(u) du > \vartheta_h$: the integral outside $[-1, 1]$ is strictly positive and on that interval $\cosh(\alpha u) \geq 1$. Hence $d_h > \alpha > 0$. Taking logarithms of (AAM.15) gives the exact identity

$$\begin{aligned} \log(A_k/a_k) &= (k-1) \log M_\alpha - (k-3) \log \vartheta_h + \alpha(k-3) + (p+1) \log k + B \log(k-2) \\ &+ \log \frac{C_h C_\Gamma 2^M}{c_\Gamma c_h} = k d_h + (p+1+B) \log k + O_h(1). \end{aligned} \quad (\text{AAM.19})$$

The last remainder is bounded because $\log(k-2) - \log k = \log(1-2/k)$ is bounded for $k \geq 3$. Since $(k+1)^2 \leq q_k \leq mk(k+1)^2$ and $\log D_{2q} = O_h(\log q)$, these equalities prove

$$\frac{\Lambda_k}{k} \longrightarrow d_h, \quad \frac{\mathcal{E}_k}{k} \longrightarrow 2d_h, \quad \frac{\mathcal{E}_k}{\mathcal{L}_k} \longrightarrow 0, \quad \frac{(2q_k-1)\Lambda_k}{\mathcal{L}_k} \longrightarrow \frac{4d_h}{\delta} > 0. \quad (\text{AAM.20})$$

Thus the small norm error and the four-volume comparison error have different rates on the original amplified scale, with their exact dimension factors displayed.

Equations (AAM.5), (AAM.13), and (AAM.17) now give the particularly direct quantitative correspondence

$$\frac{\mathfrak{n}_k}{\mathcal{L}_k} \sim \frac{8}{e\delta k} \longrightarrow 0, \quad \mathfrak{c}_k \geq \frac{\mathcal{L}_k}{\mathfrak{n}_k}, \quad \liminf_{k \rightarrow \infty} \frac{\mathfrak{c}_k}{k} \geq \frac{e\delta}{8}. \quad (\text{AAM.21})$$

The vanishing first ratio is therefore not an upper estimate on $\bar{\varepsilon}_k/\mathcal{L}_k$. The exact second factor in the original source identity has at least the stated compensating growth. This proves the relationship between the small norm-window factor and the retained arithmetic control, instead of merely declaring them to be different quantities.

The exact threshold itself has the computed asymptotic

$$\frac{\mathcal{B}_k^{\text{crit}}}{q_k} - 4 \log k \longrightarrow 4 \log(e\delta/8), \quad \frac{\mathcal{B}_k^{\text{crit}}}{\mathcal{L}_k} \longrightarrow 0. \quad (\text{AAM.22})$$

Indeed $\mathcal{B}_k^{\text{crit}}/(4q) = \log(\mathcal{L}_k/\mathfrak{n}_k)$ and (AAM.21) evaluates this logarithm. The actual finite lower estimate in (CA20) follows as well:

$$\mathcal{B}_k \geq 4q_k \log(\delta e k/8) - \mathcal{E}_k. \quad (\text{AAM.23})$$

All further contraction, phase, control and trace savings in (TW20) remain nonnegative. Its final trace ratio is exactly $2\mathcal{L}_k/(\delta k q_k) = 1 + 1/k$ for odd k and $1 + 1/(k+1)$ for even k , by (AAM.5).

136.4 The available upper functions on the identical window

The full finite reference number $\mathcal{B}_k^\sigma$ is evaluated with the original χ_k by (CA18)–(CA19); in particular it is nonnegative. On the common degree- $2q$ source let $D_* = (H_{2q}^\sigma)^{-1} H_{k,2q}$ have ordered positive eigenvalues $b_1 \leq \dots \leq b_{2q+1}$ and put

$$\begin{aligned} L_q(D_*) &= \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}, \\ \widehat{\Phi}_q(B) &= 2 \operatorname{arcosh}(e^{B/(4q-2)}), \quad \widehat{\Psi}_q(t) = (4q-2) \log \cosh(t/2), \\ \widehat{A}_\sigma &= \widehat{\Phi}_q(\mathcal{B}_k^\sigma), \quad U_k^{\operatorname{spec}} = \mathcal{B}_k^\sigma + L_q(D_*), \quad U_k^{\operatorname{ang}} = \widehat{\Psi}_q(\widehat{A}_\sigma + \Lambda_k). \end{aligned} \tag{AAM.24}$$

These are the actual full-spectrum and angle bounds proved in (CA14), (CA17b). They give $\mathcal{B}_k \leq \min(U_k^{\operatorname{spec}}, U_k^{\operatorname{ang}})$ and $L_q(D_*) \leq (2q-1)\Lambda_k$. The full spectrum in $L_q(D_*)$ is retained; its value has not been replaced by the scalar envelope when taking the first minimum.

The precise asymptotic cost of the displayed angle upper function can be calculated even without an asymptotic for $\mathcal{B}_k^\sigma$ at the moving endpoints. For $t, x \geq 0$,

$$\frac{e^x}{2} \leq \frac{\cosh(t+x)}{\cosh t} \leq e^x.$$

The upper inequality follows by expanding both hyperbolic cosines into exponentials; the lower follows from $\cosh(t+x) \geq e^{t+x}/2$ and $\cosh t \leq e^t$. Use $t = \widehat{A}_\sigma/2$ and $x = \Lambda_k/2$, and use the inverse relation between $\widehat{\Phi}_q$ and $\widehat{\Psi}_q$. It gives

$$\begin{aligned} (2q-1)\Lambda_k - (4q-2) \log 2 &\leq U_k^{\operatorname{ang}} - \mathcal{B}_k^\sigma \leq (2q-1)\Lambda_k, \\ \frac{U_k^{\operatorname{ang}} - \mathcal{B}_k^\sigma}{\mathcal{L}_k} &\longrightarrow \frac{4d_h}{\delta}. \end{aligned} \tag{AAM.25}$$

The discarded constant term divided by $\mathcal{L}_k$ tends to zero by (AAM.5). This is a statement about the proved upper function; it is not an asymptotic assertion about the signed actual difference.

For an independent upper function retain exactly the original (HC8) constants. Set $R_0 = \sqrt{\delta^2 + \gamma^2}$, choose the original $0 < b < \pi/2$, and put

$$D = \max(1, 2/b, 2R_0), \quad a = \alpha D + \log 256, \quad X = \max(1, M_h(b), M_h(-b)), \quad K = \max(1, \vartheta_h^{-1}),$$

$$C_{\operatorname{env}} = \max(1, 2/(3c_h D)), \quad M_h(t) = \int e^{tu} w_h(u) du,$$

$$\widehat{\mathcal{U}}_k = 2aq^2 + 2 \left(\log(XK) + \alpha + \frac{16R_0}{3D} \right) kq + 2Bq \log(1 + (D+1)q) + 2q \log C_{\operatorname{env}} + q \log 20. \tag{AAM.26}$$

All these constants are fixed by the original anchor, and the retained proof gives $\mathcal{B}_k \leq \widehat{\mathcal{U}}_k$. Since $k/q \rightarrow 0$ and $\log q/q \rightarrow 0$, direct division yields

$$\frac{\widehat{\mathcal{U}}_k}{q_k^2} \longrightarrow 2a, \quad \frac{\widehat{\mathcal{U}}_k}{\mathcal{L}_k} \sim \frac{4a}{\delta} \frac{q_k}{k} \longrightarrow \infty. \tag{AAM.27}$$

Combine these proved bounds on the identical actual scalar by defining

$$U_k^{\operatorname{all}} = \min\{\widehat{\mathcal{U}}_k, U_k^{\operatorname{spec}}, U_k^{\operatorname{ang}}\}. \tag{AAM.28}$$

The following are exact finite comparisons, obtained by substituting $\mathcal{B}_k \leq U_k^{\operatorname{all}}$ into (AAM.12)–

(AAM.14):

$$\begin{aligned}
1 \leq \frac{\bar{\varepsilon}_k}{\mathcal{L}_k} &\leq \exp\left(\frac{U_k^{\text{all}} - \mathcal{B}_k^{\text{crit}} - P_k - \Phi_k}{4q_k}\right) \\
&\leq \frac{4q_k}{e\mathcal{L}_k} \exp\left(\frac{U_k^{\text{all}} + \mathcal{E}_k}{4q_k}\right), \\
1 \leq \frac{\varepsilon_{k,N}}{\mathcal{L}_k} &\leq \exp\left(\frac{U_k^{\text{all}} - \mathcal{B}_k^{\text{crit}} - P_k}{2w_N}\right) \quad (q_k - 1 \leq N \leq 2q_k - 1).
\end{aligned} \tag{AAM.29}$$

For the individual bound, isolate its one term in the nonnegative sum in (AAM.14), and use $\log((\varepsilon_{k,N}^2 + \phi_N^2)/\mathcal{L}_k^2) \geq 2\log(\varepsilon_{k,N}/\mathcal{L}_k)$. These formulas retain every known finite input. They do not supply an upper ratio below one: their exponent with the actual data is nonnegative by (AAM.14). The coarser scalar function $\hat{\mathcal{U}}_k$ gives

$$\frac{\hat{\mathcal{U}}_k - \mathcal{B}_k^{\text{crit}}}{4q_k} = \frac{a}{2}q_k + O_h(k + \log q_k), \tag{AAM.30}$$

which follows from (AAM.22) and (AAM.26), and grows without bound. The angle upper function has the strictly positive $\mathcal{L}_k$ -scale overhead (AAM.25). The full-spectrum expression U_k^{spec} remains the explicitly defined original finite matrix calculation in (AAM.24); none of (CA)–(TW) evaluates its moving- k spectrum by a smaller scalar error. In particular the proved subquadratic comparison $(\mathcal{B}_k - \mathcal{B}_k^\sigma)/q_k^2 \rightarrow 0$ does not give a sublinear upper bound for the normalized control (AAM.8).

136.5 What the fixed-packet degree limit preserves

For each fixed k , the full-jet theorem (FPK.23)–(FPK.29) and the actual comparison (LC.26)–(LC.28) give the exact leading coefficient

$$\begin{aligned}
\lim_{N \rightarrow \infty} \frac{\log V_{k,N}^{\text{ar}}}{\log N} &= -\mathcal{L}_k, \quad \log V_{k,N}^\sigma = -\mathcal{L}_k \log N - \mathcal{B}_{\chi_k} \log \log N + C_{\sigma,k} + o(1), \\
\log V_{k,N}^\Gamma &= -\mathcal{L}_k \log N - \mathcal{B}_{\chi_k} \log \log N + C_{\Gamma,k} + o(1), \\
\mathcal{B}_{\chi_k} &= \begin{cases} (k+1)\ell_k^2, & k \text{ even}, \\ 0, & k \text{ odd}. \end{cases}
\end{aligned} \tag{AAM.31}$$

The original tensor-Gamma reference in the third line has mass $(2\pi)^{k/2}$; its full constant $C_{\Gamma,k}$ is the one in (FPK.29). The fixed comparison in the second line has mass $\sqrt{2\pi}$. The original remainder and full unit maps are the same for these statements. Thus, for $r_{k,N} = V_{k,N}^{\text{ar}}/V_{k,N}^\Gamma$,

$$\frac{\log r_{k,N}}{\log N} \rightarrow 0. \tag{AAM.32}$$

Equivalently, for every positive ϵ and this fixed k , all sufficiently large N satisfy $N^{-\epsilon} \leq r_{k,N} \leq N^\epsilon$. The threshold here depends on the complete fixed k -packet, and is not specified by the moving endpoints $q_k, 2q_k$.

There are useful exact consequences without exchanging limits. For fixed $t > 1$, (AAM.31) proves

$$\frac{V_{k,N}^\sigma}{V_{k,[tN]}^\sigma} \rightarrow t^{\mathcal{L}_k}, \quad \frac{V_{k,N}^\Gamma}{V_{k,[tN]}^\Gamma} \rightarrow t^{\mathcal{L}_k}, \quad \frac{\log(V_{k,N}^{\text{ar}}/V_{k,[tN]}^{\text{ar}})}{\log N} \rightarrow 0. \tag{AAM.33}$$

The first two assertions follow by subtraction of their complete asymptotics: the constants cancel, the logarithmic ratios tend to $\log t$, the log log differences tend to zero, and both remainders tend to zero. For the third, divide each of the two actual logarithms by its own degree logarithm and use

$\log \lfloor tN \rfloor / \log N \rightarrow 1$. It does not prove that the actual ratio tends to $t^{\mathcal{L}_k}$. For a fixed power $t > 1$ the same argument with $\lfloor N^t \rfloor$ instead gives the nonzero actual exponent

$$\frac{\log(V_{k,N}^{\text{ar}}/V_{k,\lfloor N^t \rfloor}^{\text{ar}})}{\log N} \rightarrow (t-1)\mathcal{L}_k. \quad (\text{AAM.34})$$

These are degree limits on a fixed original quotient; neither proof substitutes a growing k into a fixed- k error term.

Finally the full operator result of the Hilbert-completion chapter is $\|G_{k,N}^{\text{ar}}\| \rightarrow 0$ for each fixed k , while $\mathcal{O}_{k,N}R_{k,N} = \mathcal{I}_k \neq 0$. Its exact effect on the control matrix can be computed. Put $W_{k,N} = A^*G_{k,N} + G_{k,N}A - kG_{k,N}$. Then

$$\|W_{k,N}\| \leq 2\|A - cI\| \|G_{k,N}\| \rightarrow 0, \quad G_{k,N}^{-1/2}W_{k,N}G_{k,N}^{-1/2} = H_N, \quad \|H_N\| \geq \mathcal{L}_k. \quad (\text{AAM.35})$$

The first inequality expands $W = (A - cI)^*G + G(A - cI)$ and applies submultiplicativity in the original fixed frame. The second is its literal congruence (AAM.6). There is no bounded inverse factor in that congruence: $G_{k,N} \rightarrow 0$ forces $\|G_{k,N}^{-1/2}\| \rightarrow \infty$. In the actual source norm the normalized lift remains exactly isometric:

$$(R_{k,N}G_{k,N}^{-1/2})^*H_{k,N}(R_{k,N}G_{k,N}^{-1/2}) = I_{E_k}, \quad \|R_{k,N}G_{k,N}^{-1/2}\| = 1, \quad \|R_{k,N}G_{k,N}^{-1/2}\|_{\text{HS}}^2 = q_k. \quad (\text{AAM.36})$$

This is direct substitution of $R_{k,N}^*H_{k,N}R_{k,N} = G_{k,N}$. Thus the original vanishing representatives, their nonzero arithmetic classes, and the amplified normalized boundary are connected by the explicit maps (AAM.35)–(AAM.36). Their Hilbert reduction is the proved quotient map killing the dense relation space; it is not an exclusion of the nonzero original tensor class.

In Deligne’s paragraph 7.3 the tensor eigenvalue and the proved exclusion band belong to the same amplified object, and its exponent error stays constant while the displacement grows. In the present original arithmetic data the corresponding displacement survives as $k\delta$ and the full trace as $\mathcal{L}_k$. The exact upper comparisons currently proved here are (AAM.24)–(AAM.30) on the window scalar and (AAM.29) on its normalized boundary. Their rates are calculated above: the small norm-window factor is paired with the forced growing quotient factor (AAM.21), the scalar comparison overhead has the positive amplified rate (AAM.20), (AAM.25), and the fixed-packet Gram limit retains the normalizing inverses (AAM.35). These statements prove the exact arithmetic match of the available elements; they do not insert Deligne’s finite-field exclusion theorem into the original source.

137 Deligne’s final amplification: the exact contradiction

The particular argument requested here is in Pierre Deligne, *La conjecture de Weil I* (1974), Lemma 7.1 and paragraph 7.3, printed pages 298 and 301. It is not a quotation from *Weil II* (1980). The [original paper](#) is the primary source; the [English translation](#) was checked against it. The source input is the proved estimate below and the Frobenius-equivariant Künneth isomorphism. The subsequent calculation spells out their contradiction mechanism.

137.1 The proved bound being reused

Let $q > 1$ be the cardinality of the finite base field and let ℓ be a prime different from its characteristic. For a smooth, projective, geometrically irreducible variety $Y_0/\mathbb{F}_q$ of **even** dimension D , put $Y = Y_0 \times_{\mathbb{F}_q} \overline{\mathbb{F}_q}$. Deligne’s Lemma 7.1 establishes that each eigenvalue β of geometric Frobenius on $H^D(Y, \mathbb{Q}_\ell)$ is algebraic and that every complex conjugate satisfies

$$q^{D/2-1/2} \leq |\beta| \leq q^{D/2+1/2}. \quad (\text{DA1})$$

This already excludes everything outside a band of width one in the exponent. The additive error $1/2$ is the same for every such variety and every even dimension. There is no unrecorded constant depending on its Betti numbers in (DA1).

137.2 Constructing the object to which the earlier exclusion applies

Take a smooth, projective, geometrically irreducible $X_0/\mathbb{F}_q$ of dimension d . Let X be its geometric base change and F_X^* its geometric Frobenius action. Take an eigenvalue α in the middle group $H^d(X, \mathbb{Q}_\ell)$, and an eigenvector $v \neq 0$ after extending coefficients to $\overline{\mathbb{Q}_\ell}$.

For every positive even integer k , form the actual product variety

$$X_0^k = \underbrace{X_0 \times_{\mathbb{F}_q} \cdots \times_{\mathbb{F}_q} X_0}_{k \text{ factors}}.$$

It is again smooth, projective and geometrically irreducible. Its dimension is kd , which is even. The field cardinality stays q . The Frobenius-equivariant Künneth map has the precise form

$$\bigoplus_{i_1 + \cdots + i_k = kd} \bigotimes_{j=1}^k H^{i_j}(X, \overline{\mathbb{Q}_\ell}) \xrightarrow{\sim} H^{kd}(X^k, \overline{\mathbb{Q}_\ell}),$$

$$x_1 \otimes \cdots \otimes x_k \mapsto \text{pr}_1^* x_1 \smile \cdots \smile \text{pr}_k^* x_k. \quad (\text{DA2})$$

In particular, the summand with $i_1 = \cdots = i_k = d$ injects into the middle cohomology of the product. The tensor $v^{\otimes k}$ is nonzero: choose a linear functional λ with $\lambda(v) = 1$; then $\lambda^{\otimes k}(v^{\otimes k}) = 1$. It stays nonzero under the isomorphism (DA2). Frobenius acts on it by

$$(F_X^*)^{\otimes k} v^{\otimes k} = (\alpha v) \otimes \cdots \otimes (\alpha v) = \alpha^k v^{\otimes k}. \quad (\text{DA3})$$

Thus the construction retains the offending eigenvalue as α^k in exactly the cohomological degree covered by (DA1). No semisimplicity assertion is needed. Nor is a symmetric or exterior quotient taken: even when d is odd, the external tensor of v with itself in different factors survives.

Algebraicity is not an extra assumption: applying (DA1) to X_0^2 shows α^2 is algebraic; then α is algebraic over the algebraic extension containing α^2 . Every complex embedding of $\mathbb{Q}(\alpha)$ restricts to one on $\mathbb{Q}(\alpha^k)$, so the following inequalities hold for each fixed complex conjugate of α .

137.3 Apply the earlier bound to the newly constructed product

Substitute $Y_0 = X_0^k$, $D = kd$ and $\beta = \alpha^k$ into (DA1):

$$q^{kd/2-1/2} \leq |\alpha^k| \leq q^{kd/2+1/2}. \quad (\text{DA4})$$

Taking positive real k th roots, and using $|\alpha^k| = |\alpha|^k$, gives

$$q^{d/2-1/(2k)} \leq |\alpha| \leq q^{d/2+1/(2k)} \quad (k = 2, 4, 6, \dots). \quad (\text{DA5})$$

The expected exponent $kd/2$ and the actual exponent of $|\alpha|^k$ both scale by k . The already-proved error remains $1/2$. This is precisely why its contribution after taking the root is $1/(2k)$.

137.4 The finite contradiction, without relying on informal limiting language

For a fixed complex conjugate define

$$\varepsilon = \log_q |\alpha| - \frac{d}{2}.$$

Suppose $\varepsilon \neq 0$. Choose the explicit even positive integer

$$k = 2 \left(\left\lfloor \frac{1}{4|\varepsilon|} \right\rfloor + 1 \right). \quad (\text{DA6})$$

Then $k > 1/(2|\varepsilon|)$, hence $k|\varepsilon| > 1/2$.

If $\varepsilon > 0$, (DA3) supplies an actual eigenvalue with

$$|\alpha^k| = q^{kd/2+k\varepsilon} > q^{kd/2+1/2},$$

contradicting the upper bound in (DA4). If $\varepsilon < 0$, it supplies

$$|\alpha^k| = q^{kd/2-k|\varepsilon|} < q^{kd/2-1/2},$$

contradicting the lower bound in (DA4). Thus $\varepsilon = 0$ and

$$\boxed{|\alpha| = q^{d/2}}. \quad (\text{DA7})$$

An arbitrarily small fixed deviation is enough. A smaller deviation merely requires a larger finite product. The exact boundary $\varepsilon = 0$ is retained and satisfies every bound. This closes the middle-degree argument; the cited paper's paragraph 7.2 then uses weak Lefschetz, Poincaré duality, components and finite field extensions to cover the other degrees.

137.5 Why repeating a bound is not sufficient by itself

In exponent coordinates the entire product family is the intersection

$$\bigcap_{k \in 2\mathbb{N}_{>0}} \left[-\frac{1}{2k}, \frac{1}{2k} \right] = \{0\}. \quad (\text{DA8})$$

To prove the equality, zero belongs to every interval; a nonzero real number is excluded by the explicit k in (DA6). This is an exhaustive exclusion, not a computation for finitely many chosen dimensions.

Both quantitative and geometric ingredients are essential to the calculation. The same eigenclass maps to a nonzero tensor class; here the exclusion for the resulting class has error exactly $1/2$. With a nonnegative error e_k , the corresponding calculation would produce $|\varepsilon| \leq e_k/k$. The resulting intersection is the singleton zero exactly when $\inf_{k \in 2\mathbb{N}_{>0}} e_k/k = 0$. Sublinear error $e_k = o(k)$ is sufficient; convergence along every even integer is not necessary. If e_k were a fixed positive multiple of k , that calculation would leave a positive-width band. No such proportional error is present in (DA4).

Extending the base field alone gives a different calculation. Take d even so that (DA1) applies directly. Replacing $\mathbb{F}_q$ by $\mathbb{F}_{q^r}$ replaces α by α^r but leaves dimension d unchanged. The same weak bound would read

$$(q^r)^{d/2-1/2} \leq |\alpha|^r \leq (q^r)^{d/2+1/2}.$$

Its r th root is the original weak bound; the error does not shrink. The product construction keeps q fixed while increasing dimension and tensor exponent together.

137.6 The logical pattern recorded for the actual Split-Zero object

The pattern is: an offending class survives an exact amplification map; the amplified class belongs to a previously bounded object; its fixed nonzero displacement grows linearly with tensor degree; a proved exclusion has smaller growth; a finite tensor degree contradicts that exclusion.

In the actual programme the additive tensor generator is $A_h^{(k)} = \sum_j A_{h,j}$. A nonzero eigenvector with eigenvalue $\rho = 1/2 + \delta + i\gamma$ has nonzero tensor power with eigenvalue $k\rho$. Its real displacement from $k/2$ is exactly $k\delta$. This statement follows by applying each summand to the original tensor and by the same linear-functional test proving nonvanishing. The complete local nilpotent sum remains $\sum_j N_j$; on a full order- m block its top nonzero power is $k(m-1)$ with coefficient $(k(m-1))!/((m-1)!)^k$ on $\prod_j N_j^{m-1}$. Consequently no multiplicity is discarded in making this comparison.

Deligne's numerical bound is a theorem about his finite-field cohomology. It is not inserted into the Split-Zero tensor source as an assumption. The present construction keeps every already-calculated original arithmetic bound and its actual error term on the same amplified source. Their compatibility or contradiction must be calculated there. The finite contradiction (DA6) records exactly what a successful amplification/exclusion calculation accomplishes.

138 The matching passage in Weil II

The local S20 text identifies a second, particularly close match to the recollection about a bound involving a minus sign and two: *Weil II*, Lemma 1.8.1, its formulas 1.8.1.1–1.8.1.2, and the explicit return to Corollary 1.4.3. The controlling text is [current English S20 article \(source locator\)](#), lines 1073–1095, checked against the current French transcription. The [published paper](#) is Deligne, *La conjecture de Weil II*, IHÉS 52 (1980), 137–252.

Let $j : U_0 \hookrightarrow X_0$ be an open immersion of smooth geometrically irreducible curves over $\mathbb{F}_q$, with finite complement S_0 . Fix $\ell \neq \text{char } \mathbb{F}_q$ and the coefficient embedding $\iota : \overline{\mathbb{Q}}_\ell \rightarrow \mathbb{C}$ in Deligne's convention. Let $\mathcal{F}_0$ be lisse on U_0 and pointwise ι -pure of weight β . For $N(x) = q^{\deg x}$ use the exact convention

$$w_{N(x)}(\alpha) = 2 \log_{N(x)} |\iota\alpha|.$$

After making X_0 affine, the cohomological identity is

$$\begin{aligned} \prod_{x \in |U_0|} \iota \det(1 - F_x t^{\deg x}, \mathcal{F}_0)^{-1} & \prod_{x \in |S_0|} \iota \det(1 - F_x t^{\deg x}, j_* \mathcal{F}_0)^{-1} \\ &= \frac{\iota \det(1 - Ft, H_c^1(X, j_* \mathcal{F}))}{\iota \det(1 - Ft, H_c^2(X, j_* \mathcal{F}))}. \end{aligned} \quad (\text{DII1})$$

The open-set Euler product is holomorphic and nonzero in $|t| < q^{-(\beta+2)/2}$. Corollary 1.4.3 excludes poles of the right side there. The remaining finite product has numerator one, so no denominator root can cancel inside that product. Dividing (DII1) by its nonzero open-set factor therefore excludes each boundary local pole in that disc.

For an eigenvalue α in a boundary factor, a root of $1 - \iota\alpha t^{\deg x}$ has modulus $|\iota\alpha|^{-1/\deg x}$. Pole exclusion gives

$$|\iota\alpha|^{-1/\deg x} \geq q^{-(\beta+2)/2}, \quad |\iota\alpha| \leq N(x)^{(\beta+2)/2}, \quad w_{N(x)}(\alpha) \leq \beta + 2. \quad (\text{DII2})$$

Now take tensor powers. Write $W = \mathcal{F}_{\bar{\eta}}$ for the geometric generic fibre near x , and I_x for its local inertia group. The boundary stalk is $(j_* \mathcal{F})_{\bar{x}} = W^{I_x}$. The relevant map is literally

$$(W^{I_x})^{\otimes k} \hookrightarrow (W^{\otimes k})^{I_x}, \quad v_1 \otimes \cdots \otimes v_k \longmapsto v_1 \otimes \cdots \otimes v_k. \quad (\text{DII3})$$

The tensor inclusion is injective by a basis extension. Its image is invariant because inertia fixes every factor; it commutes with Frobenius because Frobenius normalizes inertia. Consequently an eigenvector $v \neq 0$ at the boundary has a nonzero image $v^{\otimes k}$ with eigenvalue α^k . The sheaf $\mathcal{F}_0^{\otimes k}$ is pointwise pure of weight $k\beta$: eigenvalues in a tensor product are products of eigenvalues, so their complex moduli multiply. Applying the already-proved (DII2) to it yields

$$k w_{N(x)}(\alpha) = w_{N(x)}(\alpha^k) \leq k\beta + 2, \quad w_{N(x)}(\alpha) \leq \beta + \frac{2}{k}. \quad (\text{DII4})$$

A violation $w_{N(x)}(\alpha) = \beta + \varepsilon$ with $\varepsilon > 0$ contradicts (DII4) at the finite integer $k = \lfloor 2/\varepsilon \rfloor + 1$. Thus $w_{N(x)}(\alpha) \leq \beta$. This lemma gives an upper bound at the boundary; it does not assert equality of all boundary weights.

This is the exact pattern requested: first prove a larger forbidden region by returning to an earlier cohomological exclusion; then map the same offending class injectively into tensor powers until it would enter that forbidden region. The earlier exclusion is reapplied to an object proved to retain the offending eigenvalue.

The older English math-mode file has an incorrect H^0 denominator in its transcription of 1.8.1.1. The current S20 text has H_c^2 , as used in (DII1). The historical file is retained unchanged and its status is recorded in the source index.

139 The actual final bootstrap in Weil II

The proof of the curve theorem in *Weil II*, 3.2.3–3.2.15, uses a more specific mechanism than tensor amplification alone. A local calculation makes the weights of every relevant nonconstant constituent integral. An earlier analytic theorem excludes weight 2 and all larger weights. Consequently these integral weights are at most 1. The remaining constituents are geometrically constant on the projective line, where their first cohomology vanishes. These two exclusions make a product-square argument improve a universal error e to $e/2$. The proof below retains the schemes, coefficient sheaves, boundary terms, maps, twists, and indices which make that improvement possible.

The primary source is Pierre Deligne, *La conjecture de Weil II*, Publications mathématiques de l’IHÉS 52 (1980), 137–252: the introduction, printed pp. 140–141; 1.8.4, pp. 175–176; 2.2.10, p. 196; 3.1, pp. 197–200; 3.2, pp. 200–204; and 3.3, pp. 204–207. All numbered results cited in this section are Deligne’s published results unless a displayed tag begins with WDB. The local current S20 English and French texts were read alongside the controlling published French scan. This section is an exposition of that proof and its exact algebraic steps, not a claim that a construction over the absolute base has already acquired the finite-field sheaves in this proof.

139.1 Conventions, original weight, and the universal assertion

Fix a finite field $\mathbb{F}_q$, an algebraic closure $\overline{\mathbb{F}}_q$, a prime $\ell \neq \text{char } \mathbb{F}_q$, and Deligne’s coefficient isomorphism $\iota : \overline{\mathbb{Q}}_\ell \rightarrow \mathbb{C}$. For a scheme or sheaf with subscript 0, omission of that subscript means extension to $\overline{\mathbb{F}}_q$. Use geometric Frobenius and the weight convention

$$w_q(\alpha) = 2 \log_q |\iota \alpha|, \quad w_q(\alpha^d) = w_q(\alpha), \quad w_q(\alpha^r) = r w_q(\alpha). \quad (\text{WDB1})$$

A Tate twist (a) multiplies Frobenius eigenvalues by q^{-a} and lowers their weights by $2a$.

Let U_0 be a smooth curve and let $\mathcal{F}_0$ be a lisse pointwise ι -pure sheaf of weight β on U_0 . Deligne proves the universal assertions

$$\mathbf{B}_k : \quad w_q(\alpha) \leq \beta + 1 + 2^{-k} \quad \text{for every eigenvalue of } F \text{ on } H_c^1(U, \mathcal{F}), \quad k = 0, 1, 2, \dots \quad (\text{WDB2})$$

The quantifiers range over all such curves, sheaves, weights, and finite fields. This universality is used when the induction is applied to new coefficient sheaves on the base of a pencil, rather than only to the original $\mathcal{F}_0$.

Here is the precise relation to the weight-zero formulation of 3.2.4. Choose $c \in \overline{\mathbb{Q}}_\ell^*$ with $\iota(c) = q^{-\beta/2}$, and let $\mathcal{L}_c$ be the constant geometric Weil sheaf whose arithmetic datum is Frobenius c . Deligne's twisting operation 1.2.7 gives

$$\mathcal{F}_0^{[0]} = \mathcal{F}_0 \otimes \mathcal{L}_c, \quad H_c^1(U, \mathcal{F}^{[0]}) = H_c^1(U, \mathcal{F}) \otimes \mathcal{L}_c, \quad \alpha^{[0]} = c\alpha, \quad w_q(\alpha^{[0]}) = w_q(\alpha) - \beta. \quad (\text{WDB3})$$

Thus the original weight and eigenvalue are recovered by tensoring with $\mathcal{L}_{c^{-1}}$ and multiplying by c^{-1} . We use $\mathcal{F}_0^{[0]}$, not a change in the meaning of $\mathcal{F}_0$, for the auxiliary weight-zero proof. This twist is made in the Weil-sheaf setting allowed by Deligne; it is not an assertion that every such character extends to an ℓ -adically continuous character of the profinite arithmetic Galois group.

We will repeatedly use the following elementary linear algebra. If a linear automorphism preserves a finite filtration, a basis adapted to the filtration makes its matrix block triangular. Its characteristic polynomial is the product of the characteristic polynomials on the successive quotients. Hence a uniform upper weight bound is inherited by subspaces, quotients, and finite extensions. For a convergent Frobenius-equivariant spectral sequence, each term on a later page is a subquotient of an earlier term; the abutment has a filtration with the E_∞ terms as successive quotients. These facts prove the weight comparisons below without assuming spectral-sequence degeneration or Frobenius semisimplicity.

139.2 The two earlier inputs: a strict bound and local integral shifts

Deligne's 1.8.2 supplies the initial estimate $w_q(\alpha) \leq \beta + 2$, hence B_0 . For a smooth affine curve it applies directly with the open immersion in 1.8.2 taken to be the identity: the Euler product and the H_c^2 denominator have no zero in $|t| < q^{-(\beta+2)/2}$, so the numerator has none there. For a projective component, remove a closed point and use the surjection from the compactly supported first cohomology of the remaining affine curve, proved explicitly in (WDB7)–(WDB8) below. Connected components are handled by a finite extension and (WDB1).

The stronger earlier result used in the induction is 2.2.10:

$$\alpha \in \text{Spec}(F; H_c^1(U, \mathcal{F})) \implies w_q(\alpha) < \beta + 2. \quad (\text{WDB4})$$

The inequality is strict. Deligne proves it in Section 2 using the Hadamard-de la Vallée-Poussin method and the cohomological expression for the relevant L -function. After weight-zero twisting and reduction to an irreducible representation, 2.2.9 excludes zeros on the boundary line $\text{Re } s = 1$; 2.2.8 and 2.2.9.1 identify this with the absence of the corresponding numerator roots on $|t| = q^{-1}$. The possible geometrically constant character is accounted for by the simple pole stated there, rather than discarded. Its pole order equals the order of the H_c^2 denominator zero, so a numerator zero at that point would contradict the exact simple pole and is excluded as well. Since a reciprocal root $t = \iota(\alpha)^{-1}$ has modulus $q^{-w_q(\alpha)/2}$, the absence of numerator roots for $|t| \leq q^{-1}$ is exactly $w_q(\alpha) < 2$ in weight zero. This is an earlier proved input in the order of the paper; it is not deduced by assuming the conclusion of 3.2.3.

The second earlier result is local monodromy purity, 1.8.4. If a lisse sheaf on a punctured smooth curve is pointwise ι -pure of weight b , and M is the centered local monodromy filtration on its geometric generic stalk V , then

$$\text{Gr}_j^M V \text{ is } \iota\text{-pure of weight } b + j, \quad j \in \mathbb{Z}. \quad (\text{WDB5})$$

In particular every Frobenius eigenvalue of the local Weil representation has weight in $b + \mathbb{Z}$. Under unipotent inertia the graded pieces have trivial inertia: writing $\rho(\sigma) = \exp(t_\ell(\sigma)N)$, the operator N lowers M by two, so its exponential acts as the identity on every Gr_j^M .

The weight shift in (WDB5) is itself proved in 1.8.4, not read off from the existence of a nilpotent operator. To recall its numerical content, twist to weight zero and use a finite covering so that all inertia is unipotent. Then $\ker N = V^I$, and 1.8.1 says its eigenvalues have modulus at most 1. For a primitive bottom piece $P_{-j}V$, Deligne's tensor decomposition 1.6.14.4 makes

$$P_{-j}V \otimes P_{-j}V(-j) \text{ a direct summand of } P_0(V \otimes V). \quad (\text{WDB6})$$

If α occurs in $P_{-j}V$, the resulting eigenvalue $\alpha^2 q^j$ therefore has modulus at most 1, giving $|\iota\alpha| \leq q^{-j/2}$. Applying the same argument to the dual primitive piece, whose corresponding eigenvalue is $\alpha^{-1} q^{-j}$ by 1.6.14.5, gives $|\iota\alpha| \geq q^{-j/2}$. Equality follows. The primitive decomposition 1.6.14.3 and the Tate shifts on its strings give (WDB5). Thus the integral shifts later used by the pencil argument have already been tied to the actual local Weil action.

139.3 The exact open-extension map used by the induction

Let $j : W_0 \hookrightarrow C_0$ be a dense open immersion of curves, with finite complement, and let $\mathcal{K}_0$ be a constructible sheaf on C_0 . Extension by zero gives the short exact sequence

$$0 \longrightarrow j_! j^* \mathcal{K}_0 \longrightarrow \mathcal{K}_0 \longrightarrow \mathcal{K}_0 / j_! j^* \mathcal{K}_0 \longrightarrow 0. \quad (\text{WDB7})$$

The quotient is supported on finitely many points. Over the algebraic closure its positive-degree compactly supported cohomology vanishes: each geometric point has only degree-zero cohomology and a finite disjoint union has the direct sum of those cohomologies. The long exact sequence of (WDB7) consequently gives the Frobenius-equivariant surjection

$$H_c^1(W, j^* \mathcal{K}) \twoheadrightarrow H_c^1(C, \mathcal{K}). \quad (\text{WDB8})$$

If W_0 is smooth and $j^* \mathcal{K}_0$ is lisse and pointwise pure of weight b , assertion B_k applied to the source proves that every eigenvalue of the target has weight at most $b + 1 + 2^{-k}$. This is precisely 3.2.5(k). No purity of the possibly singular boundary stalks of $\mathcal{K}_0$ is assumed in this step.

139.4 The product and pencil, with all three reduction hypotheses

Assume B_k . Initially impose the three hypotheses of 3.2.6 on the auxiliary sheaf $\mathcal{F}_0^{[0]}$.

- (A) If X_0 is the smooth projective compactification of U_0 , the local monodromy of $\mathcal{F}^{[0]}$ at $X - U$ is tame and unipotent.
- (B) Put $S_0 = X_0 \times X_0$, $V_0 = U_0 \times U_0$, and $D_0 = S_0 - V_0$. Choose a projective embedding and a hyperplane pencil with axis A_0 satisfying 3.1.1(A)–(D): the axis is transverse to S and disjoint from D ; the only singularities of the pencil on S are ordinary quadratic points outside D ; its only singularities on the normalization of D are ordinary quadratic points away from the preimages of the nodes of D ; and each exceptional fibre contains exactly one exceptional point.
- (C) These exceptional points are defined over $\mathbb{F}_q$.

Write $P_0 = A_0^* \simeq \mathbb{P}_{\mathbb{F}_q}^1$ for the parameter line of the pencil, and use the incidence surface

$$\tilde{S}_0 = \{(s, t) \in S_0 \times P_0 : s \in H_t\}, \quad \pi : \tilde{S}_0 \longrightarrow S_0, \quad \bar{f} : \tilde{S}_0 \longrightarrow P_0. \quad (\text{WDB9})$$

It is the blow-up at the finite set $S_0 \cap A_0$. Put $\tilde{V}_0 = \pi^{-1}(V_0)$, let $\tilde{j} : \tilde{V}_0 \hookrightarrow \tilde{S}_0$ be the open immersion, and set $f = \tilde{f}\tilde{j}$. The actual coefficient sheaf is

$$\mathcal{G}_0 = \text{pr}_1^* \mathcal{F}_0^{[0]} \otimes \text{pr}_2^* \mathcal{F}_0^{[0]} \quad \text{on } V_0. \quad (\text{WDB10})$$

Both tensor factors are retained. In terms of the original sheaf this is $(\mathcal{F}_0 \boxtimes \mathcal{F}_0) \otimes \mathcal{L}_{c^2}$, so its original weight 2β has been recorded by an explicit invertible twist. Its auxiliary weight is zero.

Let $T_0 \subset P_0$ be the finite set of exceptional values, $W_0 = P_0 - T_0$, and $w : W_0 \hookrightarrow P_0$. Define

$$\mathcal{R}_0^b = R^b f_! \pi^* \mathcal{G}_0 = R^b \tilde{f}_* j_! \pi^* \mathcal{G}_0. \quad (\text{WDB11})$$

These sheaves are lisse over W_0 . The compact-support Leray spectral sequence is Frobenius-equivariant:

$$E_2^{ab} = H^a(P, \mathcal{R}^b) \implies H_c^{a+b}(\tilde{V}, \pi^* \mathcal{G}). \quad (\text{WDB12})$$

Since both the base and the fibres have dimension one, total degree two has only the terms $(a, b) = (0, 2), (1, 1), (2, 0)$.

139.5 Why the middle coefficient sheaf has pure constituents

Let $x \in |W_0|$. Denote the proper fibre of $\tilde{f}$ by $\tilde{S}_x$, its open part by Y_x , and the open immersion by $j_x : Y_x \hookrightarrow \tilde{S}_x$. Proper base change applied to (WDB11) gives the exact stalk identification

$$(\mathcal{R}_0^b)_{\bar{x}} \simeq H^b(\tilde{S}_{\bar{x}}, j_{x!} \pi^* \mathcal{G}) \simeq H_c^b(Y_{\bar{x}}, \pi^* \mathcal{G}). \quad (\text{WDB13})$$

These are identifications of representations of geometric Frobenius over $\kappa(x)$. The open fibre is a smooth curve for $x \in W_0$; it need not be connected.

There is a notation defect in the published display 3.2.7.1, printed p. 202: it writes ordinary $H^1(Y, \pi^* \mathcal{H})$ for an open fibre while the left side is $R^1 f_!$. The controlling French scan and both current S20 transcriptions show the same display. Equation (WDB13) states the corrected support convention and its base-change proof. Ordinary cohomology of the open fibre is not used in place of compactly supported cohomology.

Set $\mathcal{H}_0 = \mathcal{G}_0 \oplus \mathcal{G}_0^\vee$. At a closed point the eigenvalues of $\mathcal{G}_0$ have ι -modulus one. The images of the eigenvalues of its dual are their inverses, hence their complex conjugates. Therefore the characteristic polynomial of the direct sum has real coefficients, and $\mathcal{H}_0$ is pointwise pure of weight zero and ι -real. Deligne's 3.2.1–3.2.2 applied to the smooth fibre in (WDB13) shows that $w^* R^1 f_! \pi^* \mathcal{H}_0$ is ι -real. The sheaf $w^* \mathcal{R}_0^1$ is an actual direct summand of it because pullback and $R^1 f_!$ preserve finite direct sums. The purity criterion 1.5.1 now gives a finite filtration of $w^* \mathcal{R}_0^1$ whose successive quotients are lisse and pointwise ι -pure. This proves 3.2.7 with its coefficient and support maps specified.

To make this use of 3.2.1 explicit, let $\mathcal{E}_0$ be pointwise ι -pure of weight b and ι -real on a smooth geometrically connected curve C_0 . Put $P_a(t) = \iota \det(1 - Ft, H_c^a(C, \mathcal{E}))$. Grothendieck's formula says that $P_1/(P_0 P_2)$ has real Taylor coefficients and hence is a real rational function. The roots of P_2 all have modulus $q^{-(b+2)/2}$ by 1.4.3; those of P_0 , if any, have modulus $q^{-b/2}$; and (WDB4) excludes roots of P_1 on the former circle. Consequently the poles on that circle, with their multiplicities, are exactly the roots of P_2 . They are stable under complex conjugation, so P_2 has real coefficients and constant term one. If C is affine, $P_0 = 1$. If it is projective, the correct scalar duality is

$$H^0(C, \mathcal{E})^\vee \simeq H_c^2(C, \mathcal{E}^\vee(1)). \quad (\text{WDB13a})$$

The coefficient sheaf on the right is again ι -real and pure, so the just-proved degree-two argument and inversion of eigenvalues show that P_0 is real. It follows that P_1 is real. If geometric components are permuted in a cycle of length d , their cohomological characteristic polynomial is $\det(1 - F^d t^d, H_c^a(C', \mathcal{E}))$ for one component C' ; the preceding argument over $\mathbb{F}_{q^d}$ makes this polynomial real, proving the extension 3.2.2.

There is a second printed notation defect in the proof of 3.2.1, p. 200: it writes $\mathcal{E}^\vee(-1)$ in place of the $\mathcal{E}^\vee(1)$ in (WDB13a). The printed group equals $H^0(C, \mathcal{E})^\vee(-2)$, so it still implies the required reality after the real scalar factor q^2 is retained. Formula (WDB13a) records the exact untwisted duality used here; the later 3.2.15 itself has the correct (1) twist.

139.6 Vanishing cycles detect the nonconstant weights

The calculation in 3.1 treats exactly three exceptional geometries: an ordinary node of the fibre away from D , tangency of the fibre to one smooth branch of D , and passage of the fibre through a node of D . Let $\bar{t} \in T$ and $\bar{x}$ be its unique exceptional point. The vanishing-cycle sheaves are supported at $\bar{x}$ and vanish in every degree other than one. If $\varepsilon(B)$ is the one-dimensional sign representation of the two branches or two local sheets, the calculation is

$$\begin{aligned} \text{node outside } D : \quad & \Phi_{\bar{x}}^1 = \mathcal{G}_{\bar{x}}(-1) \otimes \varepsilon(B), \\ \text{tangency to } D : \quad & \text{Gr}^a \Phi_{\bar{x}}^1 = \text{Gr}^a \mathcal{G}_{\bar{x}}^{\text{loc}} \otimes \varepsilon(B), \\ \text{node of } D : \quad & \text{Gr}^a \Phi_{\bar{x}}^1 = \text{Gr}^a \mathcal{G}_{\bar{x}}^{\text{loc}} \otimes \varepsilon(B). \end{aligned} \tag{WDB14}$$

Here the latter two expressions mean the stalks of the constant extensions of the local graded sheaves of 3.1.2; they do not mean that the original sheaf was defined at a deleted boundary point. For the first case the Picard–Lefschetz vanishing cycle supplies the twist (-1) . For tangency, apply vanishing cycles to $0 \rightarrow j_! \overline{\mathbb{Q}}_\ell \rightarrow \overline{\mathbb{Q}}_\ell \rightarrow \overline{\mathbb{Q}}_{\ell D} \rightarrow 0$: the constant ambient term has no vanishing cycles, which shifts the divisor computation by one. At a node of D , the corresponding two-step exact sequence through the normalization of D shifts the computation by two and gives the same degree-one sign representation. These are 3.1.3.1–3.1.5.4.

For each original boundary point of $X - U$, (WDB5) applied to $\mathcal{F}_0^{[0]}$ gives integral local weights. Hypothesis (A) makes its graded sheaves locally constant across the puncture. Taking their external tensor product gives the local filtration of $\mathcal{G}_0$ used in (WDB14); its weights are sums of integers. At an interior point the weight is zero. The sign representation has Frobenius eigenvalue 1 or -1 and weight zero, and (-1) adds two to the weight. Every case of (WDB14) therefore proves

$$\text{all Frobenius eigenvalues of } \Phi_{\bar{x}}^1 \text{ have integral weights.} \tag{WDB15}$$

The proof retains the distinction between the three geometric supports while obtaining the same integrality conclusion from them.

Let $\bar{\eta}$ be the local geometric generic point at $\bar{t}$. The vanishing of Φ^a for $a \neq 1$ gives the exact sequence 3.2.9.1

$$0 \rightarrow \mathcal{R}_{\bar{t}}^1 \rightarrow \mathcal{R}_{\bar{\eta}}^1 \rightarrow \Phi_{\bar{x}}^1 \rightarrow \mathcal{R}_{\bar{t}}^2 \rightarrow \mathcal{R}_{\bar{\eta}}^2 \rightarrow 0. \tag{WDB16}$$

In particular $\mathcal{R}^1$ has no sections supported at $\bar{t}$. Varying $\bar{t}$ gives the injective sheaf map $\mathcal{R}_0^1 \hookrightarrow w_* w^* \mathcal{R}_0^1$ of 3.2.8.

Choose the finite pure-constituent filtration G on $w^* \mathcal{R}_0^1$ obtained above and extend it by intersection:

$$G^a \mathcal{R}_0^1 = \mathcal{R}_0^1 \cap w_* G^a(w^* \mathcal{R}_0^1), \quad \mathcal{K}_{a,0} = \text{Gr}_G^a \mathcal{R}_0^1. \tag{WDB17}$$

The intersection is in $w_* w^* \mathcal{R}_0^1$. Write b_a for the pure weight of $w^* \mathcal{K}_{a,0}$. At $\bar{t}$, this is the filtration induced by intersection with the subspace in (WDB16); consequently taking its associated graded sequence gives

$$0 \rightarrow (\mathcal{K}_{a,0})_{\bar{t}} \rightarrow (\mathcal{K}_{a,0})_{\bar{\eta}} \rightarrow A_{a,\bar{t}} \rightarrow 0, \quad A_{a,\bar{t}} \text{ a subquotient of } \Phi_{\bar{x}}^1. \tag{WDB18}$$

For completeness, this subquotient statement is elementary for an inclusion $E \hookrightarrow V$ and a filtration of V : filter E by $E \cap G^a V$ and V/E by the images of $G^a V$. The associated graded sequence is exact, so the cokernel in degree a is a graded piece of V/E . Here V/E injects into $\Phi_{\bar{x}}^1$ by (WDB16).

If $A_{a,\bar{t}} \neq 0$, select any one of its Frobenius eigenvalues λ . As a subquotient of the vanishing cycle it has an integral weight by (WDB15). As a quotient of the local Weil stalk of the pure sheaf $w^* \mathcal{K}_{a,0}$, its weight lies in $b_a + \mathbb{Z}$ by (WDB5). Thus

$$A_{a,\bar{t}} \neq 0 \implies w_{N(t)}(\lambda) \in \mathbb{Z} \cap (b_a + \mathbb{Z}) \implies b_a \in \mathbb{Z}. \tag{WDB19}$$

If instead every $A_{a,\bar{t}}$ vanishes, (WDB18) identifies the special stalk with the entire generic stalk at every boundary point. The image of specialization is inertia invariant, so inertia acts trivially and the sheaf is lisse across every such point. It is therefore lisse on $P \simeq \mathbb{P}^1$; its geometric monodromy is trivial because $\mathbb{P}^1$ over an algebraically closed field is simply connected. It follows that $\mathcal{K}_a$ is geometrically constant. Frobenius on its constant fibre can still be nontrivial. We have proved the exact alternative of 3.2.9:

$$\mathcal{K}_a \text{ is geometrically constant on } P, \quad \text{or} \quad b_a \in \mathbb{Z}. \quad (\text{WDB20})$$

The pure weight b_a can be measured at any closed point of W_0 . There its eigenvalues are among those of (WDB13) with $b = 1$. Applying the strict bound (WDB4) to the weight-zero coefficient sheaf on that smooth fibre proves $b_a < 2$, which is 3.2.10. Combining this with (WDB20) gives

$$\mathcal{K}_a \text{ not geometrically constant} \implies b_a \in \mathbb{Z}, \quad b_a < 2, \implies b_a \leq 1. \quad (\text{WDB21})$$

This is the decisive return to the earlier exclusion. A weak bound $b_a \leq 2$ would leave the integer 2 available and would not start the improvement from $k = 0$.

139.7 Leray transfers the surviving error only once

If $\mathcal{K}_a$ is geometrically constant with fibre L_a , then

$$H^1(P, \mathcal{K}_a) = H^1(\mathbb{P}^1, \overline{\mathbb{Q}}_\ell) \otimes L_a = 0. \quad (\text{WDB22})$$

The equality is Frobenius-equivariant and holds for every Frobenius action on L_a . No numerical weight bound for L_a is required. In the other case, (WDB8), B_k , and (WDB21) give

$$\alpha \in \text{Spec}(F; H^1(P, \mathcal{K}_a)) \implies w_q(\alpha) \leq b_a + 1 + 2^{-k} \leq 2 + 2^{-k}. \quad (\text{WDB23})$$

The long exact sequences of the finite filtration (WDB17) and the block-triangular argument following (WDB3) now give

$$w_q(\alpha) \leq 2 + 2^{-k} \quad \text{on } E_2^{11} = H^1(P, \mathcal{R}^1). \quad (\text{WDB24})$$

For the two outer terms, 3.2.12 uses the elementary degree-zero and degree-two cohomology of curves from 1.4, not the theorem being proved. On any fibre, H_c^0 is a space of sections of the weight-zero lisse sheaf and its eigenvalues have weight zero. For H_c^2 , remove the finitely many singular points and pass to smooth connected components. Formula 1.4.1.3 identifies the top cohomology with geometric coinvariants of a stalk, followed by the twist (-1) ; its eigenvalues have weight two. If components are permuted, a finite extension makes them individually defined, and the weight identity (WDB1) descends the same bound. Hence the stalk weights of $\mathcal{R}_0^0$ and $\mathcal{R}_0^2$ are respectively at most 0 and 2.

Applying the same elementary curve statements on the base proves

$$w_q(\alpha) \leq 2 \quad \text{on } E_2^{02} = H^0(P, \mathcal{R}^2) \text{ and } E_2^{20} = H^2(P, \mathcal{R}^0). \quad (\text{WDB25})$$

For the first assertion, a nonzero global eigensection is nonzero at some closed-point stalk; Frobenius there acts by the corresponding power of its global eigenvalue. For the second, removal of finitely many points does not change H_c^2 ; on a dense lisse open, 1.4.1.3 expresses it as coinvariants of a stalk with weights at most zero, twisted by (-1) . This adds exactly two. These arguments also cover constructible sheaves on the base with singular boundary stalks. The β in the printed explanation of 3.2.12 is specialized here to the auxiliary weight zero of $\mathcal{G}_0$.

Equations (WDB24)–(WDB25) and the spectral sequence (WDB12) prove

$$w_q(\mu) \leq 2 + 2^{-k} \quad \text{for every eigenvalue on } H_c^2(\tilde{V}, \pi^* \mathcal{G}). \quad (\text{WDB26})$$

Only one error 2^{-k} has appeared: it enters through the base cohomology in (WDB23). The fibre coefficient weight has already been reduced to at most one by the separate integer and strict-bound argument. Applying B_k twice without that reduction would instead give $2 + 2 \cdot 2^{-k}$ and no improvement after taking a square root.

139.8 The nonzero class survives the two exact injections

Künneth gives a Frobenius-equivariant direct-sum decomposition in degree two. Its $(1, 1)$ summand provides the first map below; the second is pullback along the blow-up:

$$\begin{aligned} H_c^1(U, \mathcal{F}^{[0]}) \otimes H_c^1(U, \mathcal{F}^{[0]}) &\hookrightarrow H_c^2(V, \mathcal{G}) \\ &\hookrightarrow H_c^2(\tilde{V}, \pi^* \mathcal{G}). \end{aligned} \quad (\text{WDB27})$$

The second injection is 3.1.1.4. More precisely 3.1.1.3 identifies

$$H_c^2(\tilde{V}, \pi^* \mathcal{G}) \simeq H_c^2(V, \mathcal{G}) \oplus H^0(V \cap A, \mathcal{G})(-1), \quad (\text{WDB28})$$

with pullback as the inclusion of the first summand. The center is disjoint from D by (B), so these are the actual blow-up centers in the open surface. Equivalently the Poincaré-dual transpose described in 3.1.1.4 supplies a retraction. The extra summand in (WDB28) is retained rather than identified with zero.

If $v \neq 0$ is an eigenvector of F with eigenvalue $\alpha^{[0]}$ in the original degree-one space, choose a linear functional λ with $\lambda(v) = 1$. Then $(\lambda \otimes \lambda)(v \otimes v) = 1$, so $v \otimes v \neq 0$. Both maps in (WDB27) are injective, hence their composite carries it to a nonzero eigenvector with eigenvalue $(\alpha^{[0]})^2$. No exterior square is being taken: the product is on two copies of the curve, so the odd cohomological degree does not force this tensor to vanish. Invertibility and the existence of an eigenvector hold over $\overline{\mathbb{Q}}_\ell$ without any diagonalizability assumption.

Applying (WDB26) to this specific image gives

$$\begin{aligned} 2(w_q(\alpha) - \beta) &= w_q((c\alpha)^2) \leq 2 + 2^{-k}, \\ w_q(\alpha) &\leq \beta + 1 + 2^{-(k+1)}. \end{aligned} \quad (\text{WDB29})$$

This proves B_{k+1} under (A)–(C), with the original eigenvalue and original coefficient weight restored exactly.

139.9 Removing the reduction hypotheses preserves the offending eigenvalue

For a finite extension $\mathbb{F}_{q^d}/\mathbb{F}_q$, the geometric cohomology space is unchanged and F is replaced by F^d . Thus an eigenvalue α is replaced by α^d , and (WDB1) proves equality of its old and new weights. A bound over the extension gives the identical bound over the original field. Deligne uses this operation in 3.2.14 to define over a finite field an embedding and a general-position pencil that exist over the algebraic closure, and then to make their finitely many exceptional points rational. This removes (B) and (C). It does not itself divide any exponent error by d .

To remove (A), the monodromy theorem supplies a finite surjective cover $g : U'_0 \rightarrow U_0$, with U'_0 smooth, for which $g^* \mathcal{F}_0^{[0]}$ has tame unipotent boundary monodromy. Purity is preserved by pullback: if x' lies over x with residue degree e , its Frobenius eigenvalues are the e -th powers of those at x , and $N(x') = N(x)^e$. The exact map used to retain cohomology is

$$g^* : H_c^a(U, \mathcal{F}^{[0]}) \hookrightarrow H_c^a(U', g^* \mathcal{F}^{[0]}). \quad (\text{WDB30})$$

Here is a trace construction which includes the multiplicities at ramification points. On a connected smooth target curve the finite surjective map is flat of constant degree $d_g > 0$: its finite local modules are torsion-free over the discrete valuation rings of the target and hence free. At a geometric point u , the trace of the constant coefficient sheaf $E = \overline{\mathbb{Q}}_\ell$ is

$$\text{Tr}_{g,u} : \bigoplus_{u'|u} E \longrightarrow E, \quad (a_{u'}) \longmapsto \sum_{u'|u} \text{length}(\mathcal{O}_{g^{-1}(u),u'}) a_{u'}. \quad (\text{WDB30a})$$

The sum of these lengths is d_g . Compatibility with restriction follows by decomposing the inverse image of an étale neighborhood into open and closed pieces: each piece is finite flat and its rank is locally constant. Thus (WDB30a) is a sheaf morphism $g_*E \rightarrow E$, with the unit followed by trace equal to $d_g \text{id}$. The projection formula tensors this identity with $\mathcal{F}^{[0]}$. Finite maps are proper and their geometric fibres have no higher étale cohomology, so $Rg_* = g_* = g_!$. Taking compact-support cohomology gives the map (WDB30) with retraction $d_g^{-1} \text{Tr}_g$. The coefficient field has characteristic zero, so the inverse d_g^{-1} exists even if ℓ divides d_g . The formula includes inseparable lengths as well. Because these maps are Frobenius-equivariant, they retain the same eigenvalue. Connected components can be treated after a finite base extension and descended by (WDB1). The universal B_{k+1} follows.

139.10 A finite contradiction, followed by the exact dual lower bound

Induction now proves (WDB2) for every integer $k \geq 0$. Suppose an actual eigenvalue had $w_q(\alpha) = \beta + 1 + \varepsilon$ with $\varepsilon > 0$. The specific finite integer

$$K = \max\{0, \lfloor \log_2(1/\varepsilon) \rfloor + 1\} \quad \text{satisfies} \quad 2^{-K} < \varepsilon. \quad (\text{WDB31})$$

Indeed if $\varepsilon > 1$, $K = 0$ works; otherwise $K > \log_2(1/\varepsilon)$. At this finite stage (WDB2) would say $\beta + 1 + \varepsilon \leq \beta + 1 + 2^{-K}$, a contradiction. Consequently

$$w_q(\alpha) \leq \beta + 1 \quad \text{on } H_c^1(U, \mathcal{F}). \quad (\text{WDB32})$$

This is the dyadic 2^{-k} bootstrap in Weil II, not the $1/k$ error obtained from arbitrarily large products in the earlier proof of Weil I. Both retain the offending eigenvalue, but their geometric estimates and induction parameters differ.

Let now $j : U_0 \hookrightarrow X_0$ with X_0 smooth projective. Equation (WDB8) transfers (WDB32) to $H^1(X, j_*\mathcal{F})$. Deligne's duality in 3.2.15 is the perfect Frobenius-equivariant pairing with values in the trivial coefficient field

$$H^1(X, j_*\mathcal{F}) \otimes H^1(X, j_*\mathcal{F}^\vee(1)) \longrightarrow \overline{\mathbb{Q}}_\ell. \quad (\text{WDB33})$$

Its perfectness on these actual image groups can also be seen directly from Poincaré duality on U . The compact-to-ordinary maps for $\mathcal{F}$ and $\mathcal{F}^\vee(1)$ are transposes, up to the degree-one cup-product sign. The kernel of either transpose is the annihilator of the other image. Quotienting the compactly supported groups by these kernels therefore induces a nondegenerate pairing on the two images. Their identification with the two j_* cohomology groups gives (WDB33), including its scalar target. The dual coefficient sheaf has weight $-\beta - 2$. For an eigenvalue α of the first factor, α^{-1} occurs in the second, whether or not Frobenius is semisimple. Applying the already proved upper bound to that factor gives

$$-w_q(\alpha) = w_q(\alpha^{-1}) \leq (-\beta - 2) + 1 = -\beta - 1. \quad (\text{WDB34})$$

Together with the upper bound this proves $w_q(\alpha) = \beta + 1$. In degrees zero and two, the invariant and coinvariant descriptions of 1.4, with the Tate twist (-1) in degree two, give weights β and $\beta + 2$. Thus all three degrees give 3.2.3:

$$w_q(\alpha) = \beta + i \quad \text{on } H^i(X, j_*\mathcal{F}). \quad (\text{WDB35})$$

For degree one this group is also the image of $H_c^1(U, \mathcal{F}) \rightarrow H^1(U, \mathcal{F})$, as stated at the start of 3.2.3. Purity is being asserted for this actual image; the mixed boundary part of all of $H_c^1(U, \mathcal{F})$ has not been declared pure.

139.11 The mixed-sheaf theorem retains and controls the boundary

Theorem 3.3.1 concerns a morphism $f : X \rightarrow Y$ of schemes of finite type over $\mathbb{Z}$, with ℓ invertible as in Deligne's conventions. It asserts that a mixed constructible sheaf $\mathcal{F}$ of weights at most n has $R^i f_! \mathcal{F}$ mixed of weights at most $n + i$. Deligne proves it by reduction to the curve theorem together with the local boundary calculation. The reductions are by exact sequences in the sheaf; decomposition into an open set and its closed complement; base change on the target; and the Frobenius-equivariant Leray spectral sequence for a composition. For the sheaf reduction involving a kernel, the preceding term in the long exact sequence has bound $n + i - 1$, which is at most $n + i$; thus that reduction also preserves the claimed bound. Relative dimension zero contributes only degree zero and preserves the pointwise weight. Universal homeomorphisms preserve the *étale* theory. Stratification and composition reduce to relative curves and then to a lisse pure coefficient sheaf. These are the explicit reductions 3.3.1(a)–(f).

On the generic relative curve one removes finitely many singular points, takes a finite covering with tame ramification at infinity, and uses the trace splitting of its coefficient sheaf. A purely inseparable field extension is allowed in making the smooth compactification. Deligne then spreads this finite geometric data over a neighborhood of the generic point of the reduced target. Reductions 3.3.1(c),(e) make this neighborhood the whole reduced target and allow the smooth reduced target used in Deligne's relative boundary calculation; the target reduction handles its complement. The resulting relative geometry is

$$\begin{aligned} X &\xrightarrow{j} \overline{X} \xleftarrow{i} D, & f &= \bar{f}j, \\ \bar{f} : \overline{X} &\longrightarrow Y \text{ smooth projective of relative dimension } 1, & & \\ D &\longrightarrow Y \text{ finite étale.} & & \end{aligned} \tag{WDB36}$$

Here $\mathcal{F}$ is lisse pure of weight n on X and tamely ramified along D . There is an actual short exact sequence on the compactification

$$0 \rightarrow j_! \mathcal{F} \rightarrow j_* \mathcal{F} \rightarrow i_* B \rightarrow 0, \quad B = i^* j_* \mathcal{F}. \tag{WDB37}$$

The boundary stalk is inertia invariants, not the entire generic stalk. By 1.8.6–1.8.8 its induced monodromy filtration satisfies

$$\mathrm{Gr}_a^M B = 0 \ (a > 0), \quad \mathrm{Gr}_a^M B \text{ pure of weight } n + a \ (a \leq 0). \tag{WDB38}$$

The signs here follow from $V^I \subset \ker N \subset M_0 V$; when a finite residual inertia group remains, its invariant functor is exact in characteristic zero and retains the same upper indices. These sheaves and their filtrations commute with passage to the fibres in (WDB36).

Applying 3.2.3 on each fibre, and for every coefficient embedding ι , proves that $R^a \bar{f}_* j_* \mathcal{F}$ is pointwise pure of weight $n + a$. Because $D \rightarrow Y$ is finite, its higher direct images vanish and its direct image carries the finite filtration (WDB38) to weights at most n . The long exact sequence of (WDB37) contains, in degrees zero and one,

$$\begin{aligned} 0 \rightarrow f_! \mathcal{F} &\rightarrow \bar{f}_* j_* \mathcal{F} \rightarrow (\bar{f}i)_* B \rightarrow R^1 f_! \mathcal{F} \\ &\rightarrow R^1 \bar{f}_* j_* \mathcal{F} \rightarrow 0, \end{aligned} \tag{WDB39}$$

and in degrees $a \geq 2$ gives $R^a f_! \mathcal{F} \simeq R^a \bar{f}_* j_* \mathcal{F}$. Thus degree zero has weights at most n ; degree one is an extension of the pure sheaf $R^1 \bar{f}_* j_* \mathcal{F}$, of weight $n + 1$, by the boundary quotient $\mathrm{coker}(\bar{f}_* j_* \mathcal{F} \rightarrow (\bar{f}i)_* B)$, of weights at most n ; and degree two has weight $n + 2$. This proves the desired upper bound in the reduced relative-curve case, and the exact reductions give 3.3.1. Boundary contributions have been included through (WDB37)–(WDB39), with their weights and maps specified.

For a finite-type $\mathbb{F}_q$ -scheme this gives 3.3.4: $H_c^i(X, \mathcal{F})$ has weights at most $n + i$ when $\mathcal{F}_0$ is mixed of weights at most n . If in addition X_0 is smooth of pure dimension d and $\mathcal{F}_0$ is lisse and mixed of

weights at least n , then $\mathcal{F}_0^\vee$ has weights at most $-n$. Apply the upper bound to the exact Poincaré dual:

$$H^i(X, \mathcal{F})^\vee \simeq H_c^{2d-i}(X, \mathcal{F}^\vee)(d), \quad -n + (2d - i) - 2d = -n - i. \quad (\text{WDB40})$$

Duality reverses weights, giving the lower bound $n + i$ for $H^i(X, \mathcal{F})$, which is 3.3.5. For a lisse pure sheaf of weight n , the natural map from compactly supported to ordinary cohomology is Frobenius-equivariant, and its image is both a quotient of a space of weights at most $n + i$ and a subspace of one of weights at least $n + i$. The characteristic-polynomial argument after (WDB3) then proves the exact conclusion 3.3.6:

$$\text{im}(H_c^i(X, \mathcal{F}) \longrightarrow H^i(X, \mathcal{F})) \quad \text{is pure of weight } n + i. \quad (\text{WDB41})$$

The original compact-support and ordinary cohomology groups are preserved in this statement; purity is proved for their specified common image.

139.12 The exact contradiction mechanism available for comparison

The decisive numerical chain in this proof is

$$\begin{aligned} \text{nonzero local boundary quotient} &\xrightarrow{(\text{WDB14})-(\text{WDB19})} b_a \in \mathbb{Z}, \\ \{b_a \in \mathbb{Z}, b_a < 2\} &\implies b_a \leq 1, \\ \text{all local boundary quotients zero} &\xrightarrow{(\text{WDB18})-(\text{WDB22})} H^1(P, \mathcal{K}_a) = 0, \\ \mathbf{B}_k &\xrightarrow{(\text{WDB23})-(\text{WDB26})} w_q(\mu) \leq 2 + 2^{-k}, \\ \alpha^{[0]} &\xrightarrow{(\text{WDB27})} (\alpha^{[0]})^2 \implies \mathbf{B}_{k+1}. \end{aligned} \quad (\text{WDB42})$$

The word “boundary” in this chain names the actual specialization-cokernel map (WDB18) into vanishing cycles, and the constant alternative has the actual cohomology-vanishing map (WDB22). The improvement is proved only after both alternatives have been treated. The finite integer (WDB31) then excludes every strict upper violation, and (WDB33)–(WDB34) exclude every strict lower violation of the pure image weight. Equations (WDB37)–(WDB41) extend this calculation to mixed coefficients without deleting their boundary-supported pieces.

140 What has been reconstructed, and what has been decided

This manuscript reconstructs the actual programme in the shared conversation [Branch · Compile Navier Stokes Literature](#), together with the two supplied continuation instructions. Its question is the counterfactual to RH inside that programme: take a genuine off-critical zero of its original arithmetic function, and carry its complete cohomological packet through the constructed maps. The question is not answered by assigning arbitrary roots to an auxiliary polynomial.

The recovered source does construct split support, an absolute base, coefficient Frobenius, coefficient purity, arithmetic cohomology over that base, its right adjoint, actual theta representatives, tensor and symmetric pushforwards, conormal maps, exponential periods, and finite holonomy comparisons. These constructions are used below. The source’s final auxiliary counterexample does not establish that RH is false, or that the whole programme fails. This continuation also establishes neither an RH contradiction nor an off-critical zeta zero. Its new results are exact comparisons, explicit retained kernels, and quantitative restrictions on an actual putative zero. Each is proved in the subsequent chapters.

140.1 Complete source coverage and its limits

The saved public response contains 5,350 mapping nodes. Following every parent from the declared current node to the root produces exactly the same 5,350 nodes in exactly the published linear order. There are 5,349 message records, of which 67 are user messages and 148 are readable assistant prose messages. All 215 readable user/assistant records were read in five complete contiguous assignments. The complete user history was also read by the integrating auditor. The original node identifiers, message hashes, verbatim bodies, assignment coverage and independent reviews are included in the source repository. A second public capture has exactly the same 5,349 message identifiers and body hashes. Differences in transient HTML metadata do not change any message body.

The share explicitly redacts tool payloads and does not embed the bodies of every historical attachment. Those absent contents are not counted as read. Original local proof files are retained separately and are cited as such. The reconstruction uses the actual visible messages and inspected proof files; it does not infer hidden mathematics from a redacted tool call.

The source begins with Navier–Stokes and thermodynamic calculations. It does not begin with the eventual tau-base construction. In particular the early function denoted $e(y)$ and early time or dual-trace coordinates denoted τ are not retrospectively identified with the later supported zero and absolute base. The user’s negative-polynomial detour is expressly withdrawn at U0010. The later user instruction at U0043 demands the tau base itself, and U0046 accepts the corrected arithmetic construction of A1523. These corrections determine the programme continued here.

140.2 Source order and the surviving mathematical content

Source	Constructed object	Exact role in this continuation
U0001–15	Heat/NS test maps and the arithmetic seed	The full early audit retains its integral identities and constants. The test-field realization is kinematic with its specified force; it does not prove that an arbitrary fixed Navier–Stokes evolution supplies arithmetic positivity.
U0016–28	Split support, origin fibres, arithmetic amplitude, mixed-support synchronization, co-efficient Frobenius	The packet chapter uses the actual localization and its integral coefficient action, and constructs a trace retract retaining the arithmetic eigenclass.
U0029–40	Original theta quotient, source labels, raw and balanced Mellin comparison, finite full jets	BK, DP and PL compute the previously retained balanced kernel and every smaller-label finite defect on these spaces.
U0041–45	Absolute base $\mathfrak{b}_\tau$, marked chart, A_τ , restriction and K_τ	The companion tau chapter computes restriction’s complete homotopy fibre and its adjoint, including the nonzero arithmetic quotient at supported zero.
U0046–54	Continuous theta retraction, tensor and symmetric source, relative sum algebra, Fisher and conormal maps	The scaling chapter calculates the original cocycle and boundary pairing. The conormal chapter retains all local factors and computes the intrinsic symmetric trace, including negative directions within one exact sum fibre.
U0055–66	Original cyclic interpolation, volume windows, exponential periods, residue, periodization, all-phase recovery	The holonomy and volume chapters calculate what the original off-line packet forces into the boundary and compare the proved actual upper and lower estimates.

Source	Constructed object	Exact role in this continuation
U0067, A2611	Auxiliary exponential/purity and Gamma-reference counterexamples	These refute specified reduced implications. Their polynomials are not asserted to divide 2ξ ; their arithmetic correction is retained, rather than set to zero.

Every row has a complete source-pinned audit in `audit/`; the table is a navigation device, not a substitute for those proofs. The original 821-page source cut, including its editable proof dependencies, is retained in `original_programme/`. The later original holonomy and audit messages occur in the complete saved transcript. None of the new results is attributed to a historical source that only supplied its starting objects.

141 The original absolute base and the arithmetic scalar square

For a commutative ring R , retain the disjoint union

$$G(R) = \{\tau\} \sqcup \{r^\bullet : r \in R\}, \quad e = 0_R^\bullet.$$

Addition has identity τ , with $r^\bullet \oplus s^\bullet = (r + s)^\bullet$; multiplication has identity $1_R^\bullet$, has absorbing element τ , and satisfies $r^\bullet s^\bullet = (rs)^\bullet$. The laws follow directly from the ring laws when all inputs are supported; cases containing τ use its stated identity or absorption law. In particular $e \neq \tau$, $e \oplus e = e$, and $er^\bullet = e$ for every supported scalar.

Let $\mathbb{B} = \{0, 1\}$ have addition OR and multiplication AND. The amplitude and support observations are the unital semiring maps

$$p_R : G(R) \longrightarrow R, \quad p_R(\tau) = 0, \quad p_R(r^\bullet) = r, \quad \chi_R : G(R) \longrightarrow \mathbb{B}, \quad \chi_R(\tau) = 0, \quad \chi_R(r^\bullet) = 1. \quad (\text{R.1})$$

To verify additivity of χ_R , two supported summands have a supported sum even if their amplitudes cancel. Their OR is still one. The cases with an absent input follow from the additive identity. Multiplicativity is the corresponding support conjunction. The pair (p_R, χ_R) is injective: support zero identifies τ uniquely, whereas support one leaves the amplitude to identify $r^\bullet$ uniquely. Thus the zero amplitude at supported zero retains an observable absent from the ordinary ring quotient.

For a unital ring map $f : R \rightarrow S$, the map $G(f)$ fixes absence and sends $r^\bullet$ to $f(r)^\bullet$. The operation rules prove it is a unital semiring map, and $p_S G(f) = f p_R$ on both sorts of input. In particular the actual scalar square is

$$\begin{array}{ccc} G(\mathbb{Z}) & \xrightarrow{G(\iota)} & G(\mathbb{C}) \\ p_{\mathbb{Z}} \downarrow & & \downarrow p_{\mathbb{C}} \\ \mathbb{Z} & \xrightarrow{\iota} & \mathbb{C}. \end{array} \quad (\text{R.2})$$

The lower-left arithmetic target is the full infinite ring $\mathbb{Z}$. No finite characteristic or Boolean quotient replaces it in (R.2).

The original pointed-monoid blueprint base has elements $\{\tau, 1\}$, absorbing τ , and the empty-sum relation $\emptyset \equiv \tau$. It does not impose $1 + 1 = 1$. Its original structural map sends these elements to absence and the unit in $G(R)$. This defines the chart's structure over $\mathfrak{b}_\tau$. The support map in (R.1), whose codomain does impose Boolean addition, is a further map, not that structural map. The stated operations prove the two maps are compatible; their different additive relations are not identified.

For a complex linear map $f : E \rightarrow F$ at an admitted support label λ , its split lift sends (λ, v) to $(\lambda, f v)$ and external τ to external τ . It is additive because f is, and commutes with supported scalar multiplication for the same reason. If $f v = 0$, its value is $(\lambda, 0)$. This proves the support rule

used by every linear complex, quotient and kernel below. Between labels, the same statement uses the explicitly specified linear transport; the PL chapter calculates a transport that kills a nonzero relation class to supported zero, without deleting its source label.

142 The actual cohomological route of a hypothetical zero

The full-space definitions of $V, \mathcal{B}, \Theta, D, \mathcal{M}$ are given in BK.1 and proved against the original source in the companion chapters. In particular

$$g(s) = 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s), \quad \mathcal{M}\Theta\phi = gH_\phi.$$

The exact arithmetic object is $Q = \mathcal{B}/\Theta V$, with its original locally convex quotient topology. The later global theta retraction proves this quotient Hausdorff in that topology; it does not substitute an L^2 completion for Q .

On the original four-point chart $+, - < \eta < \sigma$, the arithmetic diagram is

$$\mathcal{T} = (V, V, \mathcal{B}, 0; \Theta, \Theta\mathcal{F}, 0).$$

The two-leg complex in degrees 0, 1 is

$$A_\tau(\mathcal{T}) = [V \oplus V \xrightarrow{(\phi, \psi) \mapsto \Theta(\phi - \hat{\psi})} \mathcal{B}]. \quad (\text{R.3})$$

Its full H^1 is Q . The derived restriction comparison of the diagram is $A_\tau(\mathcal{T}) \rightarrow \mathcal{T}_\sigma[0] = 0$; its homotopy fibre is (R.3) itself. The companion tau proof computes the projective resolution, both representatives of restriction, their homotopy, the fibre, its right adjoint, and the induced residue map. Thus nonzero classes sent to supported zero at sigma remain in the actual relative arithmetic cohomology. There is no inference here that the zero stalk makes Q vanish.

The counterfactual studied throughout the calculations is the existence of an actual nontrivial zero

$$\rho = \frac{1}{2} + \delta + i\gamma, \quad 0 < \delta < \frac{1}{2}, \quad \gamma > 0,$$

with its full positive order m . The original conjugation and functional equation give the complete reflection-conjugation quartet of the same order. Choose that full packet and retain

$$h(s) = \prod_{\epsilon, \eta \in \{-1, 1\}} (s - \frac{1}{2} - \epsilon\delta - i\eta\gamma)^m, \quad v_h = g/h, \quad v_h = j_h(v_h). \quad (\text{R.4})$$

Here division is entire because these are stipulated actual zeros, and v_h is a unit because their complete orders were used. Its entire Taylor class, including every nonconstant coefficient, is retained. This is the temporary counterfactual input to deductions, not evidence that any such zero exists.

The original arithmetic jet sequence, proved in the retained source and extended to every nonzero polynomial in BK, is

$$0 \longrightarrow Q[h(D)] \longrightarrow E_h \xrightarrow{\times j_h g} E_h \longrightarrow Q/h(D)Q \longrightarrow 0, \quad E_h = \mathbb{C}[s]/(h). \quad (\text{R.5})$$

For the actual complete packet, $j_h g = 0$. Its finite torsion class is therefore a full copy of E_h , and the Mellin observation on that copy includes the invertible factor v_h rather than dropping it. The original representative map uses the inverse unit to obtain $J_h \sigma_h = 1$. The Duhamel chapter gives its source representatives, its nonsplit source extension and its full scaling action explicitly.

At each local zero its action under $U_a F(x) = F(x/a)$, $a > 0$, is

$$a^\rho \sum_{j=0}^{m-1} \frac{(\log a)^j}{j!} N_\rho^j. \quad (\text{R.6})$$

This is not replaced by its reduced eigenvalue. BK and DP prove that the full-source balanced Mellin kernel cannot contain, cancel or hide this finite primary block. PL proves that proper source labels have additional finite kernel classes, even at parameters that are not zeros of g , and calculates their exact transition to the full source. This is why the source labels cannot be suppressed when using (R.5).

The mixed-support chapter next carries (R.4)–(R.6) through the actual coefficient synchronization. Its trace retract proves that the original arithmetic eigenclass remains nonzero. The complex-linear lift of the integral coefficient Frobenius adds roots of unity to the spectrum, and has a fixed coefficient line on which the arithmetic eigenvalue is unchanged. All tensor amplifications in this statement are over $\mathbb{C}$, as in the original external product; tensoring the local top nilpotent over E_h instead would give a different map and could annihilate it.

The tensor programme also contains more than its cyclic sum variable. The full conormal and symmetric chapters preserve the relative occupation algebra, its local lengths, original cochain signs, residue/Jacobian comparison and source representatives. In particular two full symmetric-square occupation factors can both have sum eigenvalue 1 while the difference of their idempotents has intrinsic arithmetic trace $-2m^2$. The detailed proof identifies the actual mixed derivative jet that detects this trace. Purity of a sum eigenvalue alone therefore cannot erase these retained relative directions.

Finally the actual holonomy comparison retains the common source generated by v_h and its tensor convolution. Its canonical section has a computed relation-valued action defect. The holonomy chapter proves a lower bound for its full original boundary energy at every phase and every admitted finite degree, and a spectral-distance lower bound for the associated Laplacian boundary. The concluding volume calculation compares those restrictions with the proved scalar arithmetic upper estimate. That comparison, rather than an auxiliary Gamma example, determines the remaining numerical range obtained by this continuation.

143 What the purity construction does, and the precise remaining calculation

The original finite coefficient algebra has proved weight-zero coefficient purity. The later finite-field exponential family has its proved weight-one cohomology under its stated good-reduction hypotheses; its external k -fold product retains degree k and the corresponding weight. The original source computes specialization and period maps relating its full arithmetic packet to those families. These are actual constructions. The supplied audits retain their periods, connections, cohomological degrees and kernels, rather than calling the families unrelated to the arithmetic source.

The operational numerical use of the Deligne-style amplification in this programme is to control the original arithmetic action or its equivalent original source volume defect uniformly as tensor degree grows. A period congruence transports both the metric and its action defect. It does not set the defect to zero. For the following formula let E be the retained finite tensor coefficient space (or a specified invariant constituent), let $A_k : E \rightarrow E$ be the restriction of the sum operator, and let $R : E \rightarrow L^2((\mathbb{R}_{>0})^k, dx_1 \cdots dx_k)$ be the original source section. Its columns are in $\mathcal{B}^{\otimes k}$, so $D^{(k)} = \sum_i (-x_i \partial_{x_i})$ acts on them. Put $G = R^* R$ and $\mathcal{B} = D^{(k)} R - R A_k$ as maps on this exact E . The symbol $\mathcal{B}$ in this formula denotes the boundary map; the function space with the same inherited symbol is distinguished by its domain and codomain. The exact boundary formula, proved on the original $dx_1 \cdots dx_k$ source in the following chapters, is

$$A_k^* G + G A_k - kG = -(R^* \mathcal{B} + \mathcal{B}^* R), \quad \mathcal{B} = D^{(k)} R - R A_k. \quad (\text{R.7})$$

The source relation producing $\mathcal{B}$ is explicitly retained. Neither its zero cohomology class nor its zero observation at sigma sets either cross-pairing in (R.7) to zero. This continuation computes the contribution and gives a strictly positive counterfactual lower bound on its original energy.

For the actual four endpoints take $k \geq 2$ and the original cyclic sum quotient of length $q = (1 + k(m - 1))(k + 1)^2$. In that quotient let $V_{k,N}^\nu = \det G_{k,N}^\nu > 0$, $N \geq q - 1$, be the determinant of the canonical source Gram for the specified measure $\nu \in \{\text{ar}, \Gamma\}$, as defined in the holonomy and volume chapters. Define $\mathcal{B}_{h,k}^\nu = \log(V_{k,q-1}^\nu/V_{k,2q-1}^\nu) + \log(V_{k,q}^\nu/V_{k,2q}^\nu)$. Substituting the positive volume ratios at all four endpoints gives the exact retained comparison

$$\mathcal{B}_{h,k}^{\text{ar}} = \mathcal{B}_{h,k}^\Gamma + \log \frac{T_{k,q-1} T_{k,q}}{T_{k,2q-1} T_{k,2q}}, \quad T_{k,N} = V_{k,N}^{\text{ar}}/V_{k,N}^\Gamma. \quad (\text{R.8})$$

The final auxiliary Gamma counterexample retains the reference volumes but does not calculate the actual signed correction in (R.8). The new concluding calculation bounds the actual four-window quantity on both sides, retaining this exact signed term. The coarse scalar upper and lower bound functions are compatible; the refined common-source interval retains unevaluated quantities, as detailed in the final combined restriction. No actual off-line zero is certified by the coarse compatibility, and no RH contradiction follows from those bounds.

Consequently the remaining issue after the mathematics below is the stronger original arithmetic control of (R.7), or of the joint signed term in (R.8), that would close the amplification argument. This is a precise limit of the results obtained, not an assumption used to prove them. The manuscript supplies the new exact maps and inequalities in full and retains the complete original sources for further calculation.

144 1. Objects, provenance, and cochain conventions

The complete successor *A global retraction of the original theta complex over the tau base*, retained as `Tau_Global_Comparison_2026-09-12/RESEARCH_NOTE.md`, was also read completely. Its SHA256 is 496f3ec752e3e67ddafaae7423feb300b1faa789ca6907872f8d539bdf6e1859. Equations (6.12a)–(6.12i) below reproduce its constructive retraction and evaluate the previously general closure kernel for this exact source.

This calculation continues equations (18)–(48) of *Arithmetic cohomology over the tau-base*. The complete source `NOTE.md` has SHA256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3. Its complete retained dependency sources/`Split_Support_Actual_Comparison__CONTINUATION.tex` has SHA256 98e8aaa63b1f7ee4661c043cd985ca274646b749f36d23d2ec46cbc4b0737dc5. Both were read completely for this calculation. The category, original theta source, masks, analytic topology, multiplicities, and actions below are those sources' objects.

Let $E = \mathbb{C}$, let P have order $+$ $< \eta < \sigma$ and $-$ $< \eta < \sigma$, and let $\mathcal{A} = \text{Fun}(P, \text{Vect}_E)$. A diagram $F \in \mathcal{A}$ is specified by

$$U = F_+, \quad V_- = F_-, \quad M = F_\eta, \quad S = F_\sigma, \quad r_+ : U \rightarrow M, \quad r_- : V_- \rightarrow M, \quad t : M \rightarrow S. \quad (1.1)$$

Its remaining two arrows are the composites tr_+ and tr_- . The symbol V_- here denotes a general stalk; V in Section 5 denotes the original even Schwartz source.

Use cohomological complexes. For a chain map $f : C \rightarrow D$, define

$$\text{Cone}(f)^n = D^n \oplus C^{n+1}, \quad d(y, x) = (d_D y + f x, -d_C x), \quad d_{C[k]} = (-1)^k d_C. \quad (1.2)$$

After ordering its summands as $C^n \oplus D^{n-1}$, the homotopy fibre is

$$\text{Fib}(f) = \text{Cone}(f)[-1], \quad d(c, y) = (d_C c, -d_D y - f c). \quad (1.3)$$

For internal Hom use

$$d_{\text{Hom}} h = d_W h - (-1)^{|h|} h d_C. \quad (1.4)$$

These conventions, including the minus sign in the second component of (1.3), remain fixed throughout.

145 2. The original pushforward and the complete restriction fibre

Define $P_x(y) = E$ for $x \leq y$, and zero otherwise, with identity arrows between nonzero stalks. A natural map $P_x \rightarrow F$ is uniquely specified by the image of $1 \in P_x(x)$, so $\text{Hom}(P_x, F) = F_x$. Evaluation is exact, hence P_x is projective. The sequence

$$0 \longrightarrow P_\eta \xrightarrow{v \mapsto (v, -v)} P_+ \oplus P_- \xrightarrow{(u, v) \mapsto u+v} \mathbf{E} \longrightarrow 0 \quad (2.1)$$

is exact: at $+$ and $-$ its last arrow is identity; at η, σ its kernel is the displayed anti-diagonal; all restriction squares commute. Consequently a representative of the source functor is

$$C(F) = A_\tau(F) = [U \oplus V_- \xrightarrow{\delta} M], \quad \delta(u, v) = r_+u - r_-v, \quad (2.2)$$

in degrees 0, 1. With (1.4), applying internal Hom to (2.1) initially gives differential $-\delta$; the explicit isomorphism to (2.2) is identity in degree zero and minus identity in degree one. This is a change between two stated cochain presentations, not a modification of the arithmetic differential in (2.2).

The two representatives of derived restriction are

$$f_+(u, v) = tr_+u, \quad f_-(u, v) = tr_-v, \quad C(F) \longrightarrow S[0]. \quad (2.3)$$

They are chain maps because the target has only degree zero. Their difference is $t\delta$. Thus $h^1 = t : M \rightarrow S$ satisfies $f_+ - f_- = d_S h + h d_C$. In particular both represent the same natural derived morphism.

Using f_+ , the complete fibre is

$$B_\sigma(F) = [U \oplus V_- \xrightarrow{b} M \oplus S], \quad b(u, v) = (r_+u - r_-v, -tr_+u). \quad (2.4)$$

The cone itself has degrees $-1, 0$ and differential

$$U \oplus V_- \longrightarrow S \oplus M, \quad (u, v) \longmapsto (tr_+u, -r_+u + r_-v). \quad (2.5)$$

No stalk or quotient has been dropped in either presentation.

Put

$$I = \text{im } r_+ \cap \text{im } r_- \subset M. \quad (2.6)$$

Then the complete cohomology of (2.4) is

$$H^0 B_\sigma(F) = \{(u, v) : r_+u = r_-v \in \ker t\}, \quad (2.7)$$

$$H^1 B_\sigma(F) = \frac{M \oplus S}{\{(r_+u - r_-v, -tr_+u) : u \in U, v \in V_-\}}, \quad (2.8)$$

and all its other cohomology groups vanish. There are exact sequences

$$0 \longrightarrow \ker r_+ \oplus \ker r_- \longrightarrow H^0 B_\sigma(F) \xrightarrow{(u, v) \mapsto r_+u} I \cap \ker t \longrightarrow 0, \quad (2.9)$$

$$0 \longrightarrow S/t(I) \xrightarrow{[s] \mapsto [(0, s)]} H^1 B_\sigma(F) \xrightarrow{[(m, s)] \mapsto [m]} M/(\text{im } r_+ + \text{im } r_-) \longrightarrow 0. \quad (2.10)$$

For (2.9), every element of the displayed intersection has a preimage under each leg, and the kernel is exactly the indicated direct sum. For (2.10), the last map is well defined and surjective. A class in its kernel has $m = \delta(u, v)$; subtracting $b(u, v)$ replaces it by $(0, s + tr_+u)$. The class of $(0, s)$ vanishes exactly when there exist u, v with $r_+u = r_-v$ and $s = -tr_+u$, which is precisely $s \in t(I)$. This proves the sequence, including the sign in its presentation. These are exact sequences of specified objects, without a chosen splitting.

Equivalently the restriction long exact sequence is

$$0 \rightarrow H^0 B_\sigma(F) \rightarrow \ker \delta \xrightarrow{f_+} S \xrightarrow{s \mapsto [(0, -s)]} H^1 B_\sigma(F) \rightarrow \operatorname{coker} \delta \rightarrow 0. \quad (2.11)$$

Its signs agree with (1.2): when the fibre-to-source arrow is the positive projection, the rotated distinguished triangle has boundary arrow minus the inclusion of S in $\operatorname{Cone}(f) = B_\sigma(F)[1]$. This accounts for the minus in (2.11); the independently specified exact presentation (2.10) uses the positive inclusion. The only nonzero possible cone cohomology is $H^{-1} \operatorname{Cone}(f) = H^0 B_\sigma(F)$ and $H^0 \operatorname{Cone}(f) = H^1 B_\sigma(F)$.

The two representative fibres are related by the chain isomorphism

$$B_{\sigma,+}(F) \longrightarrow B_{\sigma,-}(F), \quad \Phi^0 = 1, \quad \Phi^1(m, s) = (m, s + tm), \quad (2.12)$$

whose inverse subtracts tm . Indeed $-f_+ + t\delta = -f_-$. Thus the fibre calculation does not depend on a privileged choice of the plus leg.

146 3. Naturality and the right-adjoint comparison

A morphism $a : F \rightarrow F'$ consists of maps $a_+, a_-, a_\eta, a_\sigma$ commuting with r_+, r_-, t . The fibre map is exactly

$$B_\sigma(a)^0 = a_+ \oplus a_-, \quad B_\sigma(a)^1 = a_\eta \oplus a_\sigma. \quad (3.1)$$

For example its second differential component is $-a_\sigma t r_+ u = -t' r'_+ a_+ u$; the first follows from the two other commutative squares. Formula (3.1) also commutes with (2.12), because $a_\sigma t = t' a_\eta$. This proves the naturality of every kernel, quotient, exact sequence, and representative comparison above.

For a vector space W , let $I_x(W)(y) = W$ for $y \leq x$, and zero otherwise. A natural map $F \rightarrow I_x(W)$ is uniquely determined by its component $F_x \rightarrow W$; the other nonzero components are precomposition with $F_y \rightarrow F_x$. Hence

$$\operatorname{Hom}_{\mathcal{A}}(F, I_x(W)) = \operatorname{Hom}_E(F_x, W). \quad (3.2)$$

Every vector space is injective over E : a linear map on a subspace extends after extending a basis. Therefore the right side is exact contravariantly in F , and $I_x(W)$ is injective.

Let

$$K_\tau(W) = [I_\eta(W) \xrightarrow{(+\operatorname{res}, -\operatorname{res})} I_+(W) \oplus I_-(W)] \quad (3.3)$$

have degrees $-1, 0$. It is a bounded injective complex. Applying (3.2) gives

$$R \operatorname{Hom}_{\mathcal{A}}(F, K_\tau(W)) = [\operatorname{Hom}(M, W) \xrightarrow{\ell \mapsto (\ell r_+, -\ell r_-)} \operatorname{Hom}(U, W) \oplus \operatorname{Hom}(V_-, W)]. \quad (3.4)$$

The internal Hom of (2.2) into $W[0]$ has exactly this differential: the element ℓ has degree -1 , so (1.4) gives $d\ell = +\ell\delta$. In particular the signs in the original single-factor adjoint and residue arrow require no repair.

For completeness the adjunction holds for bounded complexes, with all totalization signs specified. Define

$$C(F)^n = (F_+^n \oplus F_-^n) \oplus F_\eta^{n-1}, \quad d(b, m) = (d_F b, \delta b - d_F m), \quad (3.5)$$

and $K_\tau(W) = K_\tau(E) \otimes W$, with tensor differential. A degree n map $F \rightarrow K_\tau(W)$ consists of $b_p : F_+^p \oplus F_-^p \rightarrow W^{p+n}$ and $a_p : F_\eta^p \rightarrow W^{p+n+1}$. The isomorphism to $\operatorname{Hom}^n(C(F), W)$ keeps b_p and takes

$$\ell_p = (-1)^{n+1} a_p. \quad (3.6)$$

On the source differential these components become

$$a'_p = -d_W a_p - (-1)^n a_{p+1} d_F, \quad b'_p = d_W b_p + a_p \delta - (-1)^n b_{p+1} d_F. \quad (3.7)$$

On the target they become

$$\ell'_p = d_W \ell_p + (-1)^n \ell_{p+1} d_F, \quad b'_p = d_W b_p - (-1)^n (b_{p+1} d_F + \ell_p \delta). \quad (3.8)$$

Substitution of (3.6) gives equality in both components. Bounded injective targets compute derived Hom, and (2.1), with the degree n multiplier $(-1)^n$ on its eta component, gives (3.5) from its projective resolution. This proves the bounded derived adjunction as an actual natural chain isomorphism.

The stalk complexes of (3.3) are $[W \xrightarrow{1} W]$ at $+$, $[W \xrightarrow{-1} W]$ at $-$, $W[1]$ at η , and zero at σ . The stalkwise kernel diagram is $S_\eta W$, supported only at η . Its inclusion in degree -1 is a natural quasi-isomorphism

$$S_\eta W[1] \longrightarrow K_\tau(W). \quad (3.9)$$

Since every point of P lies below σ , $I_\sigma(W)$ is the constant diagram W . It represents the dual of the sigma stalk. The actual adjoint of restriction is

$$\alpha_+ : I_\sigma(W) \longrightarrow K_\tau(W), \quad (3.10)$$

given in degree zero by restriction into $I_+(W)$, and zero into $I_-(W)$. The alternative α_- restricts into $I_-(W)$. Their difference is $d_K h$, where $h : I_\sigma(W) \rightarrow I_\eta(W)$ is restriction in degree -1 . Applying Hom to (3.10) sends $w : S \rightarrow W$ to $(wtr_+, 0)$, which is exactly precomposition with f_+ . This identifies the morphism, rather than only comparing its endpoints.

147 4. The dual of the restriction fibre and its nonsplit extension

Define the bounded injective complex

$$R_\tau(W) = [I_\eta(W) \oplus I_\sigma(W) \xrightarrow{d_R} I_+(W) \oplus I_-(W)], \quad (4.1)$$

in degrees $-1, 0$, where

$$d_R(\ell, w) = (\ell \text{res}_+ - w \text{res}_{\sigma,+}, -\ell \text{res}_-). \quad (4.2)$$

Here restriction symbols denote the natural maps of injective diagrams. Formula (3.2) makes its Hom differential

$$(\ell, w) \longmapsto (\ell r_+ - wtr_+, -\ell r_-). \quad (4.3)$$

This is precisely precomposition with the two components $(\delta, -f_+)$ of (2.4), with the positive sign supplied by degree -1 in (1.4). Therefore

$$\boxed{R \text{Hom}_A(F, R_\tau(W)) \cong R \text{Hom}_E(B_\sigma(F), W).} \quad (4.4)$$

Equivalently $R_\tau(W) = \text{Cone}(-\alpha_+)$. Multiplying its $I_\sigma(W)$ cone summand by -1 identifies this presentation with $\text{Cone}(\alpha_+)$; (4.2) fixes which presentation is being used in (4.4).

At $+$, the differential is $(\ell, w) \mapsto \ell - w$, with kernel (w, w) . At $-$, it is $(\ell, w) \mapsto -\ell$, with kernel $(0, w)$. At η it has domain $W \oplus W$ and zero target, and at σ it has domain W and zero target. All degree-zero cokernels vanish. Consequently, if $D(W)$ has stalks

$$D(W)_+ = W, \quad D(W)_- = W, \quad D(W)_\eta = W \oplus W, \quad D(W)_\sigma = W, \quad (4.5)$$

and arrows

$$w \longmapsto (w, w) \quad (+ \rightarrow \eta), \quad w \longmapsto (0, w) \quad (- \rightarrow \eta), \quad (u, w) \longmapsto w \quad (\eta \rightarrow \sigma), \quad (4.6)$$

the kernel inclusion is a natural quasi-isomorphism $D(W)[1] \rightarrow R_\tau(W)$.

There is an exact sequence of diagrams

$$0 \longrightarrow S_\eta W \xrightarrow{w \mapsto (u,0)} D(W) \xrightarrow{\text{second coordinate}} I_\sigma(W) \longrightarrow 0. \quad (4.7)$$

At $+$, $-$, σ the last map is identity under (4.5); at η its kernel is the first coordinate. Naturality follows directly from (4.6). For $W \neq 0$, the extension has no natural splitting. Indeed a splitting is identity at the plus and minus stalks, since the quotient there is identity. Commutation along $+\rightarrow\eta$ forces its η component to be $w \mapsto (w, w)$, whereas commutation along $-\rightarrow\eta$ forces $w \mapsto (0, w)$. They disagree on every nonzero $w \in W$. This proves nonsplitting explicitly.

In the original case $F_\sigma = 0$, every term $\text{Hom}(F, I_\sigma(W)) = \text{Hom}(0, W)$ is zero. Thus the inclusion $K_\tau(W) \rightarrow R_\tau(W)$ induces an actual equality of the represented Hom complexes, as well as an isomorphism in the derived category. The nonzero original global arithmetic classes are therefore all in the relative fibre, and their original adjoint is precisely the restriction of (4.4) to these objects.

148 5. Calculation on the original theta source and every mask

Retain the exact original spaces and maps

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx, \quad (5.1)$$

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^k F(x)| < \infty \text{ for all } b \in \mathbb{Z}, k \geq 0\}, \quad (5.2)$$

$$\Theta\phi(x) = \sum_{n \in \mathbb{Z} \setminus \{0\}} \phi(nx), \quad JF(x) = x^{-1}F(1/x), \quad J\Theta = \Theta\mathcal{F}. \quad (5.3)$$

The last identity is the retained Poisson identity. Explicitly, the full Poisson equation is $\sum_n \phi(nx) = x^{-1} \sum_n \widehat{\phi}(n/x)$; the two zero terms vanish by (5.1), giving (5.3). At infinity every differentiated summand is bounded by a constant times $(|n|x)^{-N}$ for any chosen $N > 1$; summing $2 \sum_{n \geq 1} n^{-N}$ proves rapid decay. Applying (5.3) proves arbitrary power decay at zero, with all derivatives, so $\Theta : V \rightarrow \mathcal{B}$. The Fourier transform preserves (5.1) because it exchanges the value and integral conditions, and its square is reflection, which is identity on even functions.

The map Θ is injective. For $\Re s = c > 1$, absolute convergence gives

$$\mathcal{M}\Theta\phi(s) = 2\zeta(s)\mathcal{M}\phi(s), \quad \mathcal{M}F(s) = \int_0^\infty F(x)x^s \frac{dx}{x}. \quad (5.4)$$

For absolute convergence, the integral of $|\phi(nx)|x^{c-1}$ is $n^{-c} \int_0^\infty |\phi(u)|u^{c-1}du$, and both the integral and $\sum n^{-c}$ are finite. The Euler product is nonzero for $c > 1$, as follows from absolute convergence of its logarithm. If $\Theta\phi = 0$, (5.4) makes $\mathcal{M}\phi(c+it) = 0$ for every real t . This is the Fourier transform, with its frequency sign explicitly reversed, of the integrable function $y \mapsto e^{cy}\phi(e^y)$. Fourier uniqueness gives zero almost everywhere and continuity gives zero everywhere. Evenness then gives $\phi = 0$ on the full real line.

The joint sheaf is

$$\mathcal{T} = (V, V, \mathcal{B}, 0; \Theta, \Theta\mathcal{F}, 0), \quad C(\mathcal{T}) = [V \oplus V \xrightarrow{\Theta(\phi-\widehat{\psi})} \mathcal{B}]. \quad (5.5)$$

Its restriction map is zero on both chain representatives, so

$$B_\sigma(\mathcal{T}) = C(\mathcal{T}), \quad \text{Cone}(\text{res}_\sigma) = C(\mathcal{T})[1]. \quad (5.6)$$

Injectivity just proved gives

$$H^0 B_\sigma(\mathcal{T}) = \{(\widehat{\psi}, \psi) : \psi \in V\}, \quad H^1 B_\sigma(\mathcal{T}) = Q := \mathcal{B}/\Theta V. \quad (5.7)$$

The quotient here is the algebraic quotient with its original quotient locally convex topology. The later global retraction source proves that this image is closed; its exact retraction and the resulting zero closure kernel are included after (6.12) below.

Let $L = \mathcal{P}(\{+, -\})$. For each nonempty mask $A \in L$, retain V at each admitted leg and the zero coefficient space at a missing leg, retain $\mathcal{B}$ at eta and zero at sigma, and retain the restrictions in (5.5). The empty mask has the zero diagram. Every nonempty A has restriction fibre exactly $C(\mathcal{T}_A)$; its differential image is ΘV , since both Θ and $\Theta\mathcal{F}$ have that image. A one-leg differential is injective, with its literal plus or minus sign retained. It follows that

$$H^0 B_\sigma(\mathcal{T}_A) = \begin{cases} V, & A = \{+, -\}, \\ 0, & |A| = 1, \end{cases} \quad H^1 B_\sigma(\mathcal{T}_A) = Q \quad (A \neq \emptyset). \quad (5.8)$$

For mask inclusions the eta map is identity and leg maps are coordinate inclusions, hence the induced H^1 map is exactly identity on Q . This explicitly proves compatibility with every original mask transport.

Reconstruction gives

$$\tilde{H}^1 B_\sigma = \{\tau\} \sqcup \bigsqcup_{\emptyset \neq A \subseteq \{+, -\}} \{A\} \times Q. \quad (5.9)$$

The scalar $e = 0_E^\bullet \in G(E)$ sends (A, q) to $(A, 0)$. The scalar τ sends it to the absent element. Linear restriction to the zero coefficient at sigma sends q to zero, but its supported reconstruction is $(A, q) \mapsto (A, 0)$, preserving A . No class of (5.9) becomes absent merely because its coefficient restricts to zero. The same statement applies to (2.4), (3.4), and (4.4) fibrewise, with dual label arrows given by actual precomposition and hence indexed by L^{op} .

149 6. Finite jets, their full kernel, and the retained topology

Put $g = 2\xi$, where

$$\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s). \quad (6.1)$$

The source's full-plane multiplier identity is

$$\mathcal{M}\Theta\phi = gH_\phi, \quad H_\phi = \frac{\mathcal{M}\phi}{\frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)} \in \mathcal{O}(\mathbb{C}). \quad (6.2)$$

Here is the full continuation used in this identity. Write the Taylor expansion of the even Schwartz function at zero as $\phi(x) = \sum_{j=0}^N a_{2j}x^{2j} + O(x^{2N+2})$. Subtract this finite sum in its Mellin integral over $(0, 1)$. The remainder is holomorphic for $\Re s > -2N - 2$, while the subtracted terms have integrals $a_{2j}/(s+2j)$. The integral over $(1, \infty)$ is entire by Schwartz decay. Since N is arbitrary, $\mathcal{M}\phi$ has meromorphic continuation with only possible simple poles at the nonpositive even integers. The reciprocal $1/\Gamma(s/2)$ has a simple zero at each such integer and cancels each possible pole. At $s = 0$, the condition $a_0 = \phi(0) = 0$ removes the Mellin pole, and $1/\Gamma(s/2)$ cancels the explicit factor s in the denominator of H_ϕ . At $s = 1$, evenness and the integral condition give $\mathcal{M}\phi(1) = \frac{1}{2} \int_{\mathbb{R}} \phi = 0$, cancelling $s - 1$. No other denominator zero occurs, since the gamma function has no zeros. Thus the displayed H_ϕ is entire. Formula (5.4) proves (6.2) first on $\Re s > 1$, and analytic continuation proves it everywhere, with the original factor $g = 2\xi$ retained.

Let Z be a finite set of actual zeros of g with their actual orders m_ρ , and write

$$z_\rho = s - \rho, \quad g(s) = u_\rho(z_\rho)z_\rho^{m_\rho}, \quad u_\rho(0) \neq 0, \quad A_Z = \bigoplus_{\rho \in Z} \mathcal{O}_\rho/(g). \quad (6.3)$$

The germ coordinate z_ρ , the full jet length, and the actual unit u_ρ are retained. The jet arrow is

$$J_Z : \mathcal{B} \longrightarrow A_Z, \quad (J_Z F)_\rho = \sum_{j=0}^{m_\rho-1} \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} z_\rho^j. \quad (6.4)$$

Equation (6.2) proves $J_Z \Theta = 0$, so it induces $q_Z : Q \rightarrow A_Z$.

Here is a full finite interpolation proof, with the original dx Riesz density preserved. Index jets by $\alpha = (\rho, j)$, and fix any $R > 0$ and $0 < R' < R$. Let

$$\eta_{R'}(y) = \begin{cases} \exp[-1/((R')^2 - y^2)], & |y| < R', \\ 0, & |y| \geq R', \end{cases} \quad r_\alpha(x) = x^{\bar{\rho}-1}(\log x)^j/j!. \quad (6.5)$$

Set

$$B_{\alpha\beta} = \frac{1}{j!k!} \int_{-R'}^{R'} \eta_{R'}(y) e^{(\rho+\bar{\sigma}-1)y} y^{j+k} dy, \quad \beta = (\sigma, k). \quad (6.6)$$

This is $\ell_\alpha(\eta_{R'}(\log x)r_\beta(x))$, where ℓ_α is the corresponding component of (6.4). It is Hermitian. For a column c , its quadratic form is

$$\bar{c}^\top B c = \int_{-R'}^{R'} \eta_{R'}(y) e^{-y} \left| \sum_\alpha \bar{c}_\alpha e^{\rho y} y^j / j! \right|^2 dy. \quad (6.7)$$

The exponential polynomials are independent: for a fixed exponent ρ , apply $\prod_{\sigma \neq \rho} (\partial_y - \sigma)^{m_\sigma}$ to a vanishing linear combination. It kills every other exponent block, and acts on the remaining block by $e^{\rho y}$ times $\prod_{\sigma \neq \rho} (\partial_y + \rho - \sigma)^{m_\sigma}$. Each factor on finite-degree polynomials is invertible, since it is a nonzero constant plus a nilpotent differentiation operator, with inverse given by the terminating geometric series. Hence that polynomial block is zero. This holds for every ρ , proving independence. Therefore (6.7) is strictly positive for $c \neq 0$, so B is invertible.

For $v \in A_Z$, the function

$$s_Z(v)(x) = \eta_{R'}(\log x) \sum_\beta (B^{-1}v)_\beta r_\beta(x) \quad (6.8)$$

is smooth, belongs to $\mathcal{B}$, has support in $[e^{-R'}, e^{R'}] \subset (e^{-R}, e^R)$, and satisfies $J_Z s_Z(v) = v$ by matrix multiplication. Thus (6.4) and q_Z are surjective, with an explicitly calculated finite-dimensional continuous section of (6.4).

For continuity, choose an integer $N > |\Re \rho|$ and put $p_N(F) = \max(\sup x^N |F(x)|, \sup x^{-N} |F(x)|)$. Splitting the integral at one gives the exact bound

$$|\ell_{\rho,j}(F)| \leq p_N(F) \left((N + \Re \rho)^{-j-1} + (N - \Re \rho)^{-j-1} \right). \quad (6.9)$$

Indeed the two integrals of $|\log x|^j/j!$ against $x^{N+\Re \rho} dx/x$ and $x^{-N+\Re \rho} dx/x$ are the two displayed terms. This also proves that the Mellin jet derivatives used here are well-defined by dominated differentiation.

Define the actual retained kernel spaces, using $\mathcal{K}_Z$ to avoid changing the different space named $\mathcal{B}_Z$ in the source's finite arithmetic extension:

$$\mathcal{K}_Z = \ker J_Z, \quad Q_Z^0 = \mathcal{K}_Z / \Theta V. \quad (6.10)$$

They give exact sequences

$$0 \longrightarrow \mathcal{K}_Z \longrightarrow \mathcal{B} \xrightarrow{J_Z} A_Z \longrightarrow 0, \quad \boxed{0 \longrightarrow Q_Z^0 \longrightarrow Q \xrightarrow{q_Z} A_Z \longrightarrow 0.} \quad (6.11)$$

The first is split by (6.8); the second is split as a topological vector-space sequence by the induced section. No equivariance of this section is asserted: only the arrows (6.11) are canonical scaling morphisms.

To verify the topology assertion, the map $(F_0, v) \mapsto F_0 + s_Z(v)$ is a continuous linear bijection $\mathcal{K}_Z \oplus A_Z \rightarrow \mathcal{B}$, with continuous inverse $F \mapsto (F - s_Z J_Z F, J_Z F)$. Since $\Theta V \subset \mathcal{K}_Z$, passing to the

quotient gives the claimed topological direct sum. By (6.9), $\mathcal{K}_Z$ is closed, so $\overline{\Theta V} \subset \mathcal{K}_Z$. The same proof gives

$$0 \rightarrow \mathcal{K}_Z / \overline{\Theta V} \rightarrow Q^H := \mathcal{B} / \overline{\Theta V} \rightarrow A_Z \rightarrow 0, \quad \ker(Q \rightarrow Q^H) = \overline{\Theta V} / \Theta V. \quad (6.12)$$

Thus every finite jet survives both specified quotients, with the closure kernel written explicitly. No new global topology has been substituted.

For this actual source the kernel in (6.12) is zero. We include the later source's constructive reason, retaining its auxiliary cutoffs and contraction constant. Let μ be the arithmetic Möbius function, and define on $x \neq 0$

$$\mathcal{U}F(x) = \frac{1}{2} \sum_{n \geq 1} \mu(n) F(n|x|). \quad (6.12a)$$

For $j \geq 0$, write $x^j \partial_x^j = P_j(D)$, where $P_j(T) = (-1)^j T(T+1) \cdots (T+j-1)$, and let $C_{N,j}(F)$ be the sum of $p_{N,k}(F) = \sup x^N |D^k F|$ weighted by the absolute coefficients of P_j . For each integer $N > 1$, termwise differentiation gives

$$|\partial_x^j \mathcal{U}F(x)| \leq \frac{1}{2} \zeta(N) C_{N,j}(F) x^{-N-j} \quad (x > 0). \quad (6.12b)$$

Uniform convergence away from zero justifies each derivative. On the original theta image the double sum is absolutely convergent, bounded by $\sum_{k \geq 1} d(k) |\phi(kx)|$, which converges by Schwartz decay and $d(k) \leq k$. The identity $\sum_{n|k} \mu(n) = 1$ for $k = 1$, zero otherwise, therefore proves

$$\mathcal{U}\Theta\phi = \phi, \quad \mathcal{U}J\Theta\phi = \hat{\phi} \quad (x \neq 0). \quad (6.12c)$$

Choose the original type of real even compactly supported smooth cutoffs $0 \leq \alpha, \beta \leq 1$, each equal to one near zero, and set on $L^2(\mathbb{R}, dx)$

$$T = M_\alpha \mathcal{F}^{-1} M_\beta \mathcal{F}, \quad c = \|T\|, \quad YF = (1 - \alpha) \mathcal{U}F + \alpha \mathcal{F}^{-1}((1 - \beta) \mathcal{U}JF). \quad (6.12d)$$

The kernel of T is $\alpha(x)\beta(x-y)$, with squared L^2 norm $\|\alpha\|_2^2 \|\beta\|_2^2$, so T is compact. Both its factors are contractions. If $c = 1$, compactness supplies a norm-attaining unit vector f ; equality in both contraction inequalities forces $\hat{f}$ to have compact support where $\beta = 1$ and f to have compact support where $\alpha = 1$. Compact Fourier support makes the inverse Fourier integral entire, because the compactly supported L^2 transform is L^1 and allows all complex derivatives under its integral. This entire function vanishes on a real interval outside the support of f , hence vanishes identically, a contradiction. Therefore $c < 1$, and

$$(1 - T)^{-1} = \sum_{n \geq 0} T^n, \quad \|(1 - T)^{-1}\| \leq (1 - c)^{-1}. \quad (6.12e)$$

The cut-off exterior maps in Y are continuous into even Schwartz functions by (6.12b); their values are extended by zero where the cutoff vanishes near zero. The operator $T : L^2 \rightarrow \mathcal{S}$ is continuous: compact Fourier support bounds every derivative of $\mathcal{F}^{-1} M_\beta \mathcal{F} f$ by Cauchy-Schwarz, and multiplication by smooth compactly supported α controls every Schwartz seminorm. Thus $\Phi = (1 - T)^{-1} Y$ is Schwartz-valued and continuous: the equation $\Phi F = YF + T\Phi F$ bounds each Schwartz seminorm p by

$$p(\Phi F) \leq p(YF) + C_p (1 - c)^{-1} \|YF\|_2. \quad (6.12f)$$

It preserves evenness. With $\gamma_0 = e^{-\pi x^2}$ and $\gamma_2 = 2\pi x^2 e^{-\pi x^2}$, whose value/integral columns are $(1, 1)$, $(0, 1)$, define $P_V : \mathcal{S}(\mathbb{R})^{\text{even}} \rightarrow V$ by

$$P_V \phi = \phi - \phi(0) \gamma_0 - \left(\int_{\mathbb{R}} \phi - \phi(0) \right) \gamma_2, \quad \Lambda = P_V (1 - T)^{-1} Y. \quad (6.12g)$$

This continuous projection has image V and is identity on V . On $\Theta\phi$, (6.12c) gives $Y\Theta\phi = (1 - T)\phi$, so

$$\Lambda\Theta = 1_V, \quad K = 1_{\mathcal{B}} - \Theta\Lambda, \quad K^2 = K, \quad \ker K = \Theta V. \quad (6.12h)$$

The last equality follows in both directions by direct substitution. Since K is continuous, its kernel is closed. Therefore $\overline{\Theta V} = \Theta V$, $Q = Q^H$, and the closure kernel in (6.12) is exactly zero. The section

$$s : Q \rightarrow \mathcal{B}, \quad s[F] = KF \quad (6.12i)$$

is well-defined and continuous in the quotient topology, satisfies $qs = 1$ and $\Lambda s = 0$, and gives the topological decomposition $\mathcal{B} \cong V \oplus Q$ by $F \mapsto (\Lambda F, qF)$. Every cutoff and the factor $(1 - c)^{-1}$ remain in this construction. It establishes closedness of the theta image, and makes no assertion that the different kernel Q_Z^0 in (6.11) vanishes.

Let $\mathcal{T}_Z$ have the same source legs and sigma stalk as $\mathcal{T}$, eta stalk $\mathcal{K}_Z$, and the original restrictions. Then

$$0 \rightarrow \mathcal{T}_Z \rightarrow \mathcal{T} \xrightarrow{J_Z} S_\eta A_Z \rightarrow 0 \quad (6.13)$$

is exact at each stalk; its eta surjectivity is (6.8). Applying the explicit complexes gives a termwise exact sequence

$$0 \rightarrow C(\mathcal{T}_Z) \rightarrow C(\mathcal{T}) \rightarrow A_Z[-1] \rightarrow 0. \quad (6.14)$$

The kernel inclusion into the homotopy fibre of the last map is a quasi-isomorphism. This follows directly by quotienting that inclusion: the quotient fibre is the fibre of the identity of $A_Z[-1]$, whose two identical terms have an invertible differential and zero cohomology. Therefore the full cohomology of this jet-comparison fibre is

$$H^0 = V \quad \text{via } \psi \mapsto (\hat{\psi}, \psi), \quad H^1 = Q_Z^0, \quad (6.15)$$

and nothing else. On a nonempty one-leg mask $H^0 = 0$ and $H^1 = Q_Z^0$; the same proof applies to each exact mask diagram. On $S_\eta A_Z$ itself, sigma restriction is zero, its restriction fibre is exactly $A_Z[-1]$, and its restriction cone is $A_Z[0]$.

For disjoint finite packets Z, W of actual zeros, simultaneous application of (6.8) to $Z \cup W$ with prescribed coordinates $(0, w)$ proves the further exact surjection

$$Q_Z^0 \longrightarrow A_W. \quad (6.16)$$

Consequently the kernel in (6.11) retains all these explicitly reachable omitted packets. It has not been set to zero.

150 7. Original scaling, generator, and dual actions

For $a > 0$, retain $U_a F(x) = F(x/a)$. Substitution $x = ay$ gives

$$\mathcal{M}U_a F(s) = a^s \mathcal{M}F(s), \quad \widehat{U_a \phi} = aU_{1/a} \hat{\phi}. \quad (7.1)$$

These operators preserve the original test spaces: dilation rescales each defining Schwartz or $\mathcal{B}$ seminorm by finite constants, preserves evenness and the value-zero condition, and multiplies the integral by a . The source sheaf action is exactly

$$U_a^T : (\phi, \psi, F) \longmapsto (U_a \phi, aU_{1/a} \psi, U_a F). \quad (7.2)$$

The identities $\Theta U_a = U_a \Theta$ and (7.1) give

$$d(U_a \phi, aU_{1/a} \psi) = U_a \Theta(\phi - \hat{\psi}). \quad (7.3)$$

Thus (7.2) is a diagram automorphism and (3.1) proves equivariance of every restriction-fibre map. On $H^0 = V$ in the parameter ψ of (5.7), its action is $\psi \mapsto aU_{1/a}\psi$; on Q it is $[F] \mapsto [U_a F]$. Every support mask is fixed.

The infinitesimal generator for $a = e^t$ at $t = 0$ is $D = -x\partial_x$ on the plus and eta stalks, and $1 - D$ on the minus stalk. Differentiating (7.1) gives the original relation $\mathcal{F}D = (1 - D)\mathcal{F}$. Integration by parts, with zero boundary terms because $F \in \mathcal{B}$, gives $\mathcal{M}(DF) = s\mathcal{M}F$.

On the full local jet algebra,

$$U_a|_\rho = a^\rho \exp((\log a)N_\rho) = a^\rho \sum_{k=0}^{m_\rho-1} \frac{(\log a)^k}{k!} N_\rho^k, \quad N_\rho(z_\rho^j) = z_\rho^{j+1}, \quad (7.4)$$

where $N_\rho(z_\rho^{m_\rho-1}) = 0$. The generator is $\rho I + N_\rho$. This follows by multiplying the jet by the exact germ $a^{\rho+z_\rho}$, so (6.4), (6.11), (6.13), and (6.14) intertwine it; in particular $\mathcal{K}_Z$ and Q_Z^0 are stable under scaling. Nilpotent directions have not been replaced by their trace.

Let $\mathcal{L}_1 = E$ with action $w \mapsto aw$, the original integral-moment line. On every dual object the action is the induced Hom action

$$(U_a \ell)(v) = a\ell(U_{1/a}v). \quad (7.5)$$

The formula is forced by the evaluation map $\ell \otimes v \mapsto \ell(v) \in \mathcal{L}_1$: applying (7.5) and U_a to both inputs multiplies the result by a . Since all maps in Sections 3 and 4 are defined by precomposition and restriction, this proves their equivariance with (7.5), including every contravariant mask transport.

The known continuous section (6.12i) has an exact, retained scaling defect. Denote the induced action on Q by $\bar{U}_a$, and define

$$k_a = \Lambda U_a s : Q \rightarrow V, \quad U_a s - s\bar{U}_a = \Theta k_a. \quad (7.6)$$

To prove the second equality, use $1_{\mathcal{B}} = sq + \Theta\Lambda$ on $U_a s$, and $qU_a s = \bar{U}_a$. The group identity then gives, without dropping a boundary term,

$$k_{ab} = U_a k_b + k_a \bar{U}_b, \quad k_1 = 0. \quad (7.7)$$

Indeed expand $U_{ab}s - s\bar{U}_{ab}$ by first applying the equation for b , then that for a , and cancel the injective Θ . These maps are continuous by their formulas. Thus the known topological splitting is accompanied by the full original source-valued action defect.

151 8. Full finite residue arrow and its chain degree

The symmetry of the original $g = 2\xi$ used here follows directly from the original Gaussian Poisson formula, with no assumption on its zeros. Put $\psi_0(t) = \sum_{n \geq 1} e^{-\pi n^2 t}$. Poisson gives $\psi_0(t) = t^{-1/2} \psi_0(1/t) + \frac{1}{2}(t^{-1/2} - 1)$. For $\Re s > 1$, termwise integration gives $\pi^{-s/2} \Gamma(s/2) \zeta(s) = \int_0^\infty \psi_0(t) t^{s/2} dt/t$. Splitting at one and substituting $t = 1/v$ in the reflected term therefore yields the entire continuation

$$g(s) = 1 + s(s-1) \int_1^\infty \psi_0(t) (t^{s/2} + t^{(1-s)/2}) \frac{dt}{t}. \quad (8.0)$$

The constant is exactly one: the remaining elementary integral is $1/(s-1) - 1/s = 1/[s(s-1)]$. The bound $\psi_0(t) \leq e^{-\pi t}/(1 - e^{-\pi t})$ for $t \geq 1$ proves locally uniform convergence with all s -derivatives. The expression is invariant under $s \mapsto 1-s$, and its real coefficients give conjugation symmetry. Consequently $g^\dagger = g$, and g is not the zero function (for example its continuation has $g(0) = 1$).

Assume Z is reflection-stable, meaning the finite chosen set satisfies $\iota Z = Z$ for $\iota\rho = 1 - \bar{\rho}$; this selects an actual finite divisor, without a hypothesis on the location of its points. The completed function has $g^\dagger = g$ for $f^\dagger(s) = \overline{f(1 - \bar{s})}$. In original coordinates,

$$f_\rho^\dagger(z_\rho) = \sum_j (-1)^j \overline{f_{\iota\rho, j} z_\rho^j}, \quad u_\rho(z) = (-1)^{m_\rho} \overline{u_{\iota\rho}(-\bar{z})}. \quad (8.1)$$

The residue pairing, with its raw orientation, is

$$R_Z(f, h) = \sum_{\rho \in Z} \text{Res}_\rho \frac{f^\dagger(s)h(s)}{g(s)} ds. \quad (8.2)$$

Changing any representative by a multiple of g adds a holomorphic differential, so this is well-defined. At ρ , if $u_\rho(z)^{-1} = \sum_{k \geq 0} c_{\rho,k} z^k$, its literal formula is

$$R_Z(f, h) = \sum_{\rho} \sum_{i,j=0}^{m_\rho-1} (-1)^i \overline{f_{\iota\rho,i}} h_{\rho,j} c_{\rho,m_\rho-1-i-j}, \quad c_{\rho,k} = 0 \ (k < 0). \quad (8.3)$$

The matrix $G_{ij} = c_{\rho,m_\rho-1-i-j}$ has determinant $(-1)^{m_\rho(m_\rho-1)/2} u_\rho(0)^{-m_\rho} \neq 0$: reversing the columns makes it triangular with diagonal $u_\rho(0)^{-1}$, and reversal has the displayed sign. Multiplication of the i -th row by $(-1)^i$, together with the invertible reflection-permutation of blocks, preserves invertibility. Hence R_Z is perfect, including all nilpotent jets and actual analytic units.

For a meromorphic function k , expansion in z_ρ gives

$$\text{Res}_\rho k^\dagger(s) ds = -\overline{\text{Res}_{\iota\rho} k(s)} ds. \quad (8.4)$$

Only its coefficient of z^{-1} contributes, and reflection multiplies that coefficient by $(-1)^{-1} = -1$. Apply (8.4) to $k = u^\dagger f/g$, sum over the permuted divisor, and use $g^\dagger = g$. The result is

$$R_Z(f, h) = -\overline{R_Z(h, f)}. \quad (8.5)$$

The raw pairing is therefore skew-Hermitian. No phase has been inserted.

The identity $(a^s)^\dagger = a^{1-s}$ gives

$$R_Z(U_a f, U_a h) = a R_Z(f, h). \quad (8.6)$$

Thus the following is an injective linear equivariant map from the conjugate vector space:

$$\overline{A_Z} \longrightarrow H^{-1} R \text{Hom}_{\mathcal{A}}(\mathcal{T}, K_\tau(\mathcal{L}_1)), \quad \bar{f} \longmapsto \ell_f, \quad \ell_f(F) = R_Z(f, J_Z F). \quad (8.7)$$

Here ℓ_f is literally the degree -1 cochain on $\mathcal{B}$ in (3.4). It is closed, since (6.2) gives $\ell_f \Theta = 0$, and $\ell_f \Theta \mathcal{F} = 0$. There is no degree -2 term, so this cocycle represents zero exactly when it is the zero functional. Surjectivity of J_Z and perfectness of (8.2) then prove injectivity. Formula (8.6), evaluated on $J_Z U_{1/a} F$, proves $\ell_{U_a f}(F) = a \ell_f(U_{1/a} F)$, exactly (7.5). Bound (6.9) also proves that all these functionals are continuous on the original quotient topology, even though the adjunction (3.4) uses the full algebraic dual. Thus (8.7) exhibits a specified subspace of continuous functionals inside that full dual, by an actual injection.

The contraction $J_g : h \mapsto g' h$ retains its local form

$$g' = m_\rho u_\rho(z) z^{m_\rho-1} + u'_\rho(z) z^{m_\rho} \equiv m_\rho u_\rho(z) z^{m_\rho-1} \pmod{z^{m_\rho}}. \quad (8.8)$$

Using $g'/g = m_\rho/z + u'_\rho/u_\rho$ gives

$$R_Z(f, J_g h) = \sum_{\rho} m_\rho \overline{f(\iota\rho)} h(\rho) = \text{Tr}(M_{f^\dagger h} | A_Z). \quad (8.9)$$

The trace equality follows because multiplication by a germ in the ordered basis $1, z, \dots, z^{m-1}$ is triangular with its value repeated m times on the diagonal. The radical in either variable of (8.9) is exactly the subspace of all packets whose constant term is zero: the formula annihilates that subspace, and arbitrary constant terms in the reflected block detect every nonzero remaining value. The differentiated symmetry is $(g')^\dagger = -g'$, which together with (8.5) also confirms the Hermitian orientation of (8.9). No positivity of the raw residue form was used or asserted.

Every arrow in (8.7) is reconstructed at its original label A . A zero functional is $(A, 0)$, and the absent input alone is sent to τ . Precomposition with the mask inclusions commutes with the residue formula because H^1 transport in (5.8) is identity. This completes the labelled adjoint arrow with its degree, sign, topology, and action.

152 9. Tensor compatibility, including the dual Koszul sign

All coefficient tensors in this section are the original algebraic tensors over E ; no unproved completed tensor topology is substituted. For a product P^r , tensoring the stalkwise exact resolution (2.1) produces a finite projective resolution of the constant diagram. To see exactness without assuming a tensor theorem, at each stalk split an exact finite complex into its cohomology and elementary two-term identity complexes by choosing complements to boundaries and cycles. Tensoring an elementary identity complex with any complex is contractible, by its usual contracting homotopy tensored with identity. Only the tensor of the degree-zero constant cohomology remains. Each external product of the P_x 's represents evaluation at the corresponding product point and is projective. This proves the claimed resolution and yields the natural cochain identity

$$A_{\tau,r}(F_1 \boxtimes \cdots \boxtimes F_r) \simeq C(F_1) \otimes \cdots \otimes C(F_r), \quad (9.1)$$

with the full differential

$$d(x_1 \otimes \cdots \otimes x_r) = \sum_{j=1}^r (-1)^{\sum_{k < j} |x_k|} x_1 \otimes \cdots \otimes dx_j \otimes \cdots \otimes x_r. \quad (9.2)$$

The standard cross product of cohomology classes is an isomorphism because the same split-complex argument kills all summands with a contractible factor. The proof uses a splitting to verify that the canonical cross product is bijective; it does not make that map dependent on the splitting.

Product restriction is the tensor $f_1 \otimes \cdots \otimes f_r$ to $S_1 \otimes \cdots \otimes S_r[0]$. Changes from plus to minus representatives are compatible: for $g_i = f_{i,-}$ and $f_i = f_{i,+}$, a homotopy is

$$H = \sum_{j=1}^r g_1 \otimes \cdots \otimes g_{j-1} \otimes h_j \otimes f_{j+1} \otimes \cdots \otimes f_r, \quad (9.3)$$

where tensor maps act with the Koszul sign and $h_j^1 = t_j$. The differential of each tensor summand is the same tensor with $d_{\text{Hom}} h_j = f_j - g_j$; every other factor is a degree-zero chain map. Summing telescopes to $\otimes f_i - \otimes g_i$, proving the homotopy identity.

For the original sheaves and all nonempty masks, every $S_i = 0$. Thus product restriction is zero and

$$B_{\sigma^r}(\mathcal{T}_{A_1} \boxtimes \cdots \boxtimes \mathcal{T}_{A_r}) = \bigotimes_{i=1}^r C(\mathcal{T}_{A_i}) = \bigotimes_{i=1}^r B_{\sigma}(\mathcal{T}_{A_i}). \quad (9.4)$$

The complete cohomology is the graded tensor product of the two groups in (5.8). Explicitly its degree n is the direct sum over subsets $I \subseteq \{1, \dots, r\}$, $|I| = n$, with Q in factors indexed by I and $H^0 C(\mathcal{T}_{A_i})$ in the other factors. In particular

$$\boxed{H^r B_{\sigma^r}(\mathcal{T}^{\boxtimes r}) = Q^{\otimes r}.} \quad (9.5)$$

The numerator is $\mathcal{B}^{\otimes r}$, and its denominator is exactly

$$\sum_{j=1}^r \mathcal{B}^{\otimes(j-1)} \otimes \Theta V \otimes \mathcal{B}^{\otimes(r-j)}. \quad (9.6)$$

Signs in (9.2) change none of these subspaces but remain in the differential itself. The quotient map to $Q^{\otimes r}$ has kernel (9.6), by successive tensoring of the quotient presentation over the field.

For general diagrams one cannot replace the fibre of a tensor product by the tensor of fibres. The exact replacement can itself be computed. For composable chain maps $X \xrightarrow{f} Y \xrightarrow{g} Z$, put $B(f) = \text{Fib}(f)$ with (1.3). There are chain maps

$$u : B(f) \rightarrow B(gf), \quad (x, y) \mapsto (x, gy), \quad v : B(gf) \rightarrow B(g), \quad (x, z) \mapsto (fx, z). \quad (9.7)$$

Their composite has nullhomotopy $H(x, y) = (-y, 0)$, since $dH + Hd = (fx, gy)$. A surjective chain map

$$\text{Cone}(u) \longrightarrow B(g), \quad (x, z; x', y') \longmapsto (fx - y', z) \quad (9.8)$$

has kernel $z = 0, y' = fx$, with remaining coordinates $x \in X^n, x' \in X^{n+1}$ and differential $(x, x') \mapsto (dx + x', -dx')$. The degree -1 map $(x, x') \mapsto (0, x)$ contracts this kernel. Thus (9.8) is a quasi-isomorphism and proves the fibre triangle explicitly. Apply this with $f = f_1 \otimes 1_{C_2}$ and $g = 1_{S_1} \otimes f_2$. The resulting triangle is

$$B(f_1) \otimes C_2 \longrightarrow B(f_1 \otimes f_2) \longrightarrow S_1 \otimes B(f_2) \longrightarrow (B(f_1) \otimes C_2)[1]. \quad (9.9)$$

The first fibre identification follows immediately from (1.3) and the tensor differential; in the second, S_1 is in degree zero. This proves the general tensor relation and explains precisely why it reduces to (9.4) for the original source.

The product right adjoint is

$$K_{\tau,r}(W) = K_{\tau}(E)^{\boxtimes r} \otimes W, \quad K_{\tau,r}(W) \simeq S_{(\eta, \dots, \eta)} W[r]. \quad (9.10)$$

Its terms are finite direct sums of $I_{(x_1, \dots, x_r)}(W)$, hence injective. Its only cohomology follows by the same stalkwise contraction proof used for (3.9) and (9.1). No assertion that an infinite-dimensional algebraic dual commutes with tensor products is used.

The adjunction on the product has a sign that must be stated. In total degree $-p$, multiply the coefficient functional arising from $K_{\tau}(E)^{\boxtimes r}$ by

$$\epsilon_p = (-1)^{p(p-1)/2} \quad (9.11)$$

to identify it with $\text{Hom}^{-p}(\bigotimes C(F_i), W)$. To check this, an index set I of p eta factors contributes to degree $-p$. Removing $j \in I$ in d_K has sign $(-1)^{|I \cap \{1, \dots, j-1\}|}$. The corresponding incoming cochain differential in (9.2) has the same sign, while its internal Hom differential has the additional factor $(-1)^{p+1}$ from (1.4). The equality $\epsilon_{p-1} = (-1)^{p+1} \epsilon_p$ proves commutation in every component. This verifies the sign on every product differential.

In top degree the identification is therefore

$$H^{-r} R \text{Hom}_{\mathcal{A}(P^r)}(\mathcal{T}^{\boxtimes r}, K_{\tau,r}(W)) \cong \text{Hom}_E(Q^{\boxtimes r}, W), \quad (9.12)$$

with the coefficient multiplier ϵ_r . In particular, for $r = 2$ it is -1 . If a product residue arrow is written on the right of (9.12) as the literal functional

$$([F_1] \otimes \cdots \otimes [F_r]) \longmapsto \prod_{i=1}^r R_Z(f_i, J_Z F_i), \quad (9.13)$$

its coefficient representative in the unaltered tensor complex $K_{\tau,r}$ is ϵ_r times that product. This is the cohomological Koszul sign, not a phase inserted into (8.2) and not a modification of its positivity properties.

Tensoring (6.11) gives the exact surjection $Q^{\boxtimes r} \rightarrow A_Z^{\boxtimes r}$, with kernel

$$\sum_{j=1}^r Q^{\otimes(j-1)} \otimes Q_Z^0 \otimes Q^{\otimes(r-j)}. \quad (9.14)$$

This follows by successively quotienting each factor; a vector-space complement verifies equality of the kernel, without imposing an equivariant complement. The fibre of the cochain jet map

$$C(\mathcal{T})^{\otimes r} \longrightarrow A_Z^{\otimes r}[-r] \quad (9.15)$$

has the same cohomology as $C(\mathcal{T})^{\otimes r}$ in degrees below r , has (9.14) in degree r , and zero above r . Indeed the target has only degree r , its degree- r map is the proved surjection, and the explicit fibre long exact sequence then has exactly these kernels and cokernels.

The action in all tensor expressions is the tensor of the original (7.2) and (7.4). On a specified packet tuple $(\rho_1, \dots, \rho_r)$ it is

$$a^{\rho_1 + \dots + \rho_r} \exp \left((\log a) \sum_{j=1}^r 1 \otimes \dots \otimes N_{\rho_j} \otimes \dots \otimes 1 \right). \quad (9.16)$$

The summands commute, so their exponential is exactly the product of the terminating exponentials in (7.4). On the target line $\mathcal{L}_1^{\otimes r}$ the action is a^r ; (8.6) proves covariance of (9.13) by this exact factor. Formula (9.16) retains every nilpotent term, not only its eigenvalue. Support reconstruction is performed on each original admitted tensor fibre and its balancing relations: a zero tensor amplitude remains the supported zero of that fibre, whereas an absent tensor input is absorbing. The proof never identifies the coefficient tensor with a Cartesian product of label sets.

There is also the source's proved passage to completed projective tensor products, now obtained from the retained continuous contraction instead of an assumed exactness of completion. For the joint complex $C = C(\mathcal{T})$, let $H_0 = V[0] \oplus Q[-1]$, with zero differential, and put

$$p^0(\phi, \psi) = \psi, \quad p^1 = q, \quad i^0(\psi) = (\widehat{\psi}, \psi), \quad i^1 = s, \quad H^1(F) = (\Lambda F, 0). \quad (9.17)$$

Then $pi = 1$ and $1 - ip = dH + Hd$: in degree zero the latter equation is $(\phi, \psi) - (\widehat{\psi}, \psi) = (\phi - \widehat{\psi}, 0)$, obtained from $\Lambda\Theta = 1$; in degree one it is $1 - sq = \Theta\Lambda$. All the maps are continuous in the already specified topologies. If $P = ip$, the tensor homotopy

$$H_r = \sum_{j=1}^r P^{\otimes(j-1)} \otimes H \otimes 1^{\otimes(r-j)} \quad (9.18)$$

uses the sign $(-1)^{\sum_{k < j} |x_k|}$ on homogeneous inputs. The differential telescopes to $1 - P^{\otimes r}$, since $d_{\text{Hom}} H = 1 - P$, while $P, 1$ are chain maps of degree zero. Every finite tensor map is continuous for the projective tensor topology and therefore extends uniquely to its completion; the identity extends by density. The completed complex is thus continuously homotopy equivalent to $H_0^{\widehat{\otimes} \pi^r}$. Its degree n cohomology is the direct sum of ordered completed tensors with Q in n slots and V in the others, and in particular its top cohomology is $Q^{\widehat{\otimes} \pi^r}$. The comparison from (9.5) is the canonical completion map on these tensors. For an individual one-leg mask replace H_0 by $Q[-1]$, keep $p^1 = q, i^1 = s$, and take $H^1 = \Lambda$ on the plus leg or $H^1 = -\mathcal{F}\Lambda$ on the minus leg. On the latter the differential is $-\Theta\mathcal{F}$, so $Hd = \mathcal{F}\Lambda\Theta\mathcal{F} = 1_V$ and $dH = \Theta\Lambda = 1 - sq$; the plus leg has the same identities with its positive signs. Thus the same tensor proof applies to every mask. This specifies the exact completed continuation while retaining the algebraic tensor calculation and the action defect (7.6).

153 10. Exact consequences for continuation

The original global arithmetic object, its generic-boundary restriction, and its right adjoint are related by the explicit maps (2.3), (3.10), and (4.4), and the nonsplit extension (4.7). On the original theta sheaf, the restriction fibre is the original cochain complex itself, with every supported copy of Q retained. Finite jets give the exact kernel sequence (6.11), its sheaf and fibre realizations (6.13)–(6.15), and the injective continuous residue arrow into the original adjoint (8.7). Tensor products give (9.5), (9.14), and the full action (9.16), with the independently checked Koszul sign (9.11).

These are completed calculations on the original $\Theta, V, \mathcal{B}, \mathcal{A}_\tau, K_\tau$ and $g = 2\xi$. No vanishing of Q , of the finite-jet kernel $Q_{\mathbb{Z}}^0$, or of an arithmetic boundary contribution was used to obtain them. The calculations establish exact comparison morphisms and retain their kernels; they supply no upper estimate for the original tensor action beyond the identities proved here.

154 Finite dilation of the original arithmetic packet over the tau base

154.1 0. Scope and exact source correspondence

This calculation continues the original two-leg theta complex. The retained infinitesimal identity is (A11) of `arithmetic_input.tex`; the absolute-base pushforward, its two-leg action, and its tensor differential are (19), (21), (34), and (46) of *Arithmetic cohomology over the tau-base*. The full global retraction and its cocycle were already constructed in transcript turn **A1694**, node `1fa0ebbc-f569-40c1-b7ac-b523da19a5f0`, chain position 3576, and in *Tau_Global_Comparison*, equations (16), (19), (29)–(35), and (41). Those results are retained as prior work, not reported as newly discovered here.

The additional calculation is the explicit finite-packet dilation cocycle for every positive real dilation, its full Taylor-unit and nilpotent coefficients, convergent source-space integral, incomplete-gamma evaluation, exact finite/global change of representatives, two-leg homotopies, and tensor and boundary formulas. These formulas perform the group-level continuation of the existing infinitesimal extension. They do not assign positivity to a representative pairing.

The source bytes used are pinned at the end. Every integral on the positive half-line keeps the displayed measure. In particular the Hilbert pairing below uses dx , and its dilation mass is a , not 1. The notation $t = \log a$ is a real time parameter; the polynomial coordinate in $\mathbb{C}[X]/(h)$ is written X to avoid confusing it with that time. Thus $A = M_X$ here is exactly the source operator denoted M_t .

154.2 1. The original spaces, maps, and topology

Work over $\mathbb{C}$. Let

$$V = \left\{ \phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \quad \phi(0) = 0, \quad \int_{\mathbb{R}} \phi(x) dx = 0 \right\},$$

$$\mathcal{B} = \left\{ F \in C^\infty(\mathbb{R}_{>0}) : p_{b,k}(F) = \sup_{x>0} x^b |D^k F(x)| < \infty \quad (b \in \mathbb{Z}, k \geq 0) \right\}, \quad D = -x\partial_x.$$

Use the Schwartz seminorms

$$q_{N,k}(\phi) = \sup_{x \in \mathbb{R}} (1 + |x|)^N |\partial_x^k \phi(x)|, \quad N, k \geq 0.$$

The space V is a closed subspace of the complete Schwartz space: parity, value at zero, and integration are continuous. For example $|\int \phi| \leq q_{2,0}(\phi) \int_{\mathbb{R}} (1 + |x|)^{-2} dx$. The space $\mathcal{B}$ is complete because a Cauchy sequence in all $p_{b,k}$ converges with all derivatives on compact subsets after $x = e^y$; the weighted uniform bounds pass to its limit. These observations justify limits of Riemann sums in the actual spaces below.

Retain

$$\widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx, \quad \Theta \phi(x) = 2 \sum_{n \geq 1} \phi(nx), \quad JF(x) = x^{-1} F(1/x),$$

$$\mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}.$$

Schwartz estimates, followed by the original Poisson identity, give

$$\Theta : V \longrightarrow \mathcal{B}, \quad \Theta \widehat{\phi} = J\Theta \phi, \quad D\Theta = \Theta D.$$

Here is the continuity argument. At $x \geq 1$, each $D^k \phi(nx)$ is bounded by a finite sum of Schwartz seminorms times $(nx)^{-M}$, where M can be any sufficiently large positive integer. Summing n^{-M} gives every required bound at infinity. The Fourier transform preserves Schwartz seminorms continuously, preserves evenness, and interchanges the two vanishing moments. Poisson summation therefore gives $\Theta \phi(x) = x^{-1} \Theta \widehat{\phi}(1/x)$; applying D^k and the preceding bounds gives every required estimate at zero. Each resulting estimate involves finitely many source seminorms. Termwise differentiation is justified uniformly on every $x \geq \delta > 0$ by the same summable majorants.

The theta map is injective. For fixed $x > 0$, absolute convergence permits

$$\frac{1}{2} \sum_{m \geq 1} \mu(m) \Theta \phi(mx) = \sum_{r \geq 1} \left(\sum_{m|r} \mu(m) \right) \phi(rx) = \phi(x).$$

Indeed the rearranged absolute sum is bounded by $\sum_{r \geq 1} d(r) |\phi(rx)| < \infty$, since $d(r) \leq r$ and ϕ is Schwartz. Thus no theta relation is lost when its source is recovered.

For $a > 0$ define $U_a F(x) = F(x/a)$, and use the same formula on V . Direct substitutions give

$$p_{b,k}(U_a F) = a^b p_{b,k}(F), \quad q_{N,k}(U_a \phi) \leq a^{-k} \max(1, a)^N q_{N,k}(\phi), \quad (1)$$

$$\mathcal{M}U_a F(s) = a^s \mathcal{M}F(s), \quad \widehat{U_a \phi} = a U_{1/a} \widehat{\phi}, \quad \Theta U_a = U_a \Theta. \quad (2)$$

The two moments of $U_a \phi$ are $\phi(0)$ and $a \int \phi$, so V is invariant. Differentiating the defining formula gives

$$\frac{d}{dt} U_{e^t} \phi = D U_{e^t} \phi = U_{e^t} D \phi.$$

This is a derivative in every Schwartz seminorm. To verify it, apply the ordinary Taylor formula with integral remainder to $U_{e^{t+h}} \phi$; its second derivative is $U_{e^{t+h}} D^2 \phi$, uniformly bounded on each compact time interval by (1). The same argument, using the exact first identity in (1), proves smoothness in $\mathcal{B}$. Repeating with $D^j \phi$ proves derivatives of all orders. In particular this is a smooth group action on the retained Frechet spaces.

The four-point source poset is

$$+ < \eta < \sigma, \quad - < \eta < \sigma.$$

For the sheaf with stalks $V, V, \mathcal{B}, 0$ and restriction maps $\Theta, \Theta \mathcal{F}$, the source projective resolution computes

$$C = \mathbf{A}_\tau(\mathcal{T}) = \left[V \oplus V \xrightarrow{d} \mathcal{B} \right], \quad d(v, w) = \Theta(v - \widehat{w}), \quad |V \oplus V| = 0, |\mathcal{B}| = 1. \quad (3)$$

Its actual chain action is

$$\mathcal{U}_a^0(v, w) = (U_a v, a U_{1/a} w), \quad \mathcal{U}_a^1 F = U_a F. \quad (4)$$

Equation (2) proves $d\mathcal{U}_a^0 = \mathcal{U}_a^1 d$. On even Schwartz functions $\mathcal{F}^2 = 1$, so the exact degree-zero cycle inclusion is

$$i_0(w) = (\widehat{w}, w), \quad \mathcal{U}_a i_0(w) = i_0(a U_{1/a} w). \quad (5)$$

It follows from theta injectivity that $H^0(C) = i_0(V)$ and $H^1(C) = Q = \mathcal{B}/\Theta V$. These are the original global cohomology groups over the absolute tau base.

154.3 2. The finite arithmetic packet and its unchanged Taylor unit

Retain the original Gaussian source

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad f_0 = \Theta\phi_*.$$

It has value zero at zero, and direct Gaussian integration gives zero integral. More precisely, with $M_+\phi(s) = \int_0^\infty \phi(x)x^s dx/x$,

$$M_+\phi_*(s) = \pi^{-s/2}(2\Gamma(s/2+2) - 3\Gamma(s/2+1)) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2). \quad (6)$$

Consequently the entire function $g = \mathcal{M}f_0$ agrees, first by absolutely convergent integration in a right half-plane and then by continuation, with the original function

$$g(s) = 2\zeta(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

Entireness of the Mellin transform of $f_0 \in \mathcal{B}$ follows directly from the bounds in $\mathcal{B}$. For $0 < \operatorname{Re} s < 1$, set

$$H_\phi(s) = \frac{2\pi^{s/2}}{s(s-1)\Gamma(s/2)}M_+\phi(s).$$

Then

$$\mathcal{M}\Theta\phi = gH_\phi, \quad H_{\phi_*} = 1, \quad H_{P(D)\phi_*}(s) = P(s). \quad (7)$$

For completeness, $M_+\phi$ is holomorphic on $\operatorname{Re} s > -2$, since smooth evenness and $\phi(0) = 0$ give $\phi(x) = O(x^2)$. In $\operatorname{Re} s > 1$, interchanging its theta series and Mellin integral gives $\mathcal{M}\Theta\phi = 2\zeta(s)M_+\phi(s)$. Continue to the indicated strip to obtain the first equality in (7). Integrating $D\phi$ by parts proves $H_{D\phi} = sH_\phi$; the endpoint term $[x^s\phi(x)]_0^\infty$ vanishes on that strip. Equation (6) then proves the other two equalities.

Fix the original nonempty finite packet Z of actual nontrivial zeros, each with its complete order m_ρ , and put

$$h(X) = \prod_{\rho \in Z} (X - \rho)^{m_\rho}, \quad d_h = \deg h, \quad E = \mathbb{C}[X]/(h), \quad A = M_X,$$

$$v(s) = g(s)/h(s), \quad \varepsilon = j_h(h/g) \in E^\times.$$

The quotient h/g here is taken as a germ at each selected zero; these germs are holomorphic and nonzero because the complete multiplicity has been retained. The local unit is **not** replaced by 1. For $u \in E$, let $R_Z(u)$ be the unique polynomial of degree less than d_h representing εu , and put

$$\ell(u) = [X^{d_h-1}]R_Z(u). \quad (8)$$

We record the inverse used to define the source section, rather than taking an unproved inverse as an extra hypothesis. On $F \in \mathcal{B}$ satisfying $\mathcal{M}F(\rho) = 0$, define

$$S_\rho F(x) = x^{-\rho} \int_x^\infty F(y)y^{\rho-1} dy.$$

Differentiation gives $(D - \rho)S_\rho F = F$. The moment condition makes the upper integral the negative lower integral. If $\sigma = \operatorname{Re} \rho$, the upper estimate, for $N > \sigma$, is

$$|S_\rho F(x)| \leq \frac{p_{N,0}(F)}{N - \sigma} x^{-N}.$$

The lower estimate, for $N + \sigma > 0$, is

$$|S_\rho F(x)| \leq \frac{p_{-N,0}(F)}{N + \sigma} x^N.$$

Using the upper estimate on $x \geq 1$ and the lower estimate on $x \leq 1$ gives every weighted bound. The differential identity expresses $D^k S_\rho F$ as $\rho^k S_\rho F$ plus a finite linear combination of $D^j F$, proving all derivative bounds and continuity. The homogeneous solution $cx^{-\rho}$ cannot belong to $\mathcal{B}$ unless $c = 0$, so the inverse is unique. Integration by parts gives

$$\mathcal{M}S_\rho F(s) = \frac{\mathcal{M}F(s)}{s - \rho},$$

with the removable value filled in. Iterating this construction, removing one vanishing factor at a time, defines the continuous inverse S_h of $h(D)$ on $\ker(j_h \mathcal{M})$. The operation preserves the remaining zeros and lowers the order at the chosen zero by exactly one at each step. Conversely any $h(D)F$ has those vanishing jets. This proves

$$h(D)\mathcal{B} = \ker(j_h \mathcal{M}), \quad h(D) \text{ is injective.} \quad (9)$$

The section in the question is therefore the actual well-defined map

$$R = R_{\text{ref}} : E \longrightarrow \mathcal{B}, \quad Ru = S_h \Theta(R_Z(u)(D)\phi_*). \quad (10)$$

Indeed its input has Mellin transform $gR_Z(u)$, which vanishes to all the required orders. Equations (7) and (9) give

$$\mathcal{M}Ru = vR_Z(u), \quad J_Z R = 1_E, \quad J_Z = j_h \mathcal{M}, \quad J_Z \Theta = 0. \quad (11)$$

The Mellin-jet map is continuous: split its integral at 1, dominate the logarithmic factors at zero by a sufficiently negative weight and those at infinity by a sufficiently positive weight. This yields a finite sum of seminorm bounds for each derivative at each ρ . In (11), $j_h(v)\varepsilon = 1$ proves the middle identity. Hence R and $\sigma = qR : E \rightarrow Q$ are injective, since J_Z descends to Q .

The infinitesimal boundary is precisely the retained one:

$$DR - RA = \Theta\phi_*\ell = f_0\ell. \quad (12)$$

To prove it without losing its coefficient, the polynomial $XR_Z(u) - R_Z(Au)$ vanishes modulo h and has degree at most d_h . Since h is monic, its quotient by h is exactly $\ell(u)$. Apply $h(D)$ to (12), use (10), $D\Theta = \Theta D$, and that polynomial identity. Injectivity of $h(D)$ from (9) proves (12). For a single simple zero, $R_Z(u) = u/g'(\rho)$ and $\ell(u) = u/(2\xi'(\rho))$, with the original factor of two.

154.4 3. The finite dilation cocycle as an actual convergent source integral

For every real t , define $T_t = e^{tA}$ and

$$c_t(u) = \int_0^t U_{e^{t-r}} \phi_* \ell(T_r u) dr \in V. \quad (13)$$

If $t < 0$, $\int_0^t = -\int_t^0$; no orientation is changed. Write $c_a = c_{\log a}$ and $a^A = T_{\log a}$ when using the multiplicative parameter.

Convergence and continuity. Fix any norm on the finite-dimensional coefficient space, solely for estimates, and its induced operator norms. On the oriented interval between 0 and t , both $|r|$ and $|t - r|$ are at most $|t|$. Equation (1) and $\|T_r\| \leq e^{|r|\|A\|}$ yield

$$q_{N,k}(c_t u) \leq |t| e^{(N+k+\|A\|)|t|} q_{N,k}(\phi_*) \|\ell\| \|u\|. \quad (14)$$

The integrand is continuous in every seminorm. Its Riemann sums are Cauchy in every seminorm by uniform continuity on the compact interval. Completeness of V proves their common limit exists in V , and the inequality follows first for sums and then for their limit. Thus the integral is an actual source vector with the two original zero moments and even Schwartz regularity. It is not merely an integral in a weak dual or in L^2 .

Smoothness in t follows either by the differentiable compact-interval rule justified by the same estimates for all time derivatives, or by writing (13) as $t \int_0^1 U_{e^{t(1-r)}} \phi_* \ell(T_r u) dr$. This latter formula works without a sign convention change for negative t . Every derivative has a finite sum of terms involving $D^j \phi_*$, powers of A , and bounded polynomial factors in r . Inequality (14) with those finitely many seminorms proves local uniform convergence of the differentiated Riemann sums. Therefore $t \mapsto c_t$ is smooth as a map to continuous linear maps $E \rightarrow V$, with their bounded-set topology. Finite dimensionality of E makes the preceding uniform estimates on its unit ball sufficient for this statement.

The exact dilation identity. For all $t \in \mathbb{R}$,

$$\boxed{U_{e^t} R - R T_t = \Theta c_t.} \quad (15)$$

For fixed u , differentiate in the Frechet space $\mathcal{B}$:

$$\frac{d}{dr} (U_{e^{t-r}} R T_r u) = -U_{e^{t-r}} (DR - RA) T_r u = -\Theta U_{e^{t-r}} \phi_* \ell(T_r u).$$

The fundamental theorem of calculus follows in every defining seminorm from the same Riemann-sum argument; integrating with the indicated orientation proves (15), including $t < 0$. Continuity of Θ permits moving it through the integral.

Cocycle and derivative. Directly splitting the defect in (15) gives

$$\boxed{c_{t+s} = U_{e^t} c_s + c_t T_s, \quad c_0 = 0, \quad c_{-t} = -U_{e^{-t}} c_t T_{-t}.} \quad (16)$$

Indeed applying Θ to the asserted first equality yields the identity obtained by inserting $U_{e^t} R T_s$ in $U_{e^{t+s}} R - R T_{t+s}$. Injectivity of Θ proves equality in the actual source V . The other two statements follow by setting $t = s = 0$ and $s = -t$. Differentiating (13), or the cocycle in either variable, gives the two equal expressions

$$\boxed{\partial_t c_t = D c_t + \phi_* \ell T_t = U_{e^t} \phi_* \ell + c_t A, \quad \partial_t c_t|_{t=0} = \phi_* \ell.} \quad (17)$$

All derivatives are in V . In multiplicative notation (16) is

$$c_{ab} = U_a \circ c_b + c_a \circ b^A,$$

where the final product means the map $c_a \circ b^A$; to remove any typographical ambiguity it can also be written $c_{ab}(u) = U_a(c_b(u)) + c_a(b^A u)$.

The space $\mathcal{B}_Z = \Theta V + RE$ is a direct topological sum with coordinates $(\phi, u) \mapsto \Theta \phi + Ru$. Its inverse on that subspace is $(\Theta^{-1}(F - RJ_Z F), J_Z F)$; continuity of the inverse theta map is also proved in Section 6 below. Equations (15) and (16) integrate the source block operator to the exact group representation

$$U_a|_{\mathcal{B}_Z} = \begin{pmatrix} U_a|_V & c_a \\ 0 & a^A \end{pmatrix}. \quad (18)$$

This is the explicit group-level form of the already known extension (A12). In particular (15) proves the true quotient intertwining $\overline{U}_a \sigma = \sigma a^A$.

154.5 4. All nilpotents, the Mellin multiplier, and an incomplete-gamma evaluation

The Chinese remainder decomposition is

$$E = \bigoplus_{\rho \in Z} \mathbb{C}[z_\rho]/(z_\rho^{m_\rho}), \quad A|_\rho = \rho I + N_\rho,$$

where $N_\rho z_\rho^j = z_\rho^{j+1}$ and $N_\rho^{m_\rho} = 0$. Denote the summand projector by P_ρ , extending N_ρ by zero on other summands. These are the actual full local algebras. They can be constructed explicitly: if $H_\rho(X) = h(X)/(X - \rho)^{m_\rho}$, then P_ρ is multiplication by the remainder modulo h of

$$H_\rho(X) \sum_{j=0}^{m_\rho-1} \frac{(H_\rho^{-1})^{(j)}(\rho)}{j!} (X - \rho)^j.$$

At every other centre this has all required zero jets; at ρ it has jet 1. This verifies all its projector identities by the Chinese remainder map.

The action and the entire boundary integral therefore contain the full expressions

$$T_t = \sum_{\rho \in Z} e^{t\rho} \sum_{j=0}^{m_\rho-1} \frac{t^j}{j!} N_\rho^j P_\rho, \quad (19)$$

$$c_t u = \sum_{\rho \in Z} \sum_{j=0}^{m_\rho-1} \ell(N_\rho^j P_\rho u) \int_0^t U_{e^{t-r}\phi_*} e^{r\rho} \frac{r^j}{j!} dr. \quad (20)$$

The unit entering every coefficient is still $\varepsilon = j_h(h/g)$ through (8). If the packet has one zero of order m , and $\varepsilon = \sum_{i < m} \varepsilon_i z^i$, $u = \sum_{i < m} u_i z^i$, then $\ell(u) = \sum_{i=0}^{m-1} \varepsilon_i u_{m-1-i}$. This follows because the top coefficient of a polynomial of degree less than m is the same in the X and $z = X - \rho$ bases. Thus even the functional ℓ retains the lower coefficients of the Taylor unit, rather than only its nonzero constant value.

There is a closed expression for the integral kernels in (20). For $x > 0$ let

$$K_{\rho,t}(x) = \int_0^t e^{r\rho} \phi_*(x e^{r-t}) dr.$$

Define the oriented incomplete-gamma interval by

$$\Gamma_{[L,H]}(w) = \int_L^H y^{w-1} e^{-y} dy \quad (L, H > 0),$$

where $y^{w-1} = \exp((w-1) \log y)$ uses the real logarithm. Then substitution first of $y = x e^{r-t}$ and then of $z = \pi y^2$ gives

$$K_{\rho,t}(x) = e^{t\rho} x^{-\rho} \pi^{-\rho/2} [2\Gamma_{[\pi x^2 e^{-2t}, \pi x^2]}(\rho/2 + 2) - 3\Gamma_{[\pi x^2 e^{-2t}, \pi x^2]}(\rho/2 + 1)]. \quad (21)$$

Both substitutions preserve orientation when $t < 0$. The coefficients 2 and -3 come respectively from $4\pi^2 x^4$ and $-6\pi x^2$, including $dy/y = dz/(2z)$. No Gaussian constant is removed.

Differentiation under the compact oriented r -integral now gives the finite formula

$$c_t u = \sum_{\rho \in Z} \sum_{j=0}^{m_\rho-1} \frac{\ell(N_\rho^j P_\rho u)}{j!} \partial_\rho^j K_{\rho,t}. \quad (22)$$

The derivative here acts on the complex parameter in the entire kernel $K_{\rho,t}$ before evaluation at the indicated centre, not on the arithmetic zero or on the coefficient $\ell(N_\rho^j P_\rho u)$. The formula on $x > 0$ is extended evenly to $\mathbb{R}$, with its smooth value at 0 supplied by the integral defining K . That integral and Section 3 prove smoothness and both zero moments, so no regularity is inferred from cancelling the separate singular-looking factors in (21).

The full Mellin multiplier of the source boundary is also explicit:

$$H_{c_t u}(s) = \int_0^t e^{(t-r)s} \ell(T_r u) dr = \frac{e^{ts} R_Z(u)(s) - R_Z(T_t u)(s)}{h(s)}. \quad (23)$$

For the first equality in the original strip, use (7), $H_{U_a \phi_*} = a^s$, and the continuous source integral. For the second, differentiate $e^{(t-r)s} R_Z(T_r u)(s)$ in r . The polynomial identity proving (12) says its derivative is $-e^{(t-r)s} h(s) \ell(T_r u)$. Integration proves (23) wherever $h(s) \neq 0$. The numerator has every required vanishing jet: in the local algebra its jet is $e^{tA} \varepsilon u - \varepsilon T_t u = 0$. Hence the quotient in (23) has removable singularities at every chosen zero and is entire. This entire expression extends the original source multiplier; it is not a replacement of h or g .

For every integer $n \geq 0$ its actual Taylor coefficient at any complex centre s_0 is

$$\frac{H_{c_t u}^{(n)}(s_0)}{n!} = \int_0^t e^{(t-r)s_0} \frac{(t-r)^n}{n!} \ell(T_r u) dr. \quad (24)$$

Inserting (19) gives every mixed coefficient in $(t-r)^n r^j / (n!j!)$ and keeps all nilpotent terms. This is also a direct convergence proof for every jet, since the parameter interval is compact.

154.6 5. Actual two-leg homotopies and the support-face comparison

Regard $E[-1]$ as the complex with E in degree 1 and zero elsewhere. The finite section defines a degree-zero cochain map $r : E[-1] \rightarrow C$, with $r^1 = R$. The maps $\mathcal{U}_a r$ and ra^A have homotopies

$$\begin{aligned} H_a^+ : E[-1] &\longrightarrow C[-1], & (H_a^+)^1 u &= (c_a u, 0), \\ H_a^- : E[-1] &\longrightarrow C[-1], & (H_a^-)^1 u &= (0, -\widehat{c_a u}). \end{aligned} \quad (25)$$

Here the notation records maps of cohomological degree -1 ; the source only has degree 1. In ordinary component notation the exact identity is

$$\mathcal{U}_a r - ra^A = dH_a^\pm + H_a^\pm d_{E[-1]} = dH_a^\pm. \quad (26)$$

Indeed $d(c_a u, 0) = \Theta c_a u$, whereas $d(0, -\widehat{c_a u}) = \Theta \mathcal{F}^2 c_a u = \Theta c_a u$. This verifies the minus sign using the original differential. Equation (2) also gives the homotopy cocycle itself:

$$H_{ab}^\pm = \mathcal{U}_a^0 H_b^\pm + H_a^\pm b^A. \quad (27)$$

No extra Fourier scalar is inserted: $\widehat{U_a c} = aU_{1/a}\widehat{c}$ is exactly the second-leg action in (4).

The original support masks are $\lambda \in \{\{+\}, \{-\}, \{+, -\}\}$. The fibre C_λ^0 consists of the legs present in λ , $C_\lambda^1 = \mathcal{B}$, with the same differential. The $+$ homotopy in (25) is defined on $\{+\}$ and on the joint face. The $-$ homotopy is defined on $\{-\}$ and on the joint face. On the joint face their difference is the precisely retained cycle

$$H_a^+ - H_a^- = (c_a, \widehat{c}_a) = i_0(\widehat{c}_a). \quad (28)$$

It lies in $H^0(C)$ by (5) and theta injectivity. There is no term in degree -1 of C , so a nonzero such cycle is not a boundary in C .

The two singleton homotopies are forced. On $\{+\}$, injectivity of theta forces the first one; on $\{-\}$ it forces the second. Consequently a single homotopy that is strictly natural for both singleton-to-joint inclusions would require $(c_a, 0) = (0, -\widehat{c}_a)$, which is equivalent to $c_a = 0$. This is the exact scope of the support-naturality obstruction; it does not remove the homotopies in (25), their difference (28), or the resulting quotient action.

For completeness, c_a as a linear map is nonzero for every $a \neq 1$. If $c_a = 0$, (15) would make the nonzero finite-dimensional subspace RE invariant under U_a , with invertible action a^A . It therefore has a nonzero eigenvector $F \in \mathcal{B}$ with $U_a F = \lambda F$, $\lambda \neq 0$. Replacing a by a^{-1} if needed, take $a > 1$. Choose $x_0 > 0$ with $F(x_0) \neq 0$. Iteration gives $F(a^n x_0) = \lambda^{-n} F(x_0)$ for $n \geq 0$. The bound $p_{N,0}(F) < \infty$ implies $a^{nN} |\lambda|^{-n} |F(x_0)| \leq x_0^{-N} p_{N,0}(F)$. Choose N with $a^N > |\lambda|$ and let $n \rightarrow \infty$ to obtain a contradiction. Thus no such finite invariant subspace exists. This extends the previously proved failure of a strict equivariant section by giving its exact nonzero finite-dilation defect; the failure itself was already present in (A12).

At a fixed admitted mask the split lift of every displayed map is

$$\widetilde{f}(\lambda, u) = (\lambda, f(u)), \quad \widetilde{f}(\tau) = \tau.$$

An amplitude $f(u) = 0$ has value $(\lambda, 0)$, the supported zero, including at $a = 1$. All homotopy identities are interpreted using addition and the supported scalar $(-1)^\bullet$ in that fibre. No absent leg is inserted by the face-specific formulas.

The known synchronization comparison can be retained explicitly when a common joint target is desired. Send every active degree-one mask to $(\{+, -\}, F)$ and send the degree-zero pair to its joint-supported pair with the same two amplitudes, putting a supported zero in a formerly missing coordinate. Denote this operation by τ . It is the source map $(a, b) \mapsto (a + eb, b + ea)$, because multiplication by e gives a supported zero at a present coordinate. It preserves the differential, fixes joint masks, and is idempotent. The pair $(\text{supp } x, \tau x)$ recovers the original element by selecting the originally present coordinates, proving injectivity of that comparison. After this explicit synchronization, (25)–(28) hold in the common joint fibre. The original mask must stay attached to the comparison; forgetting it is not part of the homotopy calculation.

One can also see the extra degree-zero group in an exact equivariant roof. Let $C_Z = [V \oplus V \rightarrow \mathcal{B}_Z]$ with the same differential, and define

$$p_Z^0(v, w) = w, \quad p_Z^1 = J_Z.$$

This is a cochain map to $V[0] \oplus E[-1]$. It is equivariant for the action $aU_{1/a}$ on V and a^A on E , and induces isomorphisms on both cohomology groups: the degree-zero assertion follows from (5), while the degree-one assertion follows from the direct sum $\mathcal{B}_Z = \Theta V \oplus RE$ and (11). Thus the exact two-leg version of the source roof is

$$V[0] \oplus E[-1] \xleftarrow{p_Z} C_Z \longrightarrow C.$$

Its ordinary cochain section is $i_Z^0(w) = (\widehat{w}, w)$ and $i_Z^1 = R$. If $F = \Theta\phi + Ru$, the map $h_Z^1(F) = (\phi, 0)$ obeys $1 - i_Z p_Z = dh_Z + h_Z d$: in degree zero it returns $(v - \widehat{w}, 0)$ and in degree one it returns $\Theta\phi$. Its failure of equivariance in degree one is exactly (25). This proves the replacement on the entire original two-leg complex, retaining its $V[0]$ summand.

154.6.1 The transported minus face has an explicitly nonzero extension component

The preceding roof also computes what happens to the original support arrows when the action is retained. Work over $\mathbb{C}[X]$, with $X = D$ on $\mathcal{B}_Z$, $X = A$ on E , and $X = 1 - D$ on the degree-zero second-leg module, denoted V_- . Let $r(X) = R_Z(1)$ and $\psi = r(D)\phi_*$. Then

$$h(D)R(1) = \Theta\psi.$$

The class of ψ in $V/h(D)V$ is nonzero: applying $j_h H$ gives $j_h r = \varepsilon \neq 0$, whereas $j_h H$ vanishes on $h(D)V$ by (7). The Fourier map carries this quotient isomorphically onto $V/h(1 - D)V$, since differentiating (2) gives $\mathcal{F}D = (1 - D)\mathcal{F}$.

For the minus-face extension the injection is $i_- = -\Theta\mathcal{F}$. Its extension representative, with the convention $h(D)R(1) = i_-(w)$, is therefore

$$w = -\widehat{\psi} \quad \text{in } V/h(1 - D)V.$$

The component of the minus support arrow in the $V_-[0]$ summand of the joint roof has the opposite sign to this extension representative. Here is the exact shifted-resolution calculation. The free cochain resolution of E in degrees $-1, 0$ has differential h . We use $(C[n])^j = C^{j+n}$ and $d_{C[n]} = (-1)^n d_C$; after shifting by -1 , that resolution is in degrees $0, 1$ with differential $-h$. Its degree-one lift to the minus-face complex sends 1 to $R(1)$, extended $\mathbb{C}[X]$ -linearly. Its degree-zero lift must send 1 to $-w$, because $i_-(-w) = -h(D)R(1)$. Projection to $V_-[0]$ is identity in degree zero. Thus the induced derived map $E[-1] \rightarrow V_-[0]$ represents exactly

$$[-w] = [\widehat{\psi}] \quad \text{in} \quad \text{Ext}_{\mathbb{C}[X]}^1(E, V_-) \cong V/h(1 - D)V. \quad (28a)$$

The isomorphism here follows by applying $\text{Hom}_{\mathbb{C}[X]}(-, V_-)$ to that two-term free resolution; its cokernel is the stated quotient. The class (28a) is nonzero by the preceding source-jet calculation. The same arrow has identity as its $E[-1]$ component. By contrast, the plus support arrow has zero $V_-[0]$ component and identity $E[-1]$ component, because its degree-zero image has second coordinate zero. Consequently the two support arrows in the equivariant derived category do not both become inclusion of the $E[-1]$ summand: the exact difference carries (28a), with the original Taylor unit. The strict original cochain support diagram remains available before passage through the roof.

154.7 6. The exact bridge to the already constructed global section

We recall the global section in a form that makes its use here mathematically explicit. Choose the same fixed even real cutoffs $\alpha, \beta \in C_c^\infty(\mathbb{R})$, with $0 \leq \alpha, \beta \leq 1$, equal to 1 near zero. For $x \neq 0$ define

$$\mathcal{U}F(x) = \frac{1}{2} \sum_{n \geq 1} \mu(n) F(n|x|).$$

If $P_j(D) = (-1)^j D(D+1) \cdots (D+j-1) = x^j \partial_x^j$, and $C_{N,j}(F)$ is the sum of $p_{N,k}(F)$ weighted by the absolute coefficients of P_j , then for $x > 0$, $N > 1$,

$$|\partial_x^j \mathcal{U}F(x)| \leq \frac{1}{2} \zeta(N) C_{N,j}(F) x^{-N-j}. \quad (29)$$

Each summand is bounded by $\frac{1}{2}C_{N,j}(F)n^{-N}x^{-N-j}$; summation proves the estimate and local uniform convergence of every derivative. Thus the cutoff exterior functions $(1 - \alpha)\mathcal{U}F$ and $(1 - \beta)\mathcal{U}JF$, extended by zero near zero, are continuous Schwartz-valued maps. The theta inversion in Section 1 and Poisson give $\mathcal{U}\Theta\phi = \phi$ and $\mathcal{U}J\Theta\phi = \widehat{\phi}$ away from zero.

On $L^2(\mathbb{R}, dx)$ define

$$T = M_\alpha \mathcal{F}^{-1} M_\beta \mathcal{F}, \quad YF = (1 - \alpha)\mathcal{U}F + \alpha \mathcal{F}^{-1}((1 - \beta)\mathcal{U}JF).$$

The kernel of T is $\alpha(x)\check{\beta}(x - y)$; its squared integral is $\|\alpha\|_2^2 \|\beta\|_2^2$, so T is compact. Its norm c is strictly less than 1. Otherwise compactness would give a unit vector attaining norm 1. Equality in the two contraction inequalities forces its Fourier transform to be supported where $\beta = 1$, and then the vector itself to be supported where $\alpha = 1$. A compactly supported Fourier transform in L^2 is in L^1 , and its inverse Fourier transform extends to an entire function by its finite-interval integral. That entire function would vanish on a real open interval because of the compact spatial support, hence vanish identically, a contradiction.

Thus $(1 - T)^{-1} = \sum_{n \geq 0} T^n$ in operator norm, with bound $(1 - c)^{-1}$. The operator $T : L^2 \rightarrow \mathcal{S}$ is continuous: Cauchy-Schwarz on the compact Fourier support bounds every derivative of $\mathcal{F}^{-1}(\beta\widehat{f})$ by a constant times $\|f\|_2$, and multiplication by α gives compact spatial support and every Schwartz seminorm. It follows that $\Phi = (1 - T)^{-1}Y$ is Schwartz-valued and continuous; the explicit identity $\Phi = Y + T\Phi$ gives

$$q_{N,k}(\Phi F) \leq q_{N,k}(YF) + \frac{C_{N,k}}{1 - c} \|YF\|_2.$$

No uniform lower bound for $1 - c$ as cutoffs vary is used. On a theta input, $Y\Theta\phi = (1 - T)\phi$, so $\Phi\Theta\phi = \phi$. The range of Φ is the even Schwartz space $\mathcal{S}(\mathbb{R})^{\text{even}}$. To check this exact domain, $\mathcal{U}F$ is even because its defining series uses $|x|$, and the same is true of $\mathcal{U}JF$. The cutoffs α, β are even, and Fourier transformation and inverse Fourier transformation preserve evenness, so YF is even. Reflection $\phi(x) \mapsto \phi(-x)$ commutes with T ; hence it commutes with every partial sum of the norm-convergent inverse $(1 - T)^{-1}$ and with its limit. Thus ΦF is even as an L^2 vector, and its Schwartz representative is even pointwise by continuity. With the original Gaussian moment corrections, define the map on this precise domain by

$$P_V\phi = \phi - \phi(0)e^{-\pi x^2} - \left(\int_{\mathbb{R}} \phi - \phi(0) \right) 2\pi x^2 e^{-\pi x^2}, \quad \Lambda = P_V\Phi.$$

The moment columns of the two displayed Gaussians are $(1, 1)$ and $(0, 1)$ by direct Gaussian integration. The two subtractions therefore set the value at zero and the integral to zero, while preserving evenness. On V both correction coefficients vanish. Consequently $P_V : \mathcal{S}(\mathbb{R})^{\text{even}} \rightarrow V$ is a continuous projection and $P_V|_V = 1$. This is its stated domain; no projection of the entire Schwartz space onto the even subspace is asserted by that formula. It follows that

$$\Lambda\Theta = 1_V, \quad K = 1 - \Theta\Lambda, \quad s : Q \rightarrow \mathcal{B}, \quad s[F] = KF. \quad (30)$$

This proves all needed existence and continuity claims for the particular global construction used in A1694. Since $\ker K = \Theta V$, that image is closed. The expression for s is well-defined, $qs = 1$, $\Lambda s = 0$, and it is continuous by the definition of the quotient topology. In particular Θ^{-1} on its image is Λ , verifying the topological inverse asserted after (17).

The already existing global cocycle is $k_a = \Lambda U_a s$, with

$$U_a s - s\overline{U}_a = \Theta k_a.$$

This follows by applying $1 = K + \Theta\Lambda$ to $U_a s$. The finite/global comparison is now fully determined, with no new choice of arithmetic unit:

$$b_Z = \Lambda R : E \rightarrow V, \quad R^s = s\sigma = R - \Theta b_Z. \quad (31)$$

Define $c_a^s = k_a \sigma$. Substitution in (15) yields

$$\boxed{c_a^s = c_a - U_a b_Z + b_Z a^A.} \quad (32)$$

To verify the equality in V , use $\overline{U}_a \sigma = \sigma a^A$ from (18) to compute

$$\begin{aligned} U_a R^s - R^s a^A &= U_a R - R a^A - \Theta U_a b_Z + \Theta b_Z a^A \\ &= \Theta(c_a - U_a b_Z + b_Z a^A) = \Theta k_a \sigma. \end{aligned}$$

Theta injectivity proves (32). Its derivative is the exact infinitesimal bridge

$$\boxed{k_D \sigma = \phi_* \ell - D b_Z + b_Z A, \quad k_D = \Lambda D s.} \quad (33)$$

All terms are defined continuous maps; differentiation is allowed by Section 1. This proves that the explicitly evaluated Duhamel integral and the transcript's global continuous cocycle represent the same actual arithmetic extension, through the displayed coboundary.

The full extension class is unchanged. Applying $h(D)$ to (31) gives

$$h(D)R^s(u) = \Theta(R_Z(u)(D)\phi_* - h(D)b_Z u).$$

Modulo $h(D)V$, its source class equals that of $R_Z(u)(D)\phi_*$. Under $j_h H$ its value is exactly εu , by (7). There is no quotient operation that discards the nonconstant coefficients of ε .

At cochain level the two finite representative maps r^s and r have the difference

$$r^s - r = dL^\pm, \quad L^+(u) = (-b_Z u, 0), \quad L^-(u) = (0, \widehat{b_Z u}). \quad (34)$$

The minus-face sign follows by applying $d(0, \widehat{b}) = -\Theta b$. Equations (25), (32), and (34) give the exact homotopy comparison

$$H_a^{s,\pm} = H_a^\pm + \mathcal{U}_a^0 L^\pm - L^\pm a^A.$$

These identities retain the joint degree-zero difference as in (28), rather than asserting strict agreement of the two face homotopies.

154.8 7. Tensor powers with every cohomological sign and jet coefficient

Let $k \geq 1$. On the original ordered tensor complex $C^{\otimes k}$ use

$$d(x_1 \otimes \cdots \otimes x_k) = \sum_{j=1}^k (-1)^{\sum_{i<j} |x_i|} x_1 \otimes \cdots \otimes dx_j \otimes \cdots \otimes x_k. \quad (35)$$

This is exactly the tau-base product resolution differential. It squares to zero because the two orders of applying differentials in different factors have opposite signs; a repeated differential in one factor is zero.

Write $f_a = U_a R : E \rightarrow C^1$, $g_a = R a^A : E \rightarrow C^1$, and $h_a = H_a^\pm : E \rightarrow C^0$ for any admitted choice of face in each factor. The explicit degree- -1 homotopy on the top packet is

$$\mathcal{H}_{a,k}(u_1 \otimes \cdots \otimes u_k) = \sum_{j=1}^k (-1)^{j-1} f_a u_1 \otimes \cdots \otimes f_a u_{j-1} \otimes h_a u_j \otimes g_a u_{j+1} \otimes \cdots \otimes g_a u_k. \quad (36)$$

In this evaluated formula the factor $(-1)^{j-1}$ is displayed exactly once. If the same formula is instead written as a tensor of graded linear maps, it is the Koszul evaluation sign of the degree -1 map in slot j crossing the preceding $j-1$ inputs, each of degree 1; it must not be inserted a second time.

Only the slot containing $h_a u_j$ contributes to the differential, because the other slots are already in top degree. Its differential sign from (35) is $(-1)^{j-1}$, which cancels the prefactor. Since $dh_a = f_a - g_a$, the result is the telescoping identity

$$d\mathcal{H}_{a,k} = (U_a R)^{\otimes k} - (R a^A)^{\otimes k}. \quad (37)$$

For $k=2$ this reads $\mathcal{H}_{a,2} = h_a \otimes g_a - f_a \otimes h_a$ on evaluated inputs, and its differential is $(f_a - g_a) \otimes g_a + f_a \otimes (f_a - g_a)$. This displays the original minus sign without relying on an implicit convention.

Define

$$R_k = R^{\otimes k}, \quad A_k = \sum_{j=1}^k 1^{\otimes(j-1)} \otimes A \otimes 1^{\otimes(k-j)}, \quad T_{t,k} = T_t^{\otimes k} = e^{tA_k}.$$

For the ordered local block $(\rho_1, \dots, \rho_k)$ the action is exactly

$$T_{t,k} = e^{t \sum_i \rho_i} \sum_{0 \leq j_i < m_{\rho_i}} \frac{t^{j_1 + \cdots + j_k}}{j_1! \cdots j_k!} N_{\rho_1}^{j_1} \otimes \cdots \otimes N_{\rho_k}^{j_k}. \quad (38)$$

The formula follows by multiplying (19); the nilpotents in different factors commute, and no term has been discarded. The representative is still the tensor of the maps using ε in (10), hence the coefficient unit is $\varepsilon^{\otimes k}$ in the ordered local algebra.

For the multivariable Mellin transform $\mathcal{M}_k$ with measure $\prod_i dx_i/x_i$, the top boundary $B_{a,k} = d\mathcal{H}_{a,k}$ has, on a pure coefficient tensor, the exact expression

$$\begin{aligned} \mathcal{M}_k B_{a,k}(\mathbf{s}) &= \prod_{i=1}^k [a^{s_i} v(s_i) R_Z(u_i)(s_i)] \\ &\quad - \prod_{i=1}^k [v(s_i) R_Z(a^A u_i)(s_i)]. \end{aligned} \quad (39)$$

All integrals factor by absolute convergence of the Schwartz Mellin integrals. Applying the full packet jet in each factor gives zero, as also follows from (37). The homotopy (36) exhibits the actual tensor relation giving that zero. It is not inferred from a dimension count or an assumed vanishing tensor kernel.

Every map in (36) is continuous. More explicitly, for seminorms $p_1, \dots, p_k$ on the appropriate target factors, the projective tensor seminorm of one summand on a pure input is bounded by the product of the corresponding operator bounds from (1), (10), and (14), times $\prod_i \|u_i\|$. Sum over the k terms and use the defining infimum for the projective seminorm on arbitrary finite sums. Thus all maps extend to completed projective tensor products, and (37) persists by density and continuity. The coefficient domain $E^{\otimes k}$ is finite dimensional, but this continuity statement identifies its targets in the same completed topology used by the original global construction.

The support rule is applied to each admitted factor before the tensor balancing quotient: an external absent factor is absorbing, while a zero amplitude in an active factor remains its supported tensor

zero. The chosen face in that factor determines which of (25) occurs. Changing that face replaces its homotopy by (28); substitution into (36) gives an explicit tensor of the retained H^0 cycle with the other degree-one factors. No identification of external tensor support with a Cartesian product of labels is needed or asserted.

This tensor homotopy difference can be detected without discarding a possible lower-degree boundary. Define cochain maps $\pi_0 : C \rightarrow V[0]$ by $\pi_0^0(v, w) = w$, $\pi_0^1 = 0$, and $\pi_1 : C \rightarrow Q[-1]$ by $\pi_1^0 = 0$, $\pi_1^1 = q$. In the difference between the all-plus and all-minus versions of (36), apply π_0 in slot j and π_1 in the others. Every summand but the j -th vanishes. The result is

$$(-1)^{j-1}(\sigma a^A)^{\otimes(j-1)} \otimes \widehat{c}_a \otimes (\sigma a^A)^{\otimes(k-j)}.$$

It is a nonzero map whenever $a \neq 1$: σa^A is injective by (11), $\widehat{c}_a$ is nonzero by Section 5, and a tensor of nonzero vectors over $\mathbb{C}$ is nonzero, as witnessed by a tensor of linear functionals nonzero on those vectors. The target complex has zero differential, so the detected class cannot be a boundary. This proves the exact survival of the homotopy difference in degree $k - 1$, where one factor carries the original $H^0(C)$ and the others carry Q .

154.9 8. The complete dx boundary pairing, its derivative, and tensor mass

The inclusion $\mathcal{B} \hookrightarrow L^2(\mathbb{R}_{>0}, dx)$ is continuous. For example on $(0, 1)$ use $|F(x)| \leq p_{-1,0}(F)x$, and on $(1, \infty)$ use $|F(x)| \leq p_{1,0}(F)x^{-1}$. Both squared majorants are integrable. Use the inner product conjugate-linear in its first argument. Direct substitution, retaining dx , gives

$$\langle U_a F, U_a G \rangle = a \langle F, G \rangle. \quad (40)$$

Let $G = R^* R$ in the retained coefficient basis and let $B_a = \Theta c_a : E \rightarrow L^2(dx)$. Since $J_Z R = 1$, G is positive definite. Equation (15), $U_a R = R a^A + B_a$, gives the exact finite boundary identity

$$\boxed{(a^A)^* G a^A - a G = -(U_a R)^* B_a - B_a^* (U_a R) + B_a^* B_a.} \quad (41)$$

On vectors u, w , its right side is

$$-\langle U_a R u, \Theta c_a w \rangle - \langle \Theta c_a u, U_a R w \rangle + \langle \Theta c_a u, \Theta c_a w \rangle.$$

To check the signs, solve $R a^A = U_a R - B_a$ and expand its squared pairing. Equation (40) supplies $a G$. Equivalently the right side is $-(R a^A)^* B_a - B_a^* R a^A - B_a^* B_a$; these two forms agree by (15). Thus the positive sign in the version using $U_a R$ is forced by the expansion, not a sign choice.

Every term is finite and depends smoothly on a , by the Frechet bounds already proved and the continuous Hilbert inclusion. For a full generalized packet vector u , the left side is evaluated using (19), retaining every power of $\log a$. For a true eigenvector $Au = \rho u$ it is $(a^{2\operatorname{Re} \rho} - a) u^* G u$.

The infinitesimal identity obtained by differentiating (41) at $t = \log a = 0$ is

$$W = A^* G + G A - G = -R^* f_0 \ell - \ell^* f_0^* R. \quad (42)$$

This agrees exactly with (12) and the original integration by parts. Indeed for $F, H \in \mathcal{B}$,

$$\langle DF, H \rangle + \langle F, DH \rangle = - \int_0^\infty x (\overline{F} H)' dx = \langle F, H \rangle,$$

since the endpoint term $[x \overline{F}(x) H(x)]_0^\infty$ vanishes by the displayed weighted bounds. This independently verifies the mass term $-G$ and the two negative boundary cross terms in (42).

The finite defect is exactly the integrated infinitesimal one:

$$T_t^* G T_t - e^t G = \int_0^t e^{t-r} T_r^* W T_r dr. \quad (43)$$

Set $F(t) = T_t^* G T_t - e^t G$. Direct differentiation gives $F'(t) = F(t) + T_t^* W T_t$ and $F(0) = 0$. Multiplying by e^{-t} and integrating proves (43) with the original orientation for $t < 0$. This is a finite-dimensional exact matrix integration, valid with all the nilpotents in (19).

For the global representative R^s from (31), replace R by R^s and c_a by the fully computed c_a^s in (32). The finite expansion (41) then holds with

$$G^s = (R - \Theta b_Z)^*(R - \Theta b_Z), \quad \Theta c_a^s = \Theta(c_a - U_a b_Z + b_Z a^A).$$

Its infinitesimal boundary is the changed map

$$B_D^s = \Theta k_D \sigma = \Theta(\phi_* \ell - D b_Z + b_Z A). \quad (43a)$$

Indeed differentiating the explicit $c_{e^t}^s$ at $t = 0$ gives $k_D \sigma$ by (33), and direct differentiation of $R^s = R - \Theta b_Z$ gives $DR^s - R^s A = B_D^s$ by (12). Apply the same dx integration-by-parts identity to $R^s u, R^s w$ for arbitrary coefficient vectors. Substituting $DR^s = R^s A + B_D^s$ and moving the two boundary terms to the other side proves exactly

$$W^s = A^* G^s + G^s A - G^s = -(R^s)^* B_D^s - (B_D^s)^* R^s. \quad (43b)$$

Thus the factor $f_0 \ell$ in (42) is replaced by B_D^s , not retained as the old infinitesimal source boundary. Finally differentiating $T_t^* G^s T_t - e^t G^s$ as in the proof of (43) gives $F_s'(t) = F_s(t) + T_t^* W^s T_t$, $F_s(0) = 0$, and therefore

$$T_t^* G^s T_t - e^t G^s = \int_0^t e^{t-r} T_r^* W^s T_r dr. \quad (43c)$$

This is exactly the restriction of the A1694 global pairing identity to the actual packet σE . It proves the finite/global relationship between both the cocycle and its boundary pairings, without assuming an unproved vanishing of either cross term.

For k factors use the Hilbert pairing with measure $dx_1 \cdots dx_k$. Fubini gives its value on pure tensors as the product of the original pairings, hence

$$\langle U_a^{\otimes k} F, U_a^{\otimes k} H \rangle = a^k \langle F, H \rangle.$$

Let $G_k = G^{\otimes k}$, $B_{a,k}$ be the actual boundary (37), and $\mathcal{R}_a = (U_a R)^{\otimes k}$. Then the exact tensor version of (41) is

$$(a^A)^{* \otimes k} G_k (a^A)^{\otimes k} - a^k G_k = -\mathcal{R}_a^* B_{a,k} - B_{a,k}^* \mathcal{R}_a + B_{a,k}^* B_{a,k}. \quad (44)$$

Indeed $R_k(a^A)^{\otimes k} = \mathcal{R}_a - B_{a,k}$ by (37), and expansion proves the formula. Its derivative has the exact ordered sum

$$W_k = A_k^* G_k + G_k A_k - k G_k = \sum_{j=1}^k G^{\otimes(j-1)} \otimes W \otimes G^{\otimes(k-j)}, \quad (45)$$

because each of the k copies of the term $-G$ in (42) contributes one copy of $-G_k$. The finite integral is

$$T_{t,k}^* G_k T_{t,k} - e^{kt} G_k = \int_0^t e^{k(t-r)} T_{r,k}^* W_k T_{r,k} dr. \quad (46)$$

The proof differentiates the left side exactly as in (43), with mass exponent k . Equations (38) and (46) retain all tensor nilpotents. They are actual formulas for the original representative boundary contribution on the original tau-base tensor complex.

154.10 9. Source pins and status of the calculation

The complete input files read for this calculation were:

- `arithmetic_input.tex` (original September 12 cumulative source), SHA256 a50b0fb587b644c4ea94dba45b2b423d038f2bfbe7fef188543939ba850e58d2.
- `Tau_Base_Cohomology, NOTE.md`, SHA256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3.
- Original transcript turn A1694.md, SHA256 a87bff4960c0a1742734e9e711780e0533ea76ba6f46ceab1fea115a2fd66f18; its original locator is recorded in Section 0.
- `Tau_Global_Comparison, NOTE.tex`, SHA256 50284fcebade0dc859ac398a00839a29e15be60c008e02314ac1f35c31950ed01; its equations are cited at the beginning.

The completed new formulas are (13)–(24), their exact finite/global comparison (31)–(34), the evaluated tensor homotopy and jets (36)–(39), and the integrated finite and tensor boundary expressions (43)–(46). Sections 1, 2, 5, 6, and the unintegrated boundary pairing explicitly reprove the source interfaces needed to type and verify those formulas. The global retraction, global cocycle, and support comparison in A1694 remain credited to that earlier calculation.

The resulting boundary terms have been computed, including their orientations, topologies, full arithmetic coefficients, and product masses. None has been set to zero by calling it a theta boundary. No estimate forcing the sign or vanishing of the original global weight defect is asserted by these identities. That precise limit on the conclusion does not delete the displayed maps, the full quotient Q , or the original tau-base construction.

155 The original balanced Mellin kernel: full polynomial comparison and meromorphic remainder

The authoritative shared transcript constructs the raw Mellin realization in A1167, retains its kernel complex in A1361, and replaces it by the $\mathbb{C}[t]$ -balanced realization in A1427. This section computes the polynomial action on the remaining kernel on those original objects. It uses no replacement arithmetic function and no auxiliary zero packet.

155.1 Original objects and full-plane Euler inverses

Retain, exactly as in A1167 and A1427,

$$\begin{aligned}
 V &= \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \int_{\mathbb{R}} \phi(x) dx = 0\}, \\
 \mathcal{B} &= \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^k F(x)| < \infty \quad (b \in \mathbb{Z}, k \geq 0)\}, \quad D = -x\partial_x, \\
 \Theta\phi(x) &= 2 \sum_{n \geq 1} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}, \quad M_+\phi(s) = \int_0^\infty \phi(x) x^s \frac{dx}{x}, \quad (\text{BK.1}) \\
 g(s) &= 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s), \\
 H_\phi(s) &= \frac{2\pi^{s/2}M_+\phi(s)}{s(s-1)\Gamma(s/2)}.
 \end{aligned}$$

The original Fourier convention is $\widehat{\phi}(\nu) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \nu} dx$. The original theta construction proves

$$\mathcal{M}\Theta\phi = gH_\phi, \quad \Theta D = D\Theta, \quad \widehat{D\phi} = (1-D)\widehat{\phi}, \quad H_{D\phi}(s) = sH_\phi(s), \quad H_{\widehat{\phi}}(s) = H_\phi(1-s). \quad (\text{BK.2})$$

The last equality follows directly from Poisson's identity $\Theta\widehat{\phi}(x) = x^{-1}\Theta\phi(1/x)$, Mellin substitution, and $g(1-s) = g(s)$; cancellation holds on the nonempty open set $g \neq 0$ and then throughout the

plane by holomorphy. Here H_ϕ is entire: Taylor subtraction of the even smooth function at zero gives only simple possible poles of $M_+\phi$ at the negative even integers; the corresponding zeros of $1/\Gamma(s/2)$ cancel them. At $s = 0$, $M_+\phi$ is holomorphic because $\phi(0) = 0$, and $s\Gamma(s/2)$ tends to 2. At $s = 1$, $M_+\phi(1) = 0$ is exactly the retained integral condition. In particular

$$H_\phi(1) = 2(M_+\phi)'(1). \quad (\text{BK.3})$$

The topology and all these maps are the original Schwartz ones.

For every $\rho \in \mathbb{C}$ one has the exact range formulas

$$(D - \rho)\mathcal{B} = \ker(\mathcal{M}(\cdot)(\rho)), \quad (D - \rho)V = \ker(H_{(\cdot)}(\rho)). \quad (\text{BK.4})$$

Both operators are injective. We now prove the full-plane source formula, including the endpoint $\rho = 1$ that cannot be handled by dividing by $1 - \rho$.

On the target zero-Mellin domain the inverse is the original integral

$$S_\rho F(x) = x^{-\rho} \int_x^\infty F(y) y^{\rho-1} dy. \quad (\text{BK.5})$$

Differentiating gives $(D - \rho)S_\rho F = F$. Since the total Mellin moment is zero, the same expression is $-x^{-\rho} \int_0^x F(y) y^{\rho-1} dy$ near zero. For $\sigma = \Re \rho$, an upper bound $|F(y)| \leq C_N y^{-N}$ yields $|S_\rho F(x)| \leq C_N x^{-N}/(N - \sigma)$ when $N > \sigma$. A lower bound $|F(y)| \leq C'_N y^N$ yields $|S_\rho F(x)| \leq C'_N x^N/(N + \sigma)$ when $N + \sigma > 0$. The differential identity controls each further Euler derivative. Thus every original seminorm is finite and the inverse is continuous on the indicated kernel. The only homogeneous solution is $cx^{-\rho}$, which belongs to $\mathcal{B}$ only when $c = 0$. Integration by parts proves $\mathcal{M}((D - \rho)F) = (s - \rho)\mathcal{M}F$, so the range is exactly the first kernel in (BK.4).

For the source, first let $\Re \rho > 0$ and $H_\phi(\rho) = 0$. For $\rho \neq 1$, the multiplier of $M_+\phi(\rho)$ in (BK.1) is finite and nonzero, so this Mellin moment vanishes. For $\rho = 1$ the same moment already vanishes by the definition of V . The integral (BK.5) is consequently also

$$S_\rho \phi(x) = - \int_0^1 u^{\rho-1} \phi(xu) du. \quad (\text{BK.6})$$

For every ordinary derivative of order k , differentiating this integral inserts $u^k \phi^{(k)}(xu)$. Uniform domination on bounded x intervals follows from $\Re \rho + k > 0$. Therefore the result extends smoothly and evenly across zero with value zero there. The upper-tail expression gives Schwartz decay, with every derivative, at infinity. If $\rho \neq 1$, integration of $(D - \rho)S_\rho \phi = \phi$ over $\mathbb{R}$ gives

$$(1 - \rho) \int_{\mathbb{R}} S_\rho \phi = \int_{\mathbb{R}} \phi = 0.$$

If $\rho = 1$, integration by parts in a right half-plane gives

$$M_+(S_1 \phi)(s) = \frac{M_+\phi(s)}{s - 1}.$$

Taking its removable value at 1 and using (BK.3) gives $\int_{\mathbb{R}} S_1 \phi = 2(M_+\phi)'(1) = H_\phi(1) = 0$. Thus the original source integral condition is retained at every ρ with positive real part.

If $\Re \rho \leq 0$, put $\lambda = 1 - \rho$, so $\Re \lambda \geq 1$. Fourier preserves V , and (BK.2) gives $H_{\widehat{\phi}}(\lambda) = H_\phi(\rho) = 0$. The exact inverse is

$$S_\rho^V \phi = -\widehat{S_\lambda \widehat{\phi}}. \quad (\text{BK.7})$$

On even functions Fourier squares to the identity. The intertwiner in (BK.2) therefore gives $(D - \rho)(-\widehat{S_\lambda \widehat{\phi}}) = \phi$, with every source condition preserved. For positive real part the inverse is (BK.6). The homogeneous solution cannot be Schwartz at infinity unless zero, so the inverse is unique. Identity (BK.2) proves the reverse containment in the second formula of (BK.4). This completes the full-plane calculation without excluding either endpoint or negative even Taylor coordinate.

155.2 Every polynomial kernel and cokernel is computed on the actual theta sequence

Set $A = \mathbb{C}[t]$, with t acting as the original D , and $Q = \mathcal{B}/\Theta V$. For a nonconstant monic polynomial

$$h(t) = \prod_{\rho} (t - \rho)^{n_{\rho}}, \quad E_h = A/(h),$$

let j_h retain all Taylor jets of orders less than n_{ρ} . Iterating (BK.4) gives

$$h(D)V = \ker(j_h H), \quad h(D)\mathcal{B} = \ker(j_h \mathcal{M}). \quad (\text{BK.8})$$

Indeed after dividing by $D - \rho$, the Mellin multiplier or H is divided by $s - \rho$ by (BK.2); the remaining zero orders are exactly the orders needed at the next division. Injectivity proves that the iterated inverse is independent of the chosen ordering.

The source jet map is onto because the original vector

$$\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2} \quad \text{satisfies} \quad H_{P(D)\phi_*} = P. \quad (\text{BK.9})$$

The target jet map is onto because its functionals on compactly supported smooth logarithmic functions are the independent functions $y^j e^{\rho y} / j!$. For precision, a dependence vanishing on an interval extends to an entire exponential polynomial. Applying $\prod_{\sigma \neq \rho} (\partial_y - \sigma)^{n_{\sigma}}$ removes the other summands; its restriction to $e^{\rho y}$ times polynomials of degree less than n_{ρ} is invertible, since it is a product of nonzero constants plus nilpotent derivatives. Then $(\partial_y - \rho)$ repeatedly separates the polynomial coefficients. All coefficients vanish. If the finite vector-valued jet map were not onto, a nonzero linear functional on its missing quotient would give such a dependence, a contradiction.

Consequently the quotient square and exact theta sequence are

$$\begin{array}{ccc} V/h(D)V & \xrightarrow{\Theta} & \mathcal{B}/h(D)\mathcal{B} \\ j_h H \downarrow \wr & & \wr \downarrow j_h \mathcal{M} \\ E_h & \xrightarrow{M_{j_h g}} & E_h, \end{array} \quad (\text{BK.10})$$

$$0 \longrightarrow Q[h(D)] \xrightarrow{\delta_h} E_h \xrightarrow{M_{j_h g}} E_h \longrightarrow Q/h(D)Q \longrightarrow 0. \quad (\text{BK.11})$$

These identities now hold for every polynomial h , without a strip restriction. The map δ_h sends $[F]$ to $j_h H_{\phi}$ where $h(D)F = \Theta\phi$. The source ϕ is unique because Θ is injective. Changing F by a theta relation changes ϕ by an $h(D)$ multiple, so the map is well-defined. If its value is zero, (BK.8) writes $\phi = h(D)\psi$ and injectivity of $h(D)$ on $\mathcal{B}$ gives $F = \Theta\psi$. A vector in the kernel of $M_{j_h g}$ is represented by a polynomial P ; the zero-jet condition permits applying the actual inverse of $h(D)$ to $\Theta(P(D)\phi_*)$, producing its preimage. Quotienting the right target in (BK.10) proves the last cokernel. This proves the entire sequence with its original maps.

155.3 The balanced kernel has invertible polynomial action

Fix any analytic stalk $O = \mathcal{O}_{\mathbb{C}, s_0}$, with t acting on O by multiplication by s . Write

$$M = O \otimes_A Q, \quad N = O/(g), \quad b : M \rightarrow N, \quad b(a \otimes [F]) = [a\mathcal{M}F], \quad K = \ker b. \quad (\text{BK.12})$$

The map is balanced by (BK.2). The ring O is torsion-free over the PID A : a nonzero polynomial times a holomorphic germ is zero only when that germ is zero. It is therefore flat. One direct justification of this familiar PID fact is to write a torsion-free module as the directed union of its finitely generated submodules; each such submodule is free by the PID structure theorem. Tensoring with a free module preserves injections, and filtered colimits preserve exactness, proving flatness.

The map b is onto. In fact the original test function

$$F_0(x) = \exp[-(\log x)^2], \quad H_0(s) = \mathcal{M}F_0(s) = \sqrt{\pi} \exp(s^2/4) \quad (\text{BK.13})$$

belongs to $\mathcal{B}$ and H_0 is an invertible germ at every point. Euler derivatives of F_0 are polynomials in $\log x$ times F_0 , and $x^b F_0$ is bounded for every integer b . Its Mellin integral becomes $\int_{\mathbb{R}} e^{-y^2+sy} dy$; real completion of the square gives the formula for real s , and entire continuation gives it for every complex s . Thus $b(aH_0^{-1} \otimes [F_0]) = [a]$, proving surjectivity.

For every nonzero polynomial h , the two induced maps are isomorphisms:

$$b : M[h] \xrightarrow{\sim} N[h], \quad \bar{b} : M/hM \xrightarrow{\sim} N/hN. \quad (\text{BK.14})$$

For a nonzero constant both statements are immediate. For a nonconstant polynomial flatness gives $M[h] = O \otimes_A Q[h(D)]$ and $M/hM = O \otimes_A (Q/h(D)Q)$. Also $O \otimes_A E_h = O/(h)$ by the explicit map $a \otimes [P(t)] \mapsto [aP(s)]$, with inverse $[a] \mapsto a \otimes 1$. The cokernel assertion in (BK.11) consequently gives

$$M/hM \cong O/(h, g) = N/hN,$$

and the isomorphism is precisely the Mellin map $\bar{b}$.

For the kernel map retain the actual local units. Put $z = s - s_0$ and write

$$h(s) = a(z)z^n, \quad g(s) = u(z)z^m, \quad a(0)u(0) \neq 0, \quad n, m \geq 0. \quad (\text{BK.15})$$

Under (BK.11), a local vector v in $\ker(g : O/(h) \rightarrow O/(h))$ corresponds to a torsion class with $h\mathcal{M}F = gH_\phi$, and its image under b is exactly

$$v \mapsto \left[\frac{g}{h} v \right] \in N[h]. \quad (\text{BK.16})$$

This is well-defined: changing v by h times a germ changes the displayed product by g times a germ. The kernel condition makes the product holomorphic. Explicitly its domain is $z^{\max(n-m, 0)} O / z^n O$ and its target is $z^{\max(m-n, 0)} O / z^m O$. Formula (BK.16) is multiplication by the actual unit u/a , together with the power z^{m-n} . It sends precisely the indicated source powers to the indicated target powers and has inverse multiplication by a/u and the power z^{n-m} . It is an isomorphism, including $m = 0$ or $n = 0$ when both spaces are zero. This proves the first map in (BK.14) without dropping a local factor of g or a repeated-zero order.

Apply the kernel-cokernel exact sequence for multiplication by h to $0 \rightarrow K \rightarrow M \xrightarrow{b} N \rightarrow 0$. It is

$$0 \rightarrow K[h] \rightarrow M[h] \rightarrow N[h] \rightarrow K/hK \rightarrow M/hM \rightarrow N/hN \rightarrow 0. \quad (\text{BK.17})$$

Both maps in (BK.14) are isomorphisms, so $K[h] = 0$ and $K/hK = 0$. We have proved

$$\boxed{h : K \xrightarrow{\sim} K \quad \text{for every nonzero } h \in \mathbb{C}[t].} \quad (\text{BK.18})$$

This is a computed property of the original balanced kernel.

It has a stronger local form. Every nonzero holomorphic germ is a unit times z^r . Units already act bijectively, and (BK.18) applied to $(t - s_0)^r$ makes z^r bijective. Hence K has a unique module structure over the meromorphic germ field $\text{Frac } O$, obtained by taking these actual inverses:

$$\frac{a}{b} \cdot k = a (b|_K)^{-1} k. \quad (\text{BK.19})$$

If $a/b = c/d$, the equality $ad = bc$ and invertibility of bd show that the two prescribed actions agree. The field laws follow by multiplying through their nonzero denominators.

155.4 Canonical finite spectral part and an explicit nonzero kernel class

At a point where $m = \text{ord}_{s_0} g > 0$, (BK.14) for $h = (t - s_0)^m$ gives a unique inverse $j : N \xrightarrow{\sim} M[z^m]$ of b on that kernel. Therefore

$$M = M[z^m] \oplus K, \quad x = j(bx) + (x - j(bx)), \quad M[z^m] \cong O/(g). \quad (\text{BK.20})$$

The first summand is all the O -torsion of M . Indeed every torsion element is killed by a power of z . For larger powers than m , (BK.14) still gives the same unique preimage of each element of N , because K has no z -torsion. When $m = 0$, $N = 0$ and the formula is $M = K$. All the full nilpotent jets of an actual zero occur in the first summand of (BK.20).

The kernel K is nonzero. The only classical zero-set input needed for the following assertion is the already-retained Hardy theorem: there are distinct $T_j \rightarrow +\infty$ with $g(1/2 + iT_j) = 0$. The cumulative reader uses this exact input in `theta_gamma_reference.tex`, (TG.26), and `sum_connection_stieltjes.tex`, (FC.21), with Hardy's original 1914 source. No assumption of RH is used.

Let $q_0 = [F_0] \in Q$. It is A -nontorsion. If $P(D)F_0 = \Theta\phi$ with a polynomial P , then (BK.2) and (BK.13) give

$$P(s)\sqrt{\pi}e^{s^2/4} = g(s)H_\phi(s).$$

At every $1/2 + iT_j$, the nonzero exponential forces $P(1/2 + iT_j) = 0$. A nonzero polynomial cannot have infinitely many distinct roots, so $P = 0$. Thus $A \rightarrow Q, P \mapsto P(D)q_0$, is injective. Flatness now proves that $O \rightarrow M, a \mapsto a \otimes q_0$, is injective. In particular

$$0 \neq g \otimes q_0 \in K. \quad (\text{BK.21})$$

The corresponding cycle is explicit on the original balanced complex. Put $b_* = \Theta\phi_*$, so $\mathcal{M}b_* = g$. In $O \otimes_A \mathcal{B}$, set

$$Z_0 = g \otimes F_0 - H_0 \otimes b_*. \quad \beta Z_0 = gH_0 - H_0g = 0. \quad (\text{BK.22})$$

Its degree-one class is exactly the nonzero class in (BK.21), since its second term is the original theta boundary. For the original invariant source label $W_* = \mathbb{C}[D]\phi_*$, the map $O \otimes_A W_* \rightarrow O$ induced by H is an isomorphism by (BK.9). Thus the kernel complex at that label has degree-zero term zero, and (BK.22) is an explicitly nonzero degree-one kernel cycle. Passing to the full label V preserves its nonzero class, as proved by the A -nontorsion argument. This resolves the status left open in A1427: balancing removes the earlier displayed spurious relation, but its full degree-one kernel is not zero.

This statement does not create a spectral obstruction to RH. For every finite-dimensional A -module E , let p_E be the characteristic polynomial of its t action. Cayley–Hamilton gives $p_E E = 0$. If $u : E \rightarrow K$ is A -linear, then $p_E u(E) = 0$ and injectivity in (BK.18) gives $u = 0$. If $v : K \rightarrow E$ is A -linear, every $k \in K$ is $p_E k'$ for some k' , and $v(k) = p_E v(k') = 0$. Consequently

$$\text{Hom}_A(E, K) = 0 = \text{Hom}_A(K, E) \quad (\dim_{\mathbb{C}} E < \infty). \quad (\text{BK.23})$$

The entire kernel has no finite-dimensional invariant subspace and no nonzero finite-dimensional equivariant quotient. This does not assert the same for arbitrary subquotients of its proper submodules. Its calculated contribution to every full finite spectral jet observation is zero, whereas (BK.20) proves that the actual finite spectral torsion survives bijectively.

Finally every construction occurs in the original supported quotient. The structure assertions (BK.18)–(BK.23) concern the full source label V used in (BK.12). They are not asserted for an arbitrary proper D -invariant source label. For such a label $W \subset V$, the exact comparison that must be retained is

$$0 \longrightarrow V/W \xrightarrow{[\phi] \mapsto [\Theta\phi]} Q_W \longrightarrow Q \longrightarrow 0, \quad Q_W = \mathcal{B}/\Theta W. \quad (\text{BK.24})$$

Injectivity of Θ proves the first map injective, and the quotient definitions prove its image is the last map's kernel. All maps commute with D when W is invariant. Tensoring this sequence with the

flat $\mathcal{O}$ retains the entire kernel $\mathcal{O} \otimes_A (V/W)$, which can have additional finite spectral torsion before transport to the full label. No such proper-label torsion is discarded by the scope of the structure theorem. The inclusion of labels $W_* \hookrightarrow V$ carries $\mathcal{B}/\Theta W_* \rightarrow \mathcal{B}/\Theta V$ with the original kernel $\Theta V/\Theta W_*$. Balancing imposes the explicit linear relations $sa \otimes v - a \otimes Dv$ within each such label. A linear map L at a fixed label ℓ lifts as $(\ell, x) \mapsto (\ell, Lx)$ and sends external τ to external τ . Addition joins labels and applies their given linear transports; the displayed formulas commute with those transports. Therefore (BK.22) is sent to the supported zero $(\ell, 0)$ by Mellin evaluation, while its nonzero kernel class remains at that label. Equations (BK.18)–(BK.24), including every actual nilpotent jet and the proper-label transition kernel, describe precisely which full-source kernel assertions survive the complete original quotient diagram.

156 The exact derived comparison at every finite spectral thickening

This calculation uses the balanced comparison of the original theta complex, as constructed in the shared conversation at A1427, and the polynomial-invertibility theorem proved in the accompanying balanced-kernel chapter. It uses no replacement polynomial in place of an actual zeta packet. Write $\mathcal{O} = \mathcal{O}_{\mathbb{C}, s_0}$ for the local ring of holomorphic germs at the specified spectral coordinate s_0 , $A = \mathbb{C}[t]$, $M = \mathcal{O} \otimes_A Q$, and

$$Q = \mathcal{B}/\Theta V, \quad g = 2\xi, \quad \beta : M \longrightarrow \mathcal{O}/(g), \quad \beta(a \otimes [F]) = [a\mathcal{M}F].$$

The A -action is exactly $tF = DF = -x\partial_x F$ on the original function space and $ta = sa$ on $\mathcal{O}$. Let $K = \ker \beta$. The preceding calculation on these original spaces proves that

$$0 \longrightarrow K \longrightarrow M \xrightarrow{\beta} \mathcal{O}/(g) \longrightarrow 0 \quad \text{is exact,} \quad (s - s_0) : K \xrightarrow{\sim} K. \quad (\text{DP.1})$$

In particular this is not an assumption of injectivity of β ; the preceding chapter exhibits an explicit nonzero element of K .

Proposition 156.1 (Derived finite spectral observations). *For every nonzero holomorphic germ $h \in \mathcal{O}$, the original comparison induces a quasi-isomorphism*

$$M \otimes_{\mathcal{O}}^{\mathbf{L}} \mathcal{O}/(h) \xrightarrow{\beta \otimes 1} (\mathcal{O}/(g)) \otimes_{\mathcal{O}}^{\mathbf{L}} \mathcal{O}/(h). \quad (\text{DP.2})$$

Both the degree-minus-one kernel and the degree-zero quotient are retained. The map commutes with multiplication by every holomorphic germ, in particular the original action a^s for every real $a > 0$.

Proof. Write the specified germ as $h = (s - s_0)^n u$, where $n \geq 0$ is its actual vanishing order and $u(s_0) \neq 0$. This identity retains the entire unit u , not merely its value at s_0 . Multiplication by u is invertible on every $\mathcal{O}$ -module. By (DP.1), multiplication by $(s - s_0)^n$ is invertible on K . Thus the literal multiplication map $h : K \rightarrow K$ is invertible.

The integral domain $\mathcal{O}$ has the free resolution

$$0 \longrightarrow \mathcal{O} \xrightarrow{\times h} \mathcal{O} \longrightarrow \mathcal{O}/(h) \longrightarrow 0.$$

Place its two free terms in degrees $-1, 0$. Tensoring it with the three modules in (DP.1) gives a short exact sequence of complexes

$$0 \longrightarrow [K \xrightarrow{h} K] \longrightarrow [M \xrightarrow{h} M] \longrightarrow [\mathcal{O}/(g) \xrightarrow{h} \mathcal{O}/(g)] \longrightarrow 0. \quad (\text{DP.3})$$

The first complex has zero cohomology in both degrees because its differential is invertible. The cohomology exact sequence of (DP.3) therefore proves (DP.2), including the degree -1 terms $\ker(h : M \rightarrow M)$ and $\ker(h : \mathcal{O}/(g) \rightarrow \mathcal{O}/(g))$. Its degree-zero terms are the actual quotients by h . All maps in (DP.3) are multiplication or $\mathcal{O}$ -linear maps; they commute with multiplication by every germ. This proves the claimed action compatibility without removing a nilpotent term. $\square$

At an actual zero ρ of complete order m_ρ , retain $g(s) = (s - \rho)^{m_\rho} v_\rho(s)$ with its nonvanishing full unit. For the exact thickening $h = (s - \rho)^n$, the right complex in (DP.3) has

$$H^{-1} = \{z \in \mathcal{O}_\rho/(g) : (s - \rho)^n z = 0\}, \quad H^0 = \mathcal{O}_\rho/(g, (s - \rho)^n). \quad (\text{DP.4})$$

When $n \geq m_\rho$, its differential is zero, so both terms are the entire length- m_ρ arithmetic local algebra. When $0 < n < m_\rho$, its kernel is exactly $(s - \rho)^{m_\rho - n} \mathcal{O}_\rho/(g)$ and its quotient is $\mathcal{O}_\rho/((s - \rho)^n)$, each of length n . These statements follow by division by the retained unit v_ρ , which is an isomorphism of the specified ideals and does not change the action. On every retained full block the action is still

$$a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho[z^j] = [z^{j+1}], \quad z = s - \rho. \quad (\text{DP.5})$$

Here is the exact bridge to the original dilation, rather than only to scalar multiplication on a balanced module. Define $R_a F(x) = F(x/a)$ and $R_a \phi(x) = \phi(x/a)$ for $a > 0$. These maps preserve the original spaces, commute with D , and $\Theta R_a = R_a \Theta$ term by term. Substitution $x = ay$ gives $\mathcal{M}(R_a F)(s) = a^s \mathcal{M}F(s)$; hence the induced $\mathcal{O}$ -linear map $1 \otimes R_a$ on M satisfies $\beta(1 \otimes R_a) = a^s \beta$. It preserves $M[h]$ and hM , since it commutes with h . The proved comparison on kernels and quotients therefore transports its action to literal multiplication by a^s , giving (DP.5). This does not assert equality of $1 \otimes R_a$ and scalar a^s on the entire balanced module: their difference has image in K , which is retained.

For the counterfactual under examination, ρ is an actual off-critical nontrivial zero of g ; its existence is the temporary premise, not a conclusion. Equations (DP.2)–(DP.5) prove that its complete finite block persists through this balanced comparison, even after taking every finite derived spectral thickening. It cannot be an element of the nonzero kernel K , since multiplication by its annihilating polynomial is invertible on K .

On each of the three original nonempty two-leg masks whose admitted theta image is the full ΘV , these complexes have the split lifts $(\lambda, x) \mapsto (\lambda, f(x))$, and external τ maps to external τ . A zero in (DP.3) is the supported zero at that same mask. This assertion uses the full admitted source V . The arithmetic spectral coordinate s_0 and the absolute base point τ are connected by this labelled comparison; they are not identified by it. Smaller admitted sources have the following additional, explicitly computed finite spectral data.

Proposition 156.2 (All finite defects of a smaller source label). *Let $W \subseteq V$ be an original D -invariant admitted source, and retain $Q_W = \mathcal{B}/\Theta W$. Put*

$$M_W = \mathcal{O} \otimes_A Q_W, \quad L_W = \mathcal{O} \otimes_A (V/W), \quad \beta_W(a \otimes [F]_W) = [a \mathcal{M}F], \quad K_W = \ker \beta_W.$$

Then the source inclusion induces the exact sequences

$$0 \longrightarrow L_W \xrightarrow{[\phi] \mapsto [\Theta \phi]} M_W \xrightarrow{\pi_W} M \longrightarrow 0, \quad 0 \longrightarrow L_W \longrightarrow K_W \longrightarrow K \longrightarrow 0. \quad (\text{DP.6})$$

For every nonzero germ h , their induced maps give

$$L_W[h] \xrightarrow{\sim} K_W[h], \quad L_W/hL_W \xrightarrow{\sim} K_W/hK_W. \quad (\text{DP.7})$$

More fully, inclusion is a quasi-isomorphism

$$[L_W \xrightarrow{h} L_W] \xrightarrow{\sim} [K_W \xrightarrow{h} K_W]. \quad (\text{DP.8})$$

Proof. Injectivity of the original $\Theta : V \rightarrow \mathcal{B}$ gives the exact A -module sequence $0 \rightarrow V/W \xrightarrow{\Theta} Q_W \rightarrow Q \rightarrow 0$. The flatness proved in the balanced-kernel chapter yields the first sequence in (DP.6). The equality $\beta_W = \beta \pi_W$ follows directly from the retained Mellin formula. Every element

of L_W maps to zero under β_W , since $\mathcal{M}\Theta\phi = gH_\phi$. If $k \in K$, lift it to $x \in M_W$ using the surjection π_W ; then $\beta_W x = \beta k = 0$. This proves the second sequence in (DP.6), including surjectivity of its last map. Tensor its terms with the same two-term free resolution of $\mathcal{O}/(h)$ used in (DP.3). The quotient complex is $[K \xrightarrow{h} K]$, whose differential is invertible by (DP.1) and its unit-factor argument. Its cohomology vanishes. The resulting exact cohomology sequence proves both (DP.7) and (DP.8). Every arrow comes from the actual source inclusion, and commutes with the given actions. $\square$

Thus a finite spectral class in a smaller label's Mellin kernel is precisely a finite spectral class in its retained relation quotient V/W . It vanishes upon passing to the full arithmetic source V , by (DP.6). This is an actual transition map, not a deletion of the smaller label or its extension. The next chapter constructs such a nonzero class explicitly from the original dilates of ϕ_* , so that the restriction to the full source in (DP.1)–(DP.5) is also tested by a concrete example. At a smaller label only D -invariance has been imposed. Accordingly (DP.6)–(DP.8) commute with the D and holomorphic-scalar actions; an original dilation R_a acts between the labels W and $R_a W$, and is an endomorphism at W only when $R_a W = W$. This follows from the exact map $[F]_W \mapsto [R_a F]_{R_a W}$ and $\Theta R_a = R_a \Theta$.

157 An actual proper source label with a finite spectral kernel

The full-source calculation (BK.18) applies to $Q = \mathcal{B}/\Theta V$. It does not assert the same result for $Q_W = \mathcal{B}/\Theta W$ at an arbitrary proper, D -invariant source label $W \subset V$. The following construction proves the distinction and its exact transition map on the original source functions. It does not replace $g = 2\xi$ by a model function and does not assume an off-critical zero.

Retain $A = \mathbb{C}[t]$, $t = D = -x\partial_x$, and the original source vector and its literal dilation

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad \psi(x) = \phi_*(2x). \quad (\text{PL.1})$$

Both functions belong to V : dilation preserves evenness, Schwartz decay, and value zero at the origin, while $\int_{\mathbb{R}} \psi(x) dx = \frac{1}{2} \int_{\mathbb{R}} \phi_*(y) dy = 0$. The change of variable $y = 2x$ in the original positive Mellin integral gives

$$M_+ \psi(s) = 2^{-s} M_+ \phi_*(s), \quad H_\psi(s) = 2^{-s}, \quad \mathcal{M}\Theta\psi(s) = g(s)2^{-s}. \quad (\text{PL.2})$$

The first equality holds in its initial half-plane of absolute convergence; the entire continuation of H proved in (BK.1)–(BK.3) extends the second equality to the full plane. Here $2^{-s} = \exp(-s \log 2)$ uses the positive real logarithm of the actual dilation constant 2.

Define the original invariant source label

$$W = A\phi_* + A\psi \subset V. \quad (\text{PL.3})$$

This is a free rank-two A -module on the two displayed vectors. Indeed an equality $P(D)\phi_* + Q(D)\psi = 0$, for polynomials $P, Q \in \mathbb{C}[t]$, implies by (BK.2) and (PL.2)

$$P(s) + Q(s)2^{-s} = 0 \quad (s \in \mathbb{C}).$$

As the real variable s tends to positive infinity, $Q(s)2^{-s}$ tends to zero. Thus $P(s)$ tends to zero. A nonzero complex polynomial cannot tend to zero along that ray: division by its highest real power gives its nonzero leading coefficient. Consequently $P = 0$, and the nonvanishing exponential forces $Q = 0$. This also proves the exponential-polynomial independence used below.

Fix any $\rho \in \mathbb{C}$ and retain its exact nonzero scalar $c_\rho = 2^{-\rho}$. Set

$$\phi_\rho = \psi - c_\rho \phi_* \in W, \quad H_{\phi_\rho}(s) = 2^{-s} - c_\rho. \quad (\text{PL.4})$$

The last entire function vanishes at $s = \rho$. The already-proved full-plane inverse (BK.4), including its endpoint and Fourier-reflected cases, therefore gives the unique actual vector

$$\chi_\rho = S_\rho^V \phi_\rho \in V, \quad (D - \rho)\chi_\rho = \phi_\rho, \quad H_{\chi_\rho}(s) = \frac{2^{-s} - 2^{-\rho}}{s - \rho}. \quad (\text{PL.5})$$

Its displayed quotient is entire with its retained value $H_{\chi_\rho}(\rho) = -(\log 2)2^{-\rho} \neq 0$. The vector is specified without an implicit choice: for $\text{Re } \rho > 0$ its positive-half-line formula is

$$\chi_\rho(x) = x^{-\rho} \int_x^\infty \phi_\rho(y) y^{\rho-1} dy = - \int_0^1 u^{\rho-1} \phi_\rho(xu) du, \quad (\text{PL.6})$$

extended evenly; for $\text{Re } \rho \leq 0$ it is $-\widehat{S_{1-\rho}\phi_\rho}$, with the same positive-half-line integral for $S_{1-\rho}$. The proof in (BK.4)–(BK.7) establishes all original source conditions for these formulas.

The vector χ_ρ is not in W . Suppose otherwise and write $\chi_\rho = P(D)\phi_* + Q(D)\psi$. Multiplying the equality of their H transforms by $s - \rho$ gives the entire identity

$$((s - \rho)P(s) + 2^{-\rho}) + ((s - \rho)Q(s) - 1)2^{-s} = 0. \quad (\text{PL.7})$$

The proved exponential-polynomial independence makes both polynomial coefficients identically zero. Evaluating the first at $s = \rho$ would give $2^{-\rho} = 0$, a contradiction. This proves $\chi_\rho \notin W$, so in particular $W \neq V$.

Now take the actual theta representative and its original supported quotient class:

$$F_\rho = \Theta\chi_\rho \in \mathcal{B}, \quad q_\rho = [F_\rho]_W \in Q_W = \mathcal{B}/\Theta W. \quad (\text{PL.8})$$

It is nonzero because $F_\rho = \Theta w, w \in W$, would imply $\chi_\rho = w$ by injectivity of the original theta map. Nevertheless

$$(t - \rho)q_\rho = 0, \quad \mathcal{M}F_\rho(s) = g(s) \frac{2^{-s} - 2^{-\rho}}{s - \rho}. \quad (\text{PL.9})$$

The first equality follows from $(D - \rho)F_\rho = \Theta\phi_\rho \in \Theta W$; the second is the original identity $\mathcal{M}\Theta = gH$ applied to χ_ρ . In fact $Aq_\rho \cong A/(t - \rho)$. For any polynomial P , division by $t - \rho$ gives $P(t)q_\rho = P(\rho)q_\rho$. Since $q_\rho \neq 0$, this vanishes exactly when $P(\rho) = 0$.

Let $O = \mathcal{O}_{\mathbb{C}, \rho}$, $z = s - \rho$, and retain the actual proper-label comparison

$$M_W = O \otimes_A Q_W, \quad b_W : M_W \longrightarrow O/(g), \quad b_W(a \otimes [F]_W) = [a\mathcal{M}F], \quad K_W = \ker b_W. \quad (\text{PL.10})$$

It is well-defined because $\mathcal{M}\Theta w = gH_w$ for every $w \in W$; it is balanced because $\mathcal{M}DF = s\mathcal{M}F$. It is onto by the original F_0 and its invertible transform H_0 in (BK.13): $b_W(aH_0^{-1} \otimes [F_0]_W) = [a]$. The inclusion $Aq_\rho \hookrightarrow Q_W$ remains injective after tensoring with the flat A -module O . Since

$$O \otimes_A Aq_\rho \cong O/(z) \neq 0,$$

the element $k_\rho = 1 \otimes q_\rho$ is nonzero in M_W . Its original image (PL.9) is divisible by g , giving

$$0 \neq k_\rho \in K_W, \quad zk_\rho = 0. \quad (\text{PL.11})$$

Thus K_W has a nonzero one-dimensional spectral submodule on an actual proper source label containing the original arithmetic generator ϕ_* . Invariance of W and inclusion of that generator do not imply the polynomial-invertibility theorem for K_W .

We record the exact morphism that transports this class to the proved full-source comparison. Inclusion of source labels gives

$$0 \longrightarrow V/W \xrightarrow{[v] \mapsto [\Theta v]_W} Q_W \xrightarrow{[F]_W \mapsto [F]_V} Q \longrightarrow 0. \quad (\text{PL.12})$$

The first arrow is injective by theta injectivity. The final map is onto, and its kernel consists exactly of those representatives in ΘV , modulo ΘW . These statements prove exactness and identify its kernel with the original V/W , without changing the source quotient. The arrows commute with D because theta does. Flatness therefore gives the actual balanced exact sequence

$$0 \longrightarrow O \otimes_A (V/W) \longrightarrow M_W \xrightarrow{\pi} M \longrightarrow 0, \quad M = O \otimes_A Q, \quad b_W = b\pi. \quad (\text{PL.13})$$

Restricting π to the indicated kernels gives

$$0 \longrightarrow O \otimes_A (V/W) \longrightarrow K_W \xrightarrow{\pi} K \longrightarrow 0. \quad (\text{PL.14})$$

Indeed the first term is already in K_W since its Mellin values are multiples of g . Every element of K has a lift in M_W by (PL.13), and every such lift is in K_W because $b_W = b\pi$. This proves surjectivity of the last arrow and identifies its kernel. The explicit k_ρ is the image of $1 \otimes [\chi_\rho]$ in the left term of (PL.14), and its image in K is exactly zero. Its finite spectral contribution is therefore removed by the specified enlargement from W to V . It does not contradict the polynomial invertibility of the full-source K .

This difference is also detected by the finite derived observations. Tensor the free resolution $[O \xrightarrow{z} O]$ with the proper-label exact sequence $0 \rightarrow K_W \rightarrow M_W \xrightarrow{b_W} O/(g) \rightarrow 0$. It produces the short exact sequence of complexes

$$0 \rightarrow [K_W \xrightarrow{z} K_W] \rightarrow [M_W \xrightarrow{z} M_W] \rightarrow [O/(g) \xrightarrow{z} O/(g)] \rightarrow 0. \quad (\text{PL.15})$$

The first complex has nonzero degree-minus-one cohomology, since $k_\rho \in \ker(z : K_W \rightarrow K_W) \setminus \{0\}$. Equivalently the degree-minus-one map on the last two complexes has the nonzero kernel containing k_ρ . Thus $b_W \otimes_O^L O/(z)$ is not a quasi-isomorphism. The finite derived comparison (DP.2) is therefore a theorem for its stated full-source Q and its specified copies in the supported construction, not for arbitrary proper source labels.

Every element above retains its original label. The source-label transport carries $[\Theta\chi_\rho]_W$ to the supported zero in the V fibre; it does not send that element to the external absence point τ . Equations (PL.12)–(PL.15) prove the exact relation between the proper-label finite spectral kernel and the full-source meromorphic kernel, including the class that the transition kills. Nothing in the construction asserts $g(\rho) = 0$; it works at every specified ρ . If ρ is an actual off-critical zero, its arithmetic block in $O/(g)$ remains the one computed in (DP.4), and the proper-label class (PL.11) is the separately computed kernel of the displayed source-label transition.

158 The actual arithmetic packet through mixed-support synchronization

This calculation starts with the mixed-support construction in original shared-thread record A0961, node a7bbd422-311c-4380-ba6c-a4bdd61fce2f, chain 2032, and its full authored proof in original record A0953, node 0d2934ea-14ac-48c1-a1f3-cd918c1f5fe5, chain 1987. It does not replace the actual arithmetic function by a symmetric test polynomial. The polynomial below is the full divisor polynomial of an actual packet in the counterfactual under study.

Let Z be a nonempty finite set of actual nontrivial zeros of the original completed function $g(s) = 2\xi(s)$, with their full orders m_ρ . Retain

$$h_Z(x) = \prod_{\rho \in Z} (x - \rho)^{m_\rho}, \quad d = \sum_{\rho \in Z} m_\rho, \quad E_Z = \mathbb{C}[x]/(h_Z(x)).$$

The variable x is the original spectral variable. The additional variable t below is the cyclic coefficient coordinate; it is not substituted for x . For $a > 0$ let

$$A_a = M_{j_{h_Z}(a^s)} : E_Z \longrightarrow E_Z.$$

Here $a^s = \exp(s \log a)$ uses the real logarithm and j_{h_Z} retains all Taylor coefficients at the actual zero centres. On the summand

$$E_\rho = \mathbb{C}[z_\rho]/(z_\rho^{m_\rho}), \quad x = \rho + z_\rho,$$

this is exactly

$$A_a|_{E_\rho} = a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho = M_{z_\rho}. \quad (34)$$

Thus no multiplicity or nilpotent term is omitted.

158.1 The original mixed-support object, with its unit

Fix $n \geq 1$. Form the source object $D_{E_Z, n} = G(E_Z)^n$ with coordinatewise addition and the source product

$$(b \star c)_k = \bigoplus_{i+j=k} b_i c_j \oplus \bigoplus_{i+j=k+n} (-1)^{\bullet} b_i c_j, \quad 0 \leq k < n.$$

An empty sum is τ , and the original unit is $(1^\bullet, \tau, \dots, \tau)$. Write $e = 0^\bullet_{E_Z}$. The exact amplitude target is

$$B_n = E_Z[t]/(t^n + 1), \quad \pi_n(b) = \sum_{i=0}^{n-1} p(b_i) t^i.$$

The support mask of b has its i th entry equal to one precisely when $b_i \neq \tau$. The pair consisting of the mask and $\pi_n(b)$ is injective: the monic polynomial gives the free E_Z -basis $1, t, \dots, t^{n-1}$, and the mask then distinguishes e from τ in each zero coefficient.

Let

$$E_n = (1^\bullet, e, \dots, e).$$

Multiplication by E_n sends the wholly absent input to itself and every active input to the fully supported vector with the same ordinary coefficients. To check the support assertion, fix an active input coefficient at index j . At every output index k the summand using the E_n coefficient at $k - j$ modulo n is supported; all wrap factors are supported. Thus every output coordinate is supported, including a coordinate whose resulting amplitude is zero. The amplitude assertion follows from $\pi_n(E_n) = 1$. It follows at once that $E_n^2 = E_n$ and

$$D_{E_Z, n}[E_n^{-1}] \simeq E_n D_{E_Z, n} \simeq G(B_n). \quad (35)$$

The image has unit E_n . For completeness, a unital semiring map making E_n invertible sends it to 1 by idempotence and therefore sends b and $E_n b$ to the same value. This is the localization universal property. The inclusion of the image into the original unsynchronized object is not falsely declared to preserve the original unit.

158.2 A proved split injection and its exact retraction

Define

$$\iota_n : E_Z \longrightarrow B_n, \quad f \longmapsto f, \quad r_n : B_n \longrightarrow E_Z, \quad b \longmapsto \frac{1}{n} \text{Tr}_{B_n/E_Z}(M_b).$$

The first is a unital ring homomorphism. The second is an E_Z -linear map of modules; it is not asserted to be multiplicative. In the basis $1, t, \dots, t^{n-1}$, multiplication by t^k has no diagonal entries for $1 \leq k < n$, since it shifts every basis index by the nonzero class $k \pmod{n}$. Its wrap entries carry the original minus signs. Multiplication by $b_0 \in E_Z$ is the scalar matrix with n diagonal entries b_0 . Consequently

$$\text{Tr}_{B_n/E_Z} \left(M_{\sum_{i=0}^{n-1} b_i t^i} \right) = n b_0, \quad r_n \left(\sum_{i=0}^{n-1} b_i t^i \right) = b_0, \quad r_n \iota_n = 1_{E_Z}. \quad (36)$$

In particular the trace factor n and its inverse in the retraction are both retained. No arithmetic trace form has been rescaled.

For a linear map $T : M \rightarrow N$ over E_Z , its split lift is $T^\tau(m^\bullet) = T(m)^\bullet$ and $T^\tau(\tau) = \tau$. It is $G(E_Z)$ -linear: addition of supported inputs is the original module addition, scalar multiplication is the original module action, and the cases containing an absent scalar or input are absorbed by τ . A zero result is $(0_N)^\bullet$, not τ . Thus (36) lifts to an actual retract

$$E_Z^\tau \xrightarrow{\iota_n^\tau} G(B_n) \xrightarrow{r_n^\tau} E_Z^\tau, \quad r_n^\tau \iota_n^\tau = 1. \quad (37)$$

Through (35), the first map is the fully supported mixed vector $(f^\bullet, e, \dots, e)$ for supported f , and the wholly absent vector for τ . Therefore every nonzero amplitude packet class remains nonzero through this specific mixed-support realization and localization.

Write $\sigma_Z : E_Z \hookrightarrow Q$ and $J_Z : Q \rightarrow E_Z$ for the original arithmetic packet injection and observation, whose proved identity is $J_Z \sigma_Z = 1_{E_Z}$. Their composite with the maps just computed is

$$\sigma_Z r_n : B_n \longrightarrow Q, \quad (\sigma_Z r_n) \iota_n = \sigma_Z.$$

This is a composite of the established maps, not a new assertion that the spectral coefficients are unrelated to arithmetic cohomology.

The scaling intertwiner used here comes from the original source. Retain $Q = \mathcal{B}/\Theta V$, $D = -x\partial_x$, and $\Theta\phi(x) = \sum_{j \in \mathbb{Z} \setminus \{0\}} \phi(jx)$. On both original test spaces define

$$(\mathcal{R}_a F)(x) = F(x/a), \quad a > 0.$$

Positive dilation preserves even Schwartz functions and their two zero moments: the value at zero is unchanged and the integral is multiplied by a . Direct substitution in the theta sum proves $\Theta \mathcal{R}_a = \mathcal{R}_a \Theta$. Thus $\mathcal{R}_a$ induces the original action $\bar{\mathcal{R}}_a$ on Q . Substitution $x = ay$ in the Mellin integral gives

$$\mathcal{M}(\mathcal{R}_a F)(s) = a^s \mathcal{M}F(s), \quad J_Z \bar{\mathcal{R}}_a = A_a J_Z.$$

The source's complete finite-packet theorem identifies $\sigma_Z(E_Z) = Q[h_Z(D)]$ and makes J_Z its inverse there. Since $\mathcal{R}_a D = D \mathcal{R}_a$, that subspace is invariant. Applying the bijection J_Z to its two vectors therefore proves

$$\bar{\mathcal{R}}_a \sigma_Z = \sigma_Z A_a.$$

This carries the full factor a^ρ and every Taylor coefficient in (34) from the actual theta quotient.

158.3 The exact coefficient Frobenius comparison

Let q be an odd prime power with $\gcd(q, n) = 1$. On the integral coefficient algebra

$$C_{n, \mathbb{Z}} = \mathbb{Z}[t]/(t^n + 1)$$

define the unital algebra map

$$\Psi_q(t) = t^q, \quad \Psi_q(c) = c \quad (c \in \mathbb{Z}).$$

It is well-defined since $(t^q)^n = (-1)^q = -1$. Because $\gcd(q, 2n) = 1$, choose $r > 0$ with $q^r \equiv 1 \pmod{2n}$. The identity $t^{2n} = 1$ then gives $\Psi_q^r = 1$, proving it is an automorphism. Its matrix in the original coefficient basis is the signed permutation

$$t^i \longmapsto (-1)^{\lfloor qi/n \rfloor} t^{qi \bmod n}. \quad (38)$$

Reduction of this integral map to $\mathbb{F}_q$ is exactly the source's q -power Frobenius on $\mathbb{F}_q[t]/(t^n + 1)$, because every scalar of $\mathbb{F}_q$ has q th power equal to itself. Its extension to $\mathbb{C}$ is a coefficient-linear lift

of that integral matrix. It is not the map $c \mapsto c^q$ on complex scalars. These two specializations are linked by the displayed integral map; no ring homomorphism $\mathbb{F}_q \rightarrow \mathbb{C}$ is asserted.

There is also a map on the full unsynchronized mixed-support object: send coefficient b_i to $((-1)^\bullet)^{\lfloor qi/n \rfloor} b_i$ in slot $qi \bmod n$, fixing E_Z scalars and preserving absent inputs. It is additive. On two supported monomials, reducing the exponent before or after the map gives the same wrap factor because $((-1)^\bullet)^q = (-1)^\bullet$; the absent cases are absorbed, and distributivity proves the product identity for arbitrary vectors. Hence this is a semiring morphism, fixes E_n , preserves every mask up to the stated permutation, and induces Ψ_q through (35).

Extend Ψ_q E_Z -linearly to B_n . It fixes the subspace $\iota_n(E_Z)$ pointwise. It preserves r_n : formula (38) moves no index $i \in \{1, \dots, n-1\}$ to zero modulo n , and fixes index zero. Hence

$$\Psi_q \iota_n = \iota_n, \quad r_n \Psi_q = r_n. \quad (39)$$

Every eigenvalue of the complex coefficient operator Ψ_q is a root of unity, because $\Psi_q^r = 1$. Over $\mathbb{C}$ the polynomial $X^r - 1$ has no repeated roots, so the operator is diagonalizable. This is the exact finite coefficient purity calculation transported through its integral matrix.

158.4 The original arithmetic action, full jets, and modulus

Extend A_a to B_n by coefficient multiplication:

$$A_a^B \left(\sum b_i t^i \right) = \sum A_a(b_i) t^i.$$

Since A_a is multiplication by $j_{h_Z}(a^s) \in E_Z$, this commutes with the E_Z -linear automorphism Ψ_q . The maps in (36) intertwine the arithmetic action exactly:

$$A_a^B \iota_n = \iota_n A_a, \quad r_n A_a^B = A_a r_n.$$

Consequently they also intertwine A_a with $A_a^B \Psi_q$ because of (39). On the coefficient eigenspace of Ψ_q with eigenvalue ω , the original ρ -packet action is

$$\omega a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j. \quad (40)$$

The entire nilpotent polynomial is retained. For $a \neq 1$, its nilpotent part has the same nilpotence index as N_ρ :

$$\exp((\log a) N_\rho) - 1 = N_\rho \left((\log a) I + \sum_{j=2}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^{j-1} \right),$$

and the factor in parentheses is invertible because its constant coefficient is nonzero. The expression also states the case $m_\rho = 1$ directly.

Let e_ρ be the full Chinese-remainder idempotent in E_Z . The vector

$$v_\rho = e_\rho(x - \rho)^{m_\rho-1}$$

is nonzero: in its ρ -local quotient its coefficient of $z_\rho^{m_\rho-1}$ is one. It is killed by N_ρ and satisfies $A_a v_\rho = a^\rho v_\rho$. The vector $\iota_n(v_\rho)$ is nonzero by the retraction, lies in the fixed coefficient line of Ψ_q , and is therefore an eigenvector of $A_a^B \Psi_q$ with the unchanged eigenvalue a^ρ .

Suppose now the actual counterfactual supplies $\rho = \frac{1}{2} + \delta + i\gamma$, $0 < \delta < \frac{1}{2}$. For every $a > 1$,

$$\frac{|a^\rho|^2}{a} = a^{2\delta} > 1, \quad \log \frac{|a^\rho|^2}{a} = 2\delta \log a. \quad (41)$$

For the other coefficient eigenspaces in (40), $|\omega| = 1$ gives exactly the same modulus. At $a = q$, these eigenvalues are $q^\rho \omega$. The coefficient pure spectrum therefore preserves the actual arithmetic weight defect in this specified construction.

Take every tensor power in this paragraph over $\mathbb{C}$. The vector $\iota_n(v_\rho)^{\otimes_{\mathbb{C}} k}$ is nonzero because $(r_n)^{\otimes_{\mathbb{C}} k}$ sends it to $v_\rho^{\otimes_{\mathbb{C}} k}$. The latter is nonzero: a complex linear functional taking v_ρ to 1 has k -fold complex tensor power taking that tensor to 1. Its eigenvalue under $(A_a^B \Psi_q)^{\otimes_{\mathbb{C}} k}$ is $a^{k\rho}$, and

$$\log \frac{|a^{k\rho}|^2}{a^k} = 2k\delta \log a.$$

This is an exact input to the user's selected Deligne amplification argument. The computation does not import a cohomological upper estimate from another object. It identifies which actual nonzero class and which unchanged eigenvalue such an estimate must control.

158.5 The trace obstruction also survives the pure coefficient factor

Assume Z is stable under $\rho \mapsto 1 - \bar{\rho}$ and under conjugation, with the original multiplicities. Retain the actual derivative-residue trace contraction

$$\mathcal{T}_Z(f, u) = \sum_{\rho \in Z} m_\rho \overline{f(1 - \bar{\rho})} u(\rho).$$

This formula is the contraction of the original residue pairing using g' ; the factors in $g = 2\xi$ are not modified here. In a genuine off-line quartet let m be its common multiplicity and set $f = e_\rho - e_{1-\bar{\rho}}$. The two nonzero evaluations contribute $-m$ each, so $\mathcal{T}_Z(f, f) = -2m$.

On $C_n = \mathbb{C}[t]/(t^n + 1)$ retain the positive form

$$H_n(c, d) = \sum_{j=0}^{n-1} \overline{c(r_j)} d(r_j), \quad r_j = \exp\left(\frac{(2j+1)\pi i}{n}\right).$$

The distinct roots make evaluation an isomorphism $C_n \simeq \mathbb{C}^n$, proving positive definiteness. The operator Ψ_q permutes the evaluations, so it preserves H_n . The original constant vector has $H_n(1, 1) = n$. Under $B_n \simeq E_Z \otimes_{\mathbb{C}} C_n$ the tensor form therefore satisfies

$$(\mathcal{T}_Z \otimes_{\mathbb{C}} H_n)(\iota_n f, \iota_n f) = -2mn < 0.$$

This proves the actual negative trace vector survives this exact positive coefficient attachment, with the factor n retained. It does not assert that the global arithmetic polarization is automatically this tensor form. Any different global comparison has its own map and must be calculated on this surviving input.

159 The multiplicity boundary floor

This section proves an exact lower bound on the relative control defect of the theta-generated representatives. The bound counts every retained zero with its complete multiplicity. The source constructions are A1644, lines 2576–2718, and A1771, lines 4477–4835, in the authoritative `audit_segment_U0041_U0054.md`. The rank-two identity itself is A1771, lines 4688–4725. The invariant trace and the invariant-subspace argument below are new deductions from those source constructions.

All matrix coordinates on the packet algebra are the original polynomial coordinates. The generator is $D = -x\partial_x$, the arithmetic multiplier is $g = 2\xi$, and the Hilbert-space measure is dx on the positive half-line. The local extension unit, the unscaled orthogonal vectors, their norm squares, and all nilpotent jets are retained.

159.1 The original source, packet algebra, and arithmetic section

Write

$$\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s), \quad g(s) = 2\xi(s),$$

with the entire continuations understood at the apparent singularities. Let

$$\begin{aligned} V &= \left\{ \phi \in \mathcal{S}(\mathbb{R}) : \phi \text{ is even, } \phi(0) = 0, \int_{\mathbb{R}} \phi(x) dx = 0 \right\}, \\ \mathcal{B} &= \left\{ F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^j F(x)| < \infty \text{ for all } b \in \mathbb{Z}, j \geq 0 \right\}, \\ D &= -x\partial_x, \quad (\Theta\phi)(x) = \sum_{a \neq 0} \phi(ax) = 2 \sum_{a \geq 1} \phi(ax). \end{aligned} \quad (\text{BF.01})$$

Here $\mathcal{S}(\mathbb{R})$ is the Schwartz space, and the summation indices a in Θ are integers. The symbol $\mathcal{B}$ denotes exactly the strong-Schwartz target specified in A1694, lines 3049–3073. Put

$$Q = \mathcal{B}/\Theta V, \quad q : \mathcal{B} \longrightarrow Q, \quad \mathcal{H}_+ = L^2(\mathbb{R}_{>0}, dx).$$

The scalar product convention is

$$\langle F, H \rangle_+ = \int_0^\infty \overline{F(x)} H(x) dx,$$

antilinear in the first argument. Adjoint signs on maps into $\mathcal{H}_+$ use this scalar product and the standard scalar product in the stated polynomial coordinates on their finite-dimensional domains.

Retain the actual source function and its derivative sequence:

$$\begin{aligned} \phi_*(x) &= (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2}, \\ f_0 &= \Theta\phi_*, \quad \phi_j = D^j \phi_*, \quad f_j = \Theta\phi_j = D^j f_0 \quad (j \geq 0), \\ (\mathcal{M}F)(s) &= \int_0^\infty F(x) x^s \frac{dx}{x}, \quad \mathcal{M}f_0 = g. \end{aligned} \quad (\text{BF.02})$$

The source identity $\mathcal{M}(D^j f_0)(s) = s^j g(s)$, with these exact constants, is A1644, lines 2566–2574, and A1771, lines 4479–4529. The commutation $D\Theta\phi = \Theta D\phi$ uses the same generator on the source and target. Differentiation of the defining series is justified on each compact subinterval of $(0, \infty)$ by the Schwartz estimates.

Let Z be a nonempty finite set of actual zeros of g . For $\rho \in Z$, let $m_\rho \geq 1$ be its complete order of vanishing. Define

$$h_Z(t) = \prod_{\rho \in Z} (t - \rho)^{m_\rho}, \quad d = \deg h_Z = \sum_{\rho \in Z} m_\rho, \quad E_Z = \mathbb{C}[t]/(h_Z), \quad A = M_t : E_Z \longrightarrow E_Z. \quad (\text{BF.03})$$

The ordered coordinates on E_Z are the classes of $1, t, \dots, t^{d-1}$. Multiplication by t is not replaced by a shifted generator. The empty packet is treated separately at the end.

For a function holomorphic near every member of Z , j_{h_Z} means its complete collection of jets of orders $0, \dots, m_\rho - 1$, identified with E_Z by the Chinese remainder isomorphism. In particular, the finite Mellin-jet map is

$$J_Z : \mathcal{B} \longrightarrow E_Z, \quad J_Z F = j_{h_Z}(\mathcal{M}F).$$

In the local coordinate $z = s - \rho$, the ρ -component is

$$\sum_{j=0}^{m_\rho-1} \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} z^j \pmod{z^{m_\rho}}.$$

The map retains the factorials and the full jet length.

The actual extension unit is

$$\varepsilon_Z = (j_{h_Z}(g/h_Z))^{-1} = j_{h_Z}(h_Z/g) \in E_Z^\times. \quad (\text{BF.04})$$

To see why it is a unit, write

$$g(\rho + z) = z^{m_\rho} w_\rho(z), \quad w_\rho(0) \neq 0.$$

The polynomial $h_Z(\rho + z)$ has precisely the same zero order. Thus g/h_Z and h_Z/g are mutually inverse holomorphic units near every selected zero. Equation (BF.04) keeps their complete jets. This finite-algebra unit is distinct from the supported-zero scalar e of the original split-support construction.

For $u \in E_Z$, let $R_Z(u)$ be the unique polynomial of degree less than d representing $\varepsilon_Z u$, and define the extension row

$$\ell_Z : E_Z \longrightarrow \mathbb{C}, \quad \ell_Z(u) = [t^{d-1}]R_Z(u). \quad (\text{BF.05})$$

The established arithmetic section in A1644, lines 2594–2718, and A1771, lines 4499–4510, is the map

$$s_Z : E_Z \longrightarrow \mathcal{B}$$

with the identities

$$J_Z s_Z = I_{E_Z}, \quad J_Z \Theta = 0, \quad q s_Z = \sigma_Z : E_Z \hookrightarrow Q, \quad D s_Z - s_Z A = f_0 \ell_Z. \quad (\text{BF.06})$$

These are the inherited source identities used below, with the actual source section and its analytic construction. For a one-point packet at a simple zero, their coefficient is exactly

$$\ell_Z(1) = \frac{1}{g'(\rho)} = \frac{1}{2\xi'(\rho)}.$$

No replacement of this coefficient by a unit-free scalar is made.

159.2 Theta relation spaces and the exact rank-two boundary

Define

$$V_n = \text{span}_{\mathbb{C}}\{\phi_0, \dots, \phi_n\}, \quad L_n = \Theta V_n = \text{span}_{\mathbb{C}}\{f_0, \dots, f_n\}, \quad n \geq 0. \quad (\text{BF.07})$$

The vectors f_j are linearly independent. Indeed, a finite dependence has Mellin transform $g(s)P(s) = 0$, where $P(s) = \sum_j c_j s^j$. Since g is not identically zero, it is nonzero on a nonempty open set. Therefore P vanishes on that open set and is the zero polynomial. Every coefficient c_j is zero.

Let $F_n : \mathbb{C}^{n+1} \rightarrow \mathcal{H}_+$ have columns $f_0, \dots, f_n$, and set

$$H_n = F_n^* F_n, \quad P_n = F_n H_n^{-1} F_n^*, \quad R_n = (I - P_n) s_Z, \quad G_n = R_n^* R_n. \quad (\text{BF.08})$$

Independence gives $H_n \succ 0$. Direct multiplication gives $P_n^2 = P_n = P_n^*$, and its range is L_n ; it is the actual orthogonal projection onto the specified finite theta relation space. The expression

$$b_n(u) = \sum_{j=0}^n (H_n^{-1} F_n^* s_Z u)_j \phi_j$$

defines a map $b_n : E_Z \rightarrow V_n$ satisfying $P_n s_Z = \Theta b_n$. Consequently, by (BF.06),

$$q R_n = \sigma_Z, \quad J_Z R_n = I_{E_Z}, \quad G_n = s_Z^* s_Z - s_Z^* F_n H_n^{-1} F_n^* s_Z \succ 0. \quad (\text{BF.09})$$

For the strict inequality, $v^* G_n v = \|R_n v\|_+^2 = 0$ implies $R_n v = 0$ and hence $v = J_Z R_n v = 0$. Thus all inverses of G_n used below are inverses of strictly positive matrices at the stated finite level.

The original theta boundary and the associated control matrix are

$$\begin{aligned} B_n &= DR_n - R_n A = \Theta K_n, \\ K_n &= \phi_* \ell_Z - D_V b_n + b_n A, \\ W_n &= A^* G_n + G_n A - G_n. \end{aligned} \tag{BF.10}$$

Here D_V is D on V . The boundary formula follows by substituting $R_n = s_Z - \Theta b_n$ into (BF.06). It uses only original theta boundaries.

For $F, H \in \mathcal{B}$, integration by parts gives

$$\langle DF, H \rangle_+ + \langle F, DH \rangle_+ = - \left[x \overline{F(x)} H(x) \right]_0^\infty + \langle F, H \rangle_+ = \langle F, H \rangle_+. \tag{BF.11}$$

The defining estimates of $\mathcal{B}$ make the boundary expression zero at both endpoints. Applying (BF.11) to columns of R_n , and substituting $DR_n = R_n A + B_n$, proves

$$W_n = -(R_n^* B_n + B_n^* R_n). \tag{BF.12}$$

The coefficient of G_n in (BF.10) is exactly one because the measure in (BF.11) is dx . Even extension to the full line has squared norm twice this norm; it is not silently substituted here.

Construct the unscaled orthogonal vectors

$$u_0 = f_0, \quad u_n = (I - P_{n-1})f_n \quad (n \geq 1), \quad \mathfrak{h}_n = \langle u_n, u_n \rangle_+ > 0, \quad r_n = \mathfrak{h}_n^{-1} u_n^* s_Z : E_Z \rightarrow \mathbb{C}. \tag{BF.13}$$

The operator $u_n^* : \mathcal{H}_+ \rightarrow \mathbb{C}$ sends F to $\langle u_n, F \rangle_+$. Each u_n has leading coefficient one on f_n ; none is divided by its norm. Since the f_j are real functions, their Gram matrices are real, and each u_n is real.

Degree and orthogonality determine the recurrence

$$\begin{aligned} Du_0 &= u_1 + \frac{1}{2}u_0, \\ Du_n &= u_{n+1} + \frac{1}{2}u_n - \frac{\mathfrak{h}_n}{\mathfrak{h}_{n-1}}u_{n-1} \quad (n \geq 1). \end{aligned} \tag{BF.14}$$

Here is the complete coefficient calculation. As $u_n = f_n + \sum_{j < n} c_j f_j$, Du_n belongs to L_{n+1} and has coefficient one on u_{n+1} . For $j \leq n-2$, (BF.11) gives

$$\langle u_j, Du_n \rangle_+ = \langle u_j, u_n \rangle_+ - \langle Du_j, u_n \rangle_+ = 0,$$

because $Du_j \in L_{j+1} \subseteq L_{n-1}$. Reality and (BF.11) give

$$2\langle u_n, Du_n \rangle_+ = \mathfrak{h}_n,$$

so the full diagonal coefficient is $1/2$, not merely its real part. For $n \geq 1$,

$$\langle u_{n-1}, Du_n \rangle_+ = -\langle Du_{n-1}, u_n \rangle_+ = -\mathfrak{h}_n.$$

Dividing only this coefficient by the corresponding original norm square $\mathfrak{h}_{n-1}$ yields the last term of (BF.14).

The section coefficients satisfy

$$P_n s_Z = \sum_{j=0}^n u_j r_j, \quad \frac{\mathfrak{h}_{n+1}}{\mathfrak{h}_n} r_{n+1} = r_n \left(\frac{1}{2}I - A \right) + r_{n-1} - \mathbf{1}_{\{n=0\}} \ell_Z, \quad r_{-1} = 0. \tag{BF.15}$$

The indicator $\mathbf{1}_{\{n=0\}}$ equals one for $n = 0$ and zero otherwise. To check the row equation, pair $Ds_Z = s_Z A + u_0 \ell_Z$ against u_n . The right side is

$$\mathfrak{h}_n r_n A + \mathbf{1}_{\{n=0\}} \mathfrak{h}_0 \ell_Z.$$

By (BF.11) and (BF.14), the left side is

$$\frac{1}{2} \mathfrak{h}_n r_n - \mathfrak{h}_{n+1} r_{n+1} + \mathfrak{h}_n r_{n-1},$$

where the last term is zero for $n = 0$. Rearrangement gives (BF.15). The initial extension functional is therefore fixed by the original arithmetic section.

We now obtain the source's rank-two formula with its exact sign. Since

$$B_n = f_0 \ell_Z - DP_n s_Z + P_n s_Z A,$$

the first and third terms have image in L_n , orthogonal to the image of R_n . Equation (BF.12) becomes

$$W_n = R_n^* DP_n s_Z + (DP_n s_Z)^* R_n.$$

Equations (BF.14) and (BF.15) give

$$(I - P_n) DP_n s_Z = u_{n+1} r_n, \quad u_{n+1}^* R_n = u_{n+1}^* s_Z = \mathfrak{h}_{n+1} r_{n+1}.$$

It follows that

$$W_n = \mathfrak{h}_{n+1} (r_{n+1}^* r_n + r_n^* r_{n+1}). \quad (\text{BF.16})$$

Also $R_{n+1} = R_n - u_{n+1} r_{n+1}$, with R_{n+1} orthogonal to u_{n+1} . Taking Gram matrices proves the exact decrement

$$G_n - G_{n+1} = \mathfrak{h}_{n+1} r_{n+1}^* r_{n+1} \succeq 0. \quad (\text{BF.17})$$

These formulas are A1771, lines 4688–4734. The rank bound in (BF.16) concerns the boundary control form on E_Z ; the dimension d , and the full operator A , have not been reduced to two dimensions.

For clarity, the retained source-support transition is also exact. Write $Q_{V_n} = \mathcal{B}/\Theta V_n = \mathcal{B}/L_n$. Since $D\Theta V_n \subseteq \Theta V_{n+1}$, differentiation gives a well-defined map

$$\overline{D}_n : Q_{V_n} \longrightarrow Q_{V_{n+1}}, \quad [F] \longmapsto [DF].$$

Before that transition, the boundary class is

$$[B_n v]_{Q_{V_n}} = -[u_{n+1}]_{Q_{V_n}} r_n(v).$$

The layer map

$$\Theta V_{n+1}/\Theta V_n \longrightarrow L_{n+1} \cap L_n^\perp, \quad [z] \longmapsto (I - P_n)z$$

is well-defined and injective because its kernel in L_{n+1} is L_n . It is surjective because every vector in the displayed orthogonal complement is fixed by $I - P_n$. The subsequent support transport makes this particular class the supported zero in $Q_{V_{n+1}}$. Its earlier pairing in (BF.16) is retained. These are the actual maps of A1771, lines 4736–4773.

159.3 Relative control spectrum and its invariant trace

For $G_n \succ 0$, define its least two-sided control excess by

$$\epsilon_n = \inf\{\epsilon \geq 0 : -\epsilon G_n \preceq W_n \preceq \epsilon G_n\}. \quad (\text{BF.18})$$

Here $X \preceq Y$ means that $Y - X$ is a positive semidefinite Hermitian matrix. The operator $G_n^{-1}W_n$ is self-adjoint in the positive inner product $\langle u, v \rangle_{G_n} = u^* G_n v$:

$$\langle u, G_n^{-1}W_n v \rangle_{G_n} = u^* W_n v = \langle G_n^{-1}W_n u, v \rangle_{G_n}.$$

Thus ϵ_n is the largest absolute value of its eigenvalues. This uses the actual metric and operator and makes no assumption that A is normal for this metric.

In the unchanged coordinates, set

$$\mathbf{a}_n = r_n G_n^{-1} r_n^*, \quad \mathbf{b}_n = r_{n+1} G_n^{-1} r_{n+1}^*, \quad \mathbf{c}_n = r_n G_n^{-1} r_{n+1}^*. \quad (\text{BF.19})$$

The exact maps

$$\begin{aligned} \mathcal{T}_n : E_Z &\longrightarrow \mathbb{C}^2, & \mathcal{T}_n v &= (r_n v, r_{n+1} v), \\ \mathcal{U}_n : \mathbb{C}^2 &\longrightarrow E_Z, \\ \mathcal{U}_n(a, b) &= \mathfrak{h}_{n+1} (G_n^{-1} r_{n+1}^* a + G_n^{-1} r_n^* b) \end{aligned} \quad (\text{BF.20})$$

satisfy

$$\mathcal{U}_n \mathcal{T}_n = G_n^{-1} W_n, \quad \mathcal{T}_n \mathcal{U}_n = \mathfrak{h}_{n+1} \begin{pmatrix} \mathbf{c}_n & \mathbf{a}_n \\ \mathbf{b}_n & \overline{\mathbf{c}_n} \end{pmatrix}.$$

For every nonzero eigenvalue, applying $\mathcal{T}_n$ and $\mathcal{U}_n$ gives mutually inverse eigenspace maps up to that nonzero scalar. Therefore the nonzero eigenvalues of the two composites agree. Cauchy-Schwarz for the positive form on row covectors induced by G_n^{-1} gives $\mathbf{a}_n \mathbf{b}_n \geq |\mathbf{c}_n|^2$. The two roots of the displayed 2-by-2 characteristic polynomial are consequently

$$\lambda_{n,\pm} = \mathfrak{h}_{n+1} \left(\operatorname{Re} \mathbf{c}_n \pm \sqrt{\mathbf{a}_n \mathbf{b}_n - (\operatorname{Im} \mathbf{c}_n)^2} \right), \quad \lambda_{n,+} \geq 0 \geq \lambda_{n,-}. \quad (\text{BF.21})$$

Zero roots are included in this notation even when the corresponding eigenspace does not occur in E_Z . There are no other nonzero eigenvalues by the factorization (BF.20). Thus

$$\epsilon_n = \mathfrak{h}_{n+1} \left(|\operatorname{Re} \mathbf{c}_n| + \sqrt{\mathbf{a}_n \mathbf{b}_n - (\operatorname{Im} \mathbf{c}_n)^2} \right). \quad (\text{BF.22})$$

This is the exact expression in A1771, lines 4775–4821. In particular, G_n^{-1} remains present in every relative coefficient.

The trace of this control operator is independent of the chosen positive representative metric. Cyclicity of finite-dimensional trace and (BF.10) give

$$\begin{aligned} \operatorname{tr}(G_n^{-1} W_n) &= \operatorname{tr}(G_n^{-1} A^* G_n) + \operatorname{tr} A - d \\ &= 2 \operatorname{Re} \operatorname{tr} A - d \\ &= \sum_{\rho \in Z} m_\rho (2 \operatorname{Re} \rho - 1). \end{aligned} \quad (\text{BF.23})$$

For the final equality, the Chinese remainder decomposition preserves the local coordinates $z = t - \rho$. On the length- m_ρ summand, multiplication by t is $\rho I + M_z$. In the ordered basis $1, z, \dots, z^{m_\rho-1}$, M_z has zero diagonal and trace zero. Thus its full trace contribution is $m_\rho \rho$. No generalized eigenvector has been deleted.

Taking the trace directly in (BF.16), and using (BF.19), yields the exact row constraint

$$\boxed{2 \mathfrak{h}_{n+1} \operatorname{Re} \mathbf{c}_n = \sum_{\rho \in Z} m_\rho (2 \operatorname{Re} \rho - 1).} \quad (\text{BF.24})$$

Define the reflection $\iota\rho = 1 - \bar{\rho}$. A reflection-stable packet means that $\iota Z = Z$ and that $m_{\iota\rho} = m_\rho$ at every member. For such a packet the contributions of every two-point orbit in (BF.23) cancel. At a fixed point of ι , $\operatorname{Re} \rho = 1/2$, so its contribution is zero. Since $\mathfrak{h}_{n+1} > 0$,

$$\begin{aligned} \operatorname{tr}(G_n^{-1}W_n) &= 0, & \operatorname{Re} \mathbf{c}_n &= 0, \\ \lambda_{n,+} &= \epsilon_n = -\lambda_{n,-}, \\ \epsilon_n &= \mathfrak{h}_{n+1} \sqrt{\mathbf{a}_n \mathbf{b}_n - (\operatorname{Im} \mathbf{c}_n)^2}. \end{aligned} \tag{BF.25}$$

If $W_n \neq 0$, the two nonzero eigenvalues are ϵ_n and $-\epsilon_n$, each once. If $\epsilon_n = 0$, the self-adjoint operator $G_n^{-1}W_n$ has only the zero eigenvalue and hence is zero. Trace cancellation alone does not set the matrix W_n to zero.

159.4 The invariant-subspace projection argument

The next estimates hold for an arbitrary actual packet Z ; reflection stability will be used only for their final combination. Define

$$Z_+ = \{\rho \in Z : \operatorname{Re} \rho > 1/2\}, \quad Z_- = \{\rho \in Z : \operatorname{Re} \rho < 1/2\}.$$

Let

$$E_+ = \bigoplus_{\rho \in Z_+} \mathbb{C}[z]/(z^{m_\rho}), \quad E_- = \bigoplus_{\rho \in Z_-} \mathbb{C}[z]/(z^{m_\rho}). \tag{BF.26}$$

The inclusions $I_\pm : E_\pm \rightarrow E_Z$ are the actual Chinese remainder inclusions, not coordinate projections chosen to make A normal. Explicitly, put $h_\rho = (t - \rho)^{m_\rho}$ and $H_\rho = h_Z/h_\rho$. Since H_ρ and h_ρ are coprime, choose $b_\rho(t)$ with $H_\rho b_\rho \equiv 1 \pmod{h_\rho}$, and let e_ρ be the class of $H_\rho b_\rho$ in E_Z . It has residue one at the ρ -summand and zero at all other summands. The maps in (BF.26) are

$$I_\pm((u_\rho)_\rho) = \sum_{\rho \in Z_\pm} e_\rho u_\rho(t - \rho).$$

Changing the representative b_ρ changes nothing in E_Z . All original polynomial coordinates and every full local length remain in these maps.

Let $A_\pm$ be multiplication by $\rho + z$ on each local summand of $E_\pm$. The intertwining identities are

$$AI_\pm = I_\pm A_\pm. \tag{BF.27}$$

In particular the images are invariant generalized eigenspaces, with their nilpotent parts unchanged.

Fix $n \geq 0$. For a nonzero $E_\pm$, define

$$G_\pm = I_\pm^* G_n I_\pm, \quad P_\pm = I_\pm G_\pm^{-1} I_\pm^* G_n. \tag{BF.28}$$

The notation $G_\pm, P_\pm$ in this subsection refers to this fixed value of n . Since $I_\pm$ is injective and $G_n \succ 0$, $G_\pm \succ 0$. Multiplication gives $P_\pm^2 = P_\pm$, $P_\pm I_\pm = I_\pm$, and

$$P_\pm^* G_n = G_n P_\pm.$$

Thus $P_\pm$ is the G_n -orthogonal projection onto $\operatorname{im} I_\pm$. When $E_\pm = \{0\}$, define $P_\pm = 0$ directly; no inverse of a nonpositive-dimensional Gram matrix is needed.

For nonzero $E_\pm$, the restricted defect is exact. By (BF.27),

$$I_\pm^* W_n I_\pm = A_\pm^* G_\pm + G_\pm A_\pm - G_\pm. \tag{BF.29}$$

For nonzero $E_\pm$, cyclicity of the trace of the rectangular composites, followed by (BF.29), gives

$$\begin{aligned}\mathrm{tr}(P_\pm G_n^{-1} W_n) &= \mathrm{tr}(G_\pm^{-1} I_\pm^* W_n I_\pm) \\ &= 2 \operatorname{Re} \mathrm{tr} A_\pm - \dim E_\pm \\ &= 2 \sum_{\rho \in Z_\pm} m_\rho (\operatorname{Re} \rho - 1/2).\end{aligned}\tag{BF.30}$$

For $E_\pm = \{0\}$, the first and last expressions in (BF.30) are both zero and remain equal; the inverse-containing expression is not invoked. The last trace evaluation again uses $\rho I + M_z$ on each full local summand.

The rank-two factorization gives a stronger estimate for these compressed traces than a generic rank bound would give. Indeed, the Hermitian form $v^* W_n v$ is the pullback under $v \mapsto (r_n v, r_{n+1} v)$ of

$$\mathfrak{h}_{n+1} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.\tag{BF.31}$$

This form has one positive and one negative direction. To verify the inherited inertia bound directly, a positive definite subspace for W_n must map injectively under $v \mapsto (r_n v, r_{n+1} v)$; otherwise its kernel would contain a nonzero vector on which the form is zero. Its image is a positive definite subspace of (BF.31), so has dimension at most one. The same reasoning applies to a negative definite subspace. Therefore $G_n^{-1} W_n$, self-adjoint in the G_n metric, has at most one strictly positive and at most one strictly negative eigenvalue.

Use $\lambda_{n,+}$ and $\lambda_{n,-}$ from (BF.21). Let Π_+ and Π_- be their G_n -orthogonal spectral projections when the corresponding eigenvalue is strictly positive or strictly negative. When a sign is absent, set both its eigenvalue and its projection equal to zero. The finite-dimensional spectral theorem gives

$$G_n^{-1} W_n = \lambda_{n,+} \Pi_+ + \lambda_{n,-} \Pi_-, \quad \operatorname{rank} \Pi_\pm \leq 1.\tag{BF.32}$$

All remaining spectral directions have eigenvalue zero.

Let P be any G_n -orthogonal projection. For either of the nonzero projections $\Pi_\pm$, $\Pi_\pm P \Pi_\pm$ acts on a one-dimensional subspace as a positive contraction. Positivity follows because

$$\langle x, \Pi_\pm P \Pi_\pm x \rangle_{G_n} = \langle P \Pi_\pm x, P \Pi_\pm x \rangle_{G_n} \geq 0,$$

and the upper bound follows from $\|P \Pi_\pm x\|_{G_n} \leq \|\Pi_\pm x\|_{G_n}$. Its eigenvalue belongs to $[0, 1]$. Cyclicity and $\Pi_\pm^2 = \Pi_\pm$ then prove

$$0 \leq \operatorname{tr}(P \Pi_\pm) = \operatorname{tr}(\Pi_\pm P \Pi_\pm) \leq 1.\tag{BF.33}$$

The equality and both inequalities also hold when $\Pi_\pm = 0$. Combining (BF.32) and (BF.33) gives

$$\lambda_{n,-} \leq \operatorname{tr}(P G_n^{-1} W_n) \leq \lambda_{n,+}.\tag{BF.34}$$

For example the upper bound is $\lambda_{n,+} \operatorname{tr}(P \Pi_+) + \lambda_{n,-} \operatorname{tr}(P \Pi_-) \leq \lambda_{n,+}$; the lower bound follows with the two signs interchanged.

Apply (BF.34) to the actual projections P_+ and P_- in (BF.30). For every packet and every $n \geq 0$, this proves

$$\boxed{\begin{aligned}\lambda_{n,+} &\geq 2 \sum_{\rho \in Z_+} m_\rho (\operatorname{Re} \rho - 1/2), \\ -\lambda_{n,-} &\geq 2 \sum_{\rho \in Z_-} m_\rho (1/2 - \operatorname{Re} \rho).\end{aligned}}\tag{BF.35}$$

These estimates do not require reflection stability or semisimplicity.

For a reflection-stable packet, reflection bijects Z_+ and Z_- , preserves multiplicity, and negates $\operatorname{Re} \rho - 1/2$. Thus the two positive distance sums in (BF.35) are equal. Equation (BF.25) identifies the

two control eigenvalues with ϵ_n and $-\epsilon_n$. Their combination is the claimed multiplicity boundary floor:

$$\begin{aligned} \epsilon_n &= \mathfrak{h}_{n+1} \sqrt{\mathfrak{a}_n \mathfrak{b}_n - (\operatorname{Im} c_n)^2} \\ &\geq \sum_{\rho \in Z} m_\rho \left| \operatorname{Re} \rho - \frac{1}{2} \right| \quad (n \geq 0). \end{aligned} \quad (\text{BF.36})$$

The restriction traces in (BF.30) show explicitly why complete multiplicities occur. The proof includes every generalized eigenspace and uses its induced metric. No normality of A , deletion of nilpotent jets, or positivity of the arithmetic Weil form has entered.

159.5 Exact consequences for a putative off-line zero

An individual eigenvector gives a useful comparison. If $0 \neq v \in E_Z$ satisfies $Av = \rho v$, then directly from (BF.10),

$$v^* W_n v = (2 \operatorname{Re} \rho - 1) v^* G_n v. \quad (\text{BF.37})$$

Such a vector exists in every local summand: the class $z^{m_\rho-1}$, embedded by e_ρ , is nonzero and is annihilated by $A - \rho I$. By (BF.18), (BF.37) gives $\epsilon_n \geq |2 \operatorname{Re} \rho - 1|$. Equation (BF.36) includes the additional constraints from all other roots and their multiplicities.

For a reflected off-line pair $\{\rho, 1 - \bar{\rho}\}$, with complete multiplicity m at both points, put $\delta = \operatorname{Re} \rho - 1/2 \neq 0$. The two points are distinct, and their contributions to the sum in (BF.36) give

$$\epsilon_n \geq 2m|\delta| = m|2 \operatorname{Re} \rho - 1| \quad (n \geq 0). \quad (\text{BF.38})$$

The real structure and functional equation of the retained xi-function are $g(\bar{s}) = \overline{g(s)}$ and $g(1-s) = g(s)$. Composition of a local Taylor expansion with conjugation or the affine map $s \mapsto 1-s$ preserves its first nonzero degree, so these symmetries preserve the complete vanishing multiplicities. Consequently, when the four points $\rho, \bar{\rho}, 1-\rho, 1-\bar{\rho}$ are distinct, they form a reflection-stable packet with the same complete multiplicity m . Their exact bound is

$$\epsilon_n \geq 4m|\delta| = 2m|2 \operatorname{Re} \rho - 1| \quad (n \geq 0). \quad (\text{BF.39})$$

For a collapsed symmetry orbit, only the actual distinct points with their actual multiplicities are counted. Formula (BF.38) already treats the two-point reflection orbit.

In particular, a reflection-stable actual packet containing an off-line root forces a strictly positive right side of (BF.36) at every finite level. Then W_n is nonzero, indefinite, and of rank exactly two, with generalized eigenvalues $\epsilon_n, -\epsilon_n$. The strict positivity follows from the packet sum; both signs and exact rank follow from (BF.25) and (BF.16). For an arbitrary packet without reflection stability, the valid statements are instead the separate inequalities (BF.35); its trace need not vanish.

This lower bound is on the relative expression containing G_n^{-1} . The absolute monotonicity (BF.17) does not supply an upper bound on that inverse-weighted expression. The homotopy freedom in A1771, lines 4432–4475, does not alter this conclusion. Retain the Fourier transform

$$(\mathcal{F}\phi)(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx.$$

It restricts to an isomorphism $V \rightarrow V$: it preserves evenness and the Schwartz space, and interchanges evaluation at zero with the integral, so preserves the two zero moments in (BF.01). Its inverse on V is the inverse Fourier transform with the same convention. For the two-leg differential and its cycle map,

$$\begin{aligned} d_{\text{leg}} : V \oplus V &\longrightarrow \mathcal{B}, & d_{\text{leg}}(v, w) &= \Theta(v - \mathcal{F}w), \\ \gamma : V &\longrightarrow V \oplus V, & \gamma(v) &= (v, \mathcal{F}^{-1}v), \end{aligned}$$

one has $d_{\text{leg}}\gamma = 0$ by direct substitution. For a linear map $L : E_Z \rightarrow V$, adding γL to a primitive therefore leaves B_n unchanged, and hence leaves W_n unchanged for fixed R_n . The support transition described above likewise records where the boundary becomes a supported zero while retaining the pairing that produced (BF.16).

There is also an exact tensor obstruction independent of the rank-two argument. For an integer $k \geq 1$, keep

$$A_k = \sum_{j=1}^k I^{\otimes(j-1)} \otimes A \otimes I^{\otimes(k-j)} \quad \text{on } E_Z^{\otimes k}. \quad (\text{BF.40})$$

For any positive definite metric H on this same tensor space, set $W_{k,H} = A_k^* H + H A_k - kH$. The nonzero tensor $v^{\otimes k}$ of the eigenvector above satisfies $A_k v^{\otimes k} = k \rho v^{\otimes k}$. Consequently

$$\frac{(v^{\otimes k})^* W_{k,H} v^{\otimes k}}{(v^{\otimes k})^* H v^{\otimes k}} = k(2 \operatorname{Re} \rho - 1). \quad (\text{BF.41})$$

The denominator is strictly positive. Thus the least two-sided excess for $H, W_{k,H}$ is at least $k|2 \operatorname{Re} \rho - 1|$. In particular this applies to the actual orbit metric of A1721, lines 4102–4139,

$$H_{k,T} = \int_0^T e^{-kt} \exp(tA_k)^* G_n^{\otimes k} \exp(tA_k) dt, \quad T > 0.$$

It is positive definite because the integrand has positive quadratic form on every nonzero vector at every t ; $\exp(tA_k)$ is invertible. The same time parameter is used in every factor, and the full weight e^{-kt} remains. Changing T cannot change the Rayleigh value (BF.41).

For the empty packet, $h_Z = 1$, $E_Z = \{0\}$, and every packet sum is zero. Define its control excess to be zero. Then the boundary-floor assertion is the equality $0 = 0$. The extension row $[t^{d-1}]R_Z$ and the positive-dimensional Gram inverses above are not invoked in this empty case.

Equations (BF.35) and (BF.36) are lower bounds proved on the actual arithmetic objects. They neither assert an off-line zero nor provide the arithmetic upper estimate needed to exclude one. The source explicitly retains that missing estimate in A1721, line 4259, and A1771, line 4890. Finite regression checks, the stated integer-sum tail bound, and absolute Gram decrements do not supply it.

160 Arithmetic symmetric frontier cost and determinant growth

This section proves finite restrictions on the spectral positions of the original arithmetic packet. It retains the actual theta source, the measure $|2\xi/h|^2 dy/(2\pi)$, all zero multiplicities, and the unscaled orbit coordinates. No purity assertion is used. Stars denote conjugate transpose in the displayed finite coefficient bases, and Hilbert adjoint for maps into the source Hilbert space. For Hermitian matrices, $U \preceq V$ means that $V - U$ is positive semidefinite. The one-factor quotient coefficient basis is always $[1]_h, [t]_h, \dots, [t^{d-1}]_h$, with its specified tensor and orbit inclusions below.

Authoritative source pins. The retained construction is in the original messages A1829 and A1859 of `audit_segment_U0041_U0054.md`. The line numbers here are literal lines in that source, whose SHA-256 is recorded in the accompanying audit. A1829, lines 4956–5071, specifies the source, the arithmetic function, the full-jet map, and its exact polynomial kernel; lines 5073–5169 give the canonical minimum and its metric; lines 5383–5561 give the joint tensor source and actual next relation layer. A1859, lines 5693–5874, gives the unscaled polynomial coordinates, the relation isomorphism, and the exact metric update; lines 5876–6040 give the recurrence and finite lowering bound; lines 6042–6197 give the signed symmetric summand and its unscaled orbit factors. The aggregate inequalities proved below are new consequences of those retained objects.

160.1 The retained arithmetic source and its canonical finite metric

Keep the original operator, theta map, and arithmetic function

$$\begin{aligned} D &= -x\partial_x, & \Theta\phi(x) &= \sum_{m \neq 0} \phi(mx), \\ \phi_*(x) &= (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, & f_0 &= \Theta\phi_*, \\ g(s) &= \mathcal{M}f_0(s) = 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s). \end{aligned} \quad (\text{FD.1})$$

Here $\mathcal{M}F(s) = \int_0^\infty F(x)x^{s-1}dx$, on its original source domain. Choose a nonempty finite packet of actual zeros and retain the full order m_ρ at every selected centre:

$$\begin{aligned} h(t) &= \prod_{\rho \in Z} (t - \rho)^{m_\rho}, & d &= \deg h, \\ E_h &= \mathbb{C}[t]/(h), & v_h &= [g/h]_h \in E_h^\times. \end{aligned} \quad (\text{FD.2})$$

The bracket $[\cdot]_h$ means the complete local Taylor jets modulo h ; it includes every nilpotent jet at a multiple zero. Since each selected order is the full order of that zero, g/h is nonzero at every selected centre, proving that v_h is a unit in the finite quotient. Let A_h be multiplication by $[t]_h$ on E_h .

The retained actual source inverse supplies F_h with

$$h(D)F_h = f_0, \quad \mathcal{M}F_h = g/h, \quad \mathcal{T}_h(P) = P(D)F_h. \quad (\text{FD.3})$$

Its exact identities, retained from the original source construction, are

$$\mathcal{M}\mathcal{T}_h(P) = (g/h)P, \quad \mathcal{T}_h(hP) = \Theta(P(D)\phi_*), \quad J_h\mathcal{T}_h(P) = v_h[P]_h. \quad (\text{FD.4})$$

Here $J_h F = [\mathcal{M}F]_h$ is the full Mellin-jet map on the original analytic source. The second identity gives an actual theta primitive, and the last identity includes the arithmetic coefficient v_h . The map $\mathcal{T}_h$ is linear and injective: a zero image has identically zero Mellin transform $(g/h)P$, which forces $P = 0$.

The Hilbert observation remains $\mathcal{H} = L^2((0, \infty), dx)$. The exact change of variables and Fourier map

$$F \longmapsto (y \longmapsto e^{y/2}F(e^y)) \longmapsto \left(t \longmapsto \int_{\mathbb{R}} e^{y/2}F(e^y)e^{ity} dy \right)$$

have target measure $dt/(2\pi)$ and composite $F \mapsto \mathcal{M}F(1/2 + it)$. Consequently the arithmetic polynomial measure is exactly

$$d\nu_h(y) = \left| \frac{g(\frac{1}{2} + iy)}{h(\frac{1}{2} + iy)} \right|^2 \frac{dy}{2\pi}. \quad (\text{FD.5})$$

At selected zeros on the integration line, the quotient is evaluated as the entire function g/h . The finiteness of every polynomial moment can also be checked directly from the retained factors. If $\eta(s) = \sum_{n \geq 1} (-1)^{n-1} n^{-s}$, its alternating coefficient partial sums have absolute value at most one. Partial summation gives $|\eta(s)| \leq |s|/\Re s$ for $\Re s > 0$. The identity $\eta(s) = (1 - 2^{1-s})\zeta(s)$, first obtained by splitting the absolutely convergent series and then continued analytically, implies

$$|\zeta(\tfrac{1}{2} + iy)| \leq \frac{2|\frac{1}{2} + iy|}{\sqrt{2} - 1},$$

because $|1 - 2^{1/2 - iy}| \geq \sqrt{2} - 1$. Fix $0 < \theta < \pi/2$. Rotating the Euler gamma integral through angle $\text{sgn}(y)\theta$ gives

$$|\Gamma(\tfrac{1}{4} + iy/2)| \leq \Gamma(\tfrac{1}{4})(\cos \theta)^{-1/4} e^{-\theta|y|/2}.$$

For $y = 0$, the same bound follows from the unrotated integral. The rotation follows by integrating $z^{1/4+iy/2-1}e^{-z}$ around a truncated sector using its continuous logarithm there. The small circular arc tends to zero as its radius to the power $1/4$; the large arc tends to zero because $\cos \theta > 0$. Taking absolute values on the rotated ray yields the displayed bound. Retaining the factors in (FD.1) therefore gives

$$|g(\tfrac{1}{2} + iy)|^2 \leq \frac{4\pi^{-1/2}\Gamma(\frac{1}{4})^2}{(\sqrt{2}-1)^2\sqrt{\cos \theta}} (\tfrac{1}{4} + y^2)^3 e^{-\theta|y|}.$$

Monicity of the fixed degree- d polynomial h gives $|h(\frac{1}{2} + iy)| \geq c_h(1 + |y|)^d$ for some $c_h > 0$ outside a sufficiently large interval: divide its value by $(\frac{1}{2} + iy)^d$, whose quotient tends to one. On the remaining compact interval, the entire function g/h is bounded. These estimates prove finiteness of every moment of ν_h . The measure is positive away from a discrete set. Therefore the norm of a nonzero polynomial is strictly positive: zero norm would make the polynomial vanish almost everywhere on a line and hence identically.

Fix $k \geq 1$, and let

$$\begin{aligned} E^{(k)} &= E_h^{\otimes k}, & A_k &= \sum_{j=1}^k A_{h,j}, & D^{(k)} &= \sum_{j=1}^k D_j, \\ \mathcal{P}_M^{(k)} &= \mathbb{C}[t_1, \dots, t_k]_{\deg \leq M}, & \mathcal{T}^{(k)}(P) &= P(D_1, \dots, D_k) F_h^{\otimes k}, \\ \mathcal{J}(P) &= v_h^{\otimes k}[P]_{(h(t_1), \dots, h(t_k))}. \end{aligned} \tag{FD.6}$$

All tensor generators in this section are additive sums, as displayed in (FD.6). The multiplicative symmetric power of a linear map is a different construction and is not used here.

For $M \geq k(d-1)$, the map $\mathcal{J}$ on $\mathcal{P}_M^{(k)}$ is onto: each reduced monomial has each coordinate degree below d , hence total degree at most $k(d-1)$, and multiplication by $v_h^{\otimes k}$ is invertible. Its kernel and its actual theta image are

$$\mathcal{I}_M = \mathcal{P}_M^{(k)} \cap (h(t_1), \dots, h(t_k)), \quad \mathcal{B}_M = \mathcal{T}^{(k)} \mathcal{I}_M. \tag{FD.7}$$

Successive monic division in the variables expresses every polynomial in the kernel as $\sum_j h(t_j) P_j$. Under $\mathcal{T}^{(k)}$, each summand is an actual theta boundary in factor j , by (FD.4). Its cochain primitive has coefficient $(-1)^{j-1}$; the tensor differential has the same coefficient, so their product gives the displayed positive summand $+h(t_j) P_j$.

Let $R_M : E^{(k)} \rightarrow \mathcal{T}^{(k)} \mathcal{P}_M^{(k)}$ be the unique least-norm lift of the full jet, using the product measure induced by (FD.5), and write $G_M = R_M^* R_M$, $\mathcal{C}_M = G_M^{-1}$. The existence, uniqueness, and inverse are also obtained directly below. The minimum is orthogonal to the specified $\mathcal{B}_M$, and its full jet is identity. Its arithmetic class is that of the original product source lift with the specified jet, since all admissible changes are the actual boundaries in (FD.7).

Start with the monic, unscaled orthogonal polynomials and their actual norms

$$p_0 = 1, \quad p_n = t^n - \text{proj}_{\mathbb{C}[t]_{\leq n-1}} t^n, \quad \omega_n = \int |p_n(\tfrac{1}{2} + iy)|^2 d\nu_h(y) > 0. \tag{FD.8}$$

For a multi-index $\alpha \in \mathbb{N}_0^k$, set

$$p_\alpha = \prod_{j=1}^k p_{\alpha_j}(t_j), \quad \omega_\alpha = \prod_{j=1}^k \omega_{\alpha_j}, \quad z_\alpha = \mathcal{J}(p_\alpha). \tag{FD.9}$$

Let T_M have columns $\mathcal{T}^{(k)} p_\alpha$ for $|\alpha| \leq M$, let $J_M = [z_\alpha]_{|\alpha| \leq M}$, and let $\Omega_{\leq M} = \text{diag}_{|\alpha| \leq M} \omega_\alpha$. Product orthogonality gives $T_M^* T_M = \Omega_{\leq M}$. Surjectivity of J_M implies

$$\begin{aligned} \mathcal{C}_M &= J_M \Omega_{\leq M}^{-1} J_M^* = \sum_{|\alpha| \leq M} \frac{z_\alpha z_\alpha^*}{\omega_\alpha} > 0, \\ G_M &= \mathcal{C}_M^{-1}, \quad R_M = T_M \Omega_{\leq M}^{-1} J_M^* G_M. \end{aligned} \tag{FD.10}$$

Indeed $J_M \Omega_{\leq M}^{-1} J_M^* G_M = I$. Any other coefficient vector with jet u is $\Omega_{\leq M}^{-1} J_M^* G_M u + w$, where $J_M w = 0$. Its cross term with the first vector is $w^* J_M^* G_M u = 0$, so its squared norm is exactly $u^* G_M u + w^* \Omega_{\leq M} w$. This proves the unique minimum, its orthogonality to $\mathcal{B}_M$, and $R_M^* R_M = G_M$.

160.2 The actual next relation and its recurrence bound

For $|\beta| = M + 1$, define the frontier matrices

$$\Omega = \text{diag}_{|\beta|=M+1} \omega_\beta, \quad F = [z_\beta]_{|\beta|=M+1}, \quad T_+ = [\mathcal{T}^{(k)} p_\beta]_{|\beta|=M+1}. \quad (\text{FD.11})$$

There are $r = \binom{M+k}{k-1}$ columns. They are orthogonal to the entire degree- M source image. If $P_{\mathcal{B}_M}$ denotes orthogonal projection onto the actual boundary space, put

$$\mathcal{E}_M = (1 - P_{\mathcal{B}_M}) \mathcal{B}_{M+1}, \quad b_M = T_+ - R_M F : \mathbb{C}^r \longrightarrow \mathcal{E}_M. \quad (\text{FD.12})$$

The full jet of b_M is $F - F = 0$, and its two terms are orthogonal to $\mathcal{B}_M$, so its range is contained in $\mathcal{E}_M$. Its highest orthogonal polynomial component is T_+ , proving injectivity. Conversely, extract the highest component of a member of $\mathcal{E}_M$ and subtract its corresponding b_M -image. The remainder is simultaneously in $\mathcal{B}_M$ and orthogonal to $\mathcal{B}_M$, and is therefore zero. This proves that b_M is an isomorphism and constructs its inverse.

The exact Gram and cross-pairing are

$$H_M^{\text{rel}} := b_M^* b_M = \Omega + F^* G_M F, \quad b_M^* R_M = -F^* G_M. \quad (\text{FD.13})$$

The superscript distinguishes this relation Gram from the Hermitian control matrix introduced later. The projection of R_M onto the new layer and the updated representative are

$$Y_M = -b_M (H_M^{\text{rel}})^{-1} F^* G_M, \quad R_{M+1} = R_M - Y_M. \quad (\text{FD.14})$$

These corrections are actual boundaries. In particular, the full jet and the original arithmetic class stay fixed. The quotient-layer map

$$\mathcal{B}_{M+1}/\mathcal{B}_M \longrightarrow \mathcal{E}_M, \quad [z] \longmapsto (1 - P_{\mathcal{B}_M})z$$

is an isomorphism, whose inverse is the inclusion followed by quotient. Its further map into the quotient by $\mathcal{B}_{M+1}$ is zero. Write λ_M for the specified original joint support label recording the relation space $\mathcal{B}_M$, and write 0 for the zero amplitude in that support fibre. On the original supported reconstruction this is $(\lambda_M, u) \mapsto (\lambda_{M+1}, 0)$. For $u \neq 0$ the preceding class is nonzero. The final class is the supported zero of that fibre; it is distinct from τ , the original external-absence element. The notation $e = 0^\bullet$ denotes the nonabsent represented scalar zero in the original scalar reconstruction. Thus the relation Gram in (FD.13) measures the actual relations becoming represented zero at the next support.

Orthogonal projection and the finite sum in (FD.10) give

$$G_{M+1} = G_M - G_M F (\Omega + F^* G_M F)^{-1} F^* G_M, \quad (\text{FD.15})$$

$$\mathcal{C}_{M+1} - \mathcal{C}_M = F \Omega^{-1} F^*.$$

The second equality also follows simply by adding the degree- $M + 1$ terms to (FD.10); it does not require a limiting argument.

Set $p_{-1} = 0$. Multiplication by t on the integration line has adjoint multiplication by $1 - t$. Orthogonality and monicity therefore give

$$tp_n = p_{n+1} + b_n p_n - a_n p_{n-1}, \quad a_n = \omega_n / \omega_{n-1} \ (n \geq 1), \quad a_0 = 0, \quad (\text{FD.16})$$

$$b_n = \frac{\int (\frac{1}{2} + iy) |p_n(\frac{1}{2} + iy)|^2 d\nu_h(y)}{\omega_n}, \quad \Re b_n = \frac{1}{2}.$$

For $n \geq 1$, pairing against a polynomial of degree below $n - 1$ in the expansion of tp_n vanishes by the adjoint identity. Pairing against p_{n-1} gives $-\omega_n/\omega_{n-1}$, and pairing against p_n gives the displayed b_n . For $n = 0$, monicity gives $tp_0 = p_1 + b_0p_0$, and the term $a_0p_{-1} = 0$ is exactly the declared zero term. This proves every coefficient in the recurrence. The minus sign and the possibly nonzero imaginary part of b_n are retained.

Define

$$w_\beta = \sum_{j:\beta_j>0} a_{\beta_j} z_{\beta-e_j}, \quad E_+ = [w_\beta]_{|\beta|=M+1}. \quad (\text{FD.17})$$

Here e_j is the standard multi-index vector; it is not the supported scalar $e = 0^\bullet$. The full arithmetic jet is a module map, so $\mathcal{J}((\sum_j t_j)P) = A_k \mathcal{J}(P)$. Inserting (FD.16) into (FD.10) proves

$$\mathcal{Z}_M := A_k \mathcal{C}_M + \mathcal{C}_M A_k^* - k \mathcal{C}_M = F \Omega^{-1} E_+^* + E_+ \Omega^{-1} F^*. \quad (\text{FD.18})$$

To verify the cancellation explicitly, for every internal edge $\alpha \rightarrow \alpha + e_j$, the raising term has coefficient $1/\omega_\alpha$, while the lowering term has coefficient $-a_{\alpha_j+1}/\omega_{\alpha+e_j} = -1/\omega_\alpha$. Their adjoints cancel as well. The diagonal contribution is $2 \sum_j \Re b_{\alpha_j} = k$. The only uncanceled edges have $|\alpha| = M$ and $|\alpha + e_j| = M + 1$, and their coefficients are exactly those in the right side of (FD.18).

For completeness, the arithmetic derivative defect has the same actual relation coordinates. Set

$$B_M^{\text{der}} = D^{(k)} R_M - R_M A_k, \quad C_M^{\text{rel}} = (1 - P_{\mathcal{B}_M}) B_M^{\text{der}}.$$

Its full jet is zero, and its highest polynomial component is $T_+ \Omega^{-1} E_+^* G_M$. The latter assertion follows from the coefficient of p_β in $(\sum_j t_j) R_M$: it is $\sum_{j:\beta_j>0} z_{\beta-e_j}^* G_M / \omega_{\beta-e_j} = w_\beta^* G_M / \omega_\beta$. The layer isomorphism (FD.12) therefore proves

$$\begin{aligned} C_M^{\text{rel}} &= b_M \Omega^{-1} E_+^* G_M, \\ W_M &:= A_k^* G_M + G_M A_k - k G_M \\ &= G_M \mathcal{Z}_M G_M \\ &= -(Y_M^* C_M^{\text{rel}} + (C_M^{\text{rel}})^* Y_M). \end{aligned} \quad (\text{FD.19})$$

The last equality follows by substituting (FD.13) and (FD.14); in particular its minus sign is retained.

The recurrence constant is

$$\Gamma_{k,M} = \max_{|\alpha|=M} \sum_{j=1}^k (a_{\alpha_j+1} + (k-1)a_{\alpha_j}) > 0. \quad (\text{FD.20})$$

Strict positivity follows from $a_{n+1} > 0$ for every $n \geq 0$. We now prove its complete lowering estimate.

For coefficient calculations only, use the exact coordinate map that divides the basis vector p_α by $\sqrt{\omega_\alpha}$. Its inverse multiplies by $\sqrt{\omega_\alpha}$; the original polynomials, their norms, and the measure are unchanged. The degree- (-1) coefficient space is by definition $\{0\}$; in particular every lowering map from degree zero has that zero codomain. This retains the admitted endpoint $d = 1$, $M = 0$. In these coefficient spaces let R_j be the raising map $e_\alpha \mapsto \sqrt{a_{\alpha_j+1}} e_{\alpha+e_j}$, and let R_j^* be its lowering adjoint. Put

$$Q_M^{\text{jet}} = [z_\alpha / \sqrt{\omega_\alpha}]_{|\alpha|=M}, \quad B^{\text{inc}} = (\sum_j R_j)^*|_{M+1 \rightarrow M}.$$

The retained coefficients in (FD.17) give exactly $E_+ \Omega^{-1/2} = Q_M^{\text{jet}} B^{\text{inc}}$. Raising and lowering in distinct coordinates commute. Hence, on the degree- M coefficient space,

$$B^{\text{inc}} (B^{\text{inc}})^* = \text{diag}_{|\alpha|=M} \sum_j (a_{\alpha_j+1} - a_{\alpha_j}) + L^* L, \quad L = \sum_j R_j^*|_{M \rightarrow M-1}.$$

For every coefficient vector c , Cauchy-Schwarz gives $\|Lc\|^2 \leq k \sum_j \|R_j^* c\|^2$. Thus

$$L^* L \preceq k \text{diag}_{|\alpha|=M} \sum_j a_{\alpha_j}, \quad B^{\text{inc}} (B^{\text{inc}})^* \preceq \Gamma_{k,M} I.$$

Multiplication by Q_M^{jet} and its adjoint, followed by inclusion of the positive degree- M sum in (FD.10), proves

$$E_+ \Omega^{-1} E_+^* \preceq \Gamma_{k,M} Q_M^{\text{jet}} (Q_M^{\text{jet}})^* \preceq \Gamma_{k,M} \mathcal{C}_M. \quad (\text{FD.21})$$

160.3 Exact symmetric restriction with every orbit factor

Let P_π be ordinary factor permutation. The relevant module is

$$E_k^{\text{sym}} = (E_h^{\otimes k})^{S_k}, \quad N = \dim E_k^{\text{sym}} = \binom{k+d-1}{d-1}.$$

It is the actual top-degree summand selected on the original cochain tensor product by $S_k = (1/k!) \sum_{\pi \in S_k} \text{sgn}(\pi) T_\pi$, where T_π is permutation with its Koszul sign. In top degree $T_\pi = \text{sgn}(\pi) P_\pi$, so the two signs cancel. The numerator squares to $k!$ times itself, proving the idempotent with its literal coefficient $1/k!$. In particular, every repeated tensor $v^{\otimes k}$ remains in this summand.

Use the quotient basis formed by the unscaled orbit sums of $[t^{a_1}] \otimes \cdots \otimes [t^{a_k}]$, $0 \leq a_i < d$. Let I_k be its coefficient inclusion in the full tensor basis. If n_j counts factors with exponent j , its orbit size is $k! / \prod_{j=0}^{d-1} n_j!$. The orbit supports are disjoint, so

$$D_k = I_k^* I_k = \text{diag} \left(\frac{k!}{\prod_{j=0}^{d-1} n_j!} \right), \quad L_k = D_k^{-1} I_k^*, \quad L_k I_k = I. \quad (\text{FD.22})$$

The projector onto invariant coefficient vectors is $\Pi_k = I_k L_k$. Permutations preserve the source, the relation ideal, the product measure, and $v_h^{\otimes k}$. Uniqueness of the minimum therefore gives equivariance of R_M , and consequently of G_M and $\mathcal{C}_M$. The exact restricted matrices are

$$G_M^{\text{sym}} = I_k^* G_M I_k, \quad \mathcal{C}_M^{\text{sym}} = L_k \mathcal{C}_M L_k^*, \quad A_k I_k = I_k A_k^{\text{sym}}. \quad (\text{FD.23})$$

The first two matrices are inverse. For example,

$$G_M^{\text{sym}} \mathcal{C}_M^{\text{sym}} = I_k^* G_M \Pi_k \mathcal{C}_M L_k^* = I_k^* \Pi_k L_k^* = I,$$

because both G_M and $\mathcal{C}_M$ commute with Π_k , their product is identity, $\Pi_k L_k^* = L_k^*$, and $I_k^* L_k^* = (L_k I_k)^* = I$.

In the source frontier let Q_+ be the coefficient inclusion matrix whose columns are the 0/1 orbit indicators in the ordered basis $(p_\beta)_{|\beta|=M+1}$. Thus each column represents the unscaled orbit sum of those p_β . If $m_j(\beta)$ counts the entries of β equal to j , the corresponding source orbit norm is exactly

$$\omega_{[\beta]} = \frac{k!}{\prod_{j \geq 0} m_j(\beta)!} \prod_{i=1}^k \omega_{\beta_i}. \quad (\text{FD.24})$$

This is a sum of equal squared norms of pairwise orthogonal distinct product polynomials. Define the actual restricted frontier matrices

$$\Omega_s = Q_+^* \Omega Q_+, \quad F_s = L_k F Q_+, \quad E_s = L_k E_+ Q_+. \quad (\text{FD.25})$$

Thus Ω_s is the positive diagonal matrix with entries (FD.24); none of its orbit factors are suppressed.

The source invariant projector is $\Pi_+ = Q_+ (Q_+^* Q_+)^{-1} Q_+^*$. Since Ω is constant on each orbit, it commutes with Π_+ , and direct calculation in one orbit gives

$$Q_+ \Omega_s^{-1} Q_+^* = \Omega^{-1} \Pi_+.$$

Indeed, on an orbit of size m and weight ω , the left side is the all-ones matrix divided by $m\omega$; this is precisely $\omega^{-1} \Pi_+$ there. Equivariance implies $L_k F = L_k F \Pi_+$ and $L_k E_+ = L_k E_+ \Pi_+$: averaging any

source vector before applying an equivariant map has the same invariant component as applying the map first. Congruence of (FD.15), (FD.18), and (FD.21) therefore gives, with

$$\begin{aligned} \mathcal{C} &= \mathcal{C}_M^{\text{sym}}, \quad G = G_M^{\text{sym}} = \mathcal{C}^{-1}, \quad A = A_k^{\text{sym}}, \\ \Delta\mathcal{C} &= \mathcal{C}_{M+1}^{\text{sym}} - \mathcal{C}_M^{\text{sym}}, \quad \mathcal{Z} = AC + CA^* - k\mathcal{C}, \end{aligned} \quad (\text{FD.26})$$

the exact formulas

$$\begin{aligned} \Delta\mathcal{C} &= F_s \Omega_s^{-1} F_s^*, \\ \mathcal{Z} &= F_s \Omega_s^{-1} E_s^* + E_s \Omega_s^{-1} F_s^*, \\ E_s \Omega_s^{-1} E_s^* &\preceq \Gamma_{k,M} \mathcal{C}. \end{aligned} \quad (\text{FD.27})$$

For the operator term, equivariance also gives $L_k A_k = A_k^{\text{sym}} L_k$, proving that the congruence of $A_k \mathcal{C}_M + \mathcal{C}_M A_k^* - k\mathcal{C}_M$ is exactly the $\mathcal{Z}$ in (FD.26).

160.4 The aggregate spectral-position restriction

Positive square roots below are the unique positive square roots of the retained positive matrices. They are used as explicit comparison maps; their inverses are retained, and neither the source measure nor the arithmetic metric is redefined. Set

$$\begin{aligned} X &= G^{1/2} F_s \Omega_s^{-1/2}, \quad Y = G^{1/2} E_s \Omega_s^{-1/2}, \\ K = XX^* &= G^{1/2} \Delta\mathcal{C} G^{1/2}, \quad H = G^{1/2} \mathcal{Z} G^{1/2} = XY^* + YX^*. \end{aligned} \quad (\text{FD.28})$$

The last inequality of (FD.27) gives $YY^* \preceq \Gamma_{k,M} I$, and hence $Y^*Y \preceq \Gamma_{k,M} I$ on its own coefficient space. Here the latter statement follows from $\|Y\|_{\text{op}}^2 = \|YY^*\|_{\text{op}}$, or directly from the singular values. For the Frobenius norm $\|T\|_F^2 = \text{tr}(T^*T)$,

$$\|XY^*\|_F^2 = \text{tr}(X^*X Y^*Y) \leq \Gamma_{k,M} \text{tr}(X^*X).$$

The norm of a matrix equals the norm of its adjoint, so the triangle inequality gives the proved upper estimate

$$\|H\|_F^2 \leq 4\Gamma_{k,M} \text{tr} K. \quad (\text{FD.29})$$

List the roots of h , repeated with their original algebraic multiplicities, as $\rho_1, \dots, \rho_d$, and put

$$\delta_i = \Re \rho_i - \frac{1}{2}, \quad \eta_{\mathbf{n}} = \sum_{i=1}^d n_i \rho_i, \quad \mathbf{n} \in \mathbb{N}_0^d, \quad |\mathbf{n}| = k. \quad (\text{FD.30})$$

The eigenvalues of A , with algebraic multiplicity, are exactly the $\eta_{\mathbf{n}}$. To prove this while retaining nilpotents, triangularize A_h by induction using an eigenvector and the induced operator on the quotient. In a basis with $A_h e_j = \rho_j e_j + \sum_{i < j} c_{ij} e_i$, applying the additive generator to a symmetric monomial of occupations $\mathbf{n}$ gives diagonal coefficient $\sum_j n_j \rho_j$. Every other term replaces an index j by $i < j$, reducing the sum of the indices. Ordering monomials by that sum, and resolving ties arbitrarily, makes the operator triangular with precisely the displayed diagonal. Each weak composition contributes once; equal eigenvalues remain repeated with their algebraic multiplicities. The triangular off-diagonal entries are retained, including those caused by nontrivial Jordan blocks.

Let $B = G^{1/2} A G^{-1/2}$. Substitution into (FD.26) gives $H = B + B^* - kI$. Unitary Schur triangularization gives $T = U^* B U$, upper triangular with diagonal entries $\eta_{\mathbf{n}}$. Such a triangularization is obtained inductively by taking a unit eigenvector as the first basis vector and applying the induction to the compression on its orthogonal complement. Unitary conjugation preserves the Frobenius norm. Its diagonal and off-diagonal entries give the exact identity

$$\|H\|_F^2 = \sum_{|\mathbf{n}|=k} (2\Re \eta_{\mathbf{n}} - k)^2 + 2 \sum_{i < j} |T_{ij}|^2 \geq 4 \sum_{|\mathbf{n}|=k} \left(\sum_i n_i \delta_i \right)^2. \quad (\text{FD.31})$$

For $i < j$, the two corresponding entries of $T + T^* - kI$ are T_{ij} and $\overline{T_{ij}}$; this proves the factor two. Thus the retained nilpotent and nonnormal contributions cannot weaken the displayed lower bound.

We evaluate its sum exactly. For $d \geq 2$, the ordinary generating functions for weak compositions give

$$\begin{aligned} \sum_{|\mathbf{n}|=k} n_1 &= \binom{k+d-1}{d}, \\ \sum_{|\mathbf{n}|=k} n_1(n_1-1) &= 2 \binom{k+d-1}{d+1}, \\ \sum_{|\mathbf{n}|=k} n_1 n_2 &= \binom{k+d-1}{d+1}. \end{aligned} \tag{FD.32}$$

Indeed their generating functions are respectively

$$z(1-z)^{-d-1}, \quad 2z^2(1-z)^{-d-2}, \quad z^2(1-z)^{-d-2}.$$

These follow by differentiating the appropriate geometric-series factors. Extracting the coefficient of z^k gives (FD.32). Write $a = \binom{k+d-1}{d}$ and $b = \binom{k+d-1}{d+1}$. Then the square expands as

$$(a+2b) \sum_i \delta_i^2 + 2b \sum_{i < j} \delta_i \delta_j = (a+b) \sum_i \delta_i^2 + b \left(\sum_i \delta_i \right)^2.$$

Pascal's identity therefore proves

$$\begin{aligned} \mathcal{S}_{h,k} &:= \sum_{|\mathbf{n}|=k} \left(\sum_i n_i \delta_i \right)^2 \\ &= \binom{k+d}{d+1} \sum_i \delta_i^2 + \binom{k+d-1}{d+1} \left(\sum_i \delta_i \right)^2. \end{aligned} \tag{FD.33}$$

Binomial coefficients with smaller upper than nonnegative lower index are zero. For $d = 1$, direct evaluation gives $k^2 \delta_1^2$; the right side of (FD.33) is $[(\binom{k+1}{2} + \binom{k}{2})] \delta_1^2 = k^2 \delta_1^2$, so the same formula holds in that case.

Combining (FD.29), (FD.31), and (FD.33) proves the aggregate arithmetic restriction

$$\boxed{\Gamma_{k,M} \operatorname{tr}(G_M^{\operatorname{sym}} (\mathcal{C}_{M+1}^{\operatorname{sym}} - \mathcal{C}_M^{\operatorname{sym}})) \geq \mathcal{S}_{h,k}.} \tag{FD.34}$$

The trace in this formula is exactly $\operatorname{tr} K$, by cyclicity. All its matrices were defined from the actual measure, complete arithmetic jet unit, and unscaled orbit norms.

160.5 Coordinate invariance and determinant growth

The comparison maps have an exact coordinate-invariance statement. For invertible changes S in quotient coordinates and R in frontier coordinates, set

$$\begin{aligned} A' &= SAS^{-1}, & C' &= SCS^*, & G' &= S^{-*}GS^{-1}, \\ F'_s &= SF_sR, & E'_s &= SE_sR, & \Omega'_s &= R^*\Omega_sR. \end{aligned} \tag{FD.35}$$

Here $S^{-*} = (S^{-1})^*$. Cancellation of R, R^{-1} in the factorizations proves $\Delta C' = S \Delta C S^*$, and substitution in the generator identity gives $\mathcal{Z}' = S \mathcal{Z} S^*$. The lowering inequality is carried through the same congruence. Direct cyclic cancellation and determinant multiplicativity give

$$\begin{aligned} \operatorname{tr}(G' \Delta C') &= \operatorname{tr}(G \Delta C), \\ \frac{\det(C' + \Delta C')}{\det C'} &= \frac{\det(C + \Delta C)}{\det C}. \end{aligned} \tag{FD.36}$$

Furthermore $U_S = (\mathcal{C}')^{-1/2} S \mathcal{C}^{1/2}$ satisfies $U_S U_S^* = I$, and hence is unitary, with $H' = U_S H U_S^*$. This follows by substituting $\mathcal{C}' = S \mathcal{C} S^*$ and $\mathcal{Z}' = S \mathcal{Z} S^*$. Thus the exact trace, determinant ratio, and Frobenius quantity are preserved by the comparison-coordinate maps; no arithmetic normalization has been imposed.

The exact update and (FD.28) give

$$\frac{\det \mathcal{C}_{M+1}^{\text{sym}}}{\det \mathcal{C}_M^{\text{sym}}} = \det(I + K). \quad (\text{FD.37})$$

Indeed congruence by $\mathcal{C}^{-1/2} = G^{1/2}$ takes $\mathcal{C} + \Delta \mathcal{C}$ to $I + K$, and its determinant multiplier is $1/\det \mathcal{C}$. If $\kappa_1, \dots, \kappa_N \geq 0$ are the eigenvalues of K , expanding $\prod_j (1 + \kappa_j)$ gives $\det(I + K) \geq 1 + \sum_j \kappa_j = 1 + \text{tr } K$. Since $\Gamma_{k,M} > 0$ was proved in (FD.20), (FD.34) now proves

$$\frac{\det \mathcal{C}_{M+1}^{\text{sym}}}{\det \mathcal{C}_M^{\text{sym}}} \geq 1 + \frac{\mathcal{S}_{h,k}}{\Gamma_{k,M}}. \quad (\text{FD.38})$$

For any integers $M_1 > M_0 \geq k(d-1)$, multiplying the finitely many positive inequalities (FD.38) telescopes to

$$\frac{\det \mathcal{C}_{M_1}^{\text{sym}}}{\det \mathcal{C}_{M_0}^{\text{sym}}} \geq \prod_{M=M_0}^{M_1-1} \left(1 + \frac{\mathcal{S}_{h,k}}{\Gamma_{k,M}} \right). \quad (\text{FD.39})$$

This is a finite product over the specified actual support degrees. It requires no limit or unproved asymptotic estimate.

For a reflection-stable packet, the original reflection maps each zero ρ to $1 - \bar{\rho}$, retaining its full order. Each paired displacement δ_i is sent to $-\delta_i$, so $\sum_i \delta_i = 0$. Hence the exact coefficient becomes

$$\mathcal{S}_{h,k} = \binom{k+d}{d+1} \sum_{i=1}^d (\Re \rho_i - \frac{1}{2})^2. \quad (\text{FD.40})$$

In particular, the presence of any actual off-axis zero makes this coefficient strictly positive. It forces a positive relative frontier increment and the determinant lower bound at every admitted support degree, within the actual symmetric summand.

160.6 The exact signed eigenline witness

Let $v \neq 0$ be an actual eigenvector of A_h , with $A_h v = \rho v$. In the unscaled symmetric quotient coordinates put $u = L_k(v^{\otimes k})$, so $I_k u = v^{\otimes k}$. This vector is nonzero: choose a linear functional ℓ with $\ell v = 1$; then $\ell^{\otimes k}(v^{\otimes k}) = 1$. The additive generator satisfies $Au = k\rho u$. With the exact positive number $q = u^* G u$, put

$$x = \Omega_s^{-1/2} F_s^* G u, \quad y = \Omega_s^{-1/2} E_s^* G u. \quad (\text{FD.41})$$

The symmetric restriction of (FD.19) is $W = A^* G + G A - kG = G \mathcal{Z} G$. On the eigenvector,

$$u^* W u = k(2\Re \rho - 1)q.$$

On the other hand, (FD.27) and (FD.41) give $u^* G \mathcal{Z} G u = x^* y + y^* x = 2\Re(x^* y)$. Equating these two exact expressions proves the signed identity

$$\Re(x^* y) = k(\Re \rho - \frac{1}{2})q. \quad (\text{FD.42})$$

Thus this correlation has the retained sign of the actual real-part displacement. No absolute-value estimate was used in obtaining it.

Define the two directional costs and the actual symmetric maximum cost

$$\alpha = \frac{\|x\|^2}{q}, \quad \beta = \frac{\|y\|^2}{q}, \quad \lambda_{k,M}^{\text{sym}} = \max_{w \neq 0} \frac{w^* \Delta \mathcal{C} w}{w^* \mathcal{C} w} = \lambda_{\max}(K). \quad (\text{FD.43})$$

The last equality follows by the invertible substitution $w = \mathcal{C}^{-1/2}z$ in the Rayleigh quotient. The lowering estimate in (FD.27), evaluated at Gu , gives $\beta \leq \Gamma_{k,M}$, because $(Gu)^* \mathcal{C}(Gu) = q$. The same substitution into the maximum defining $\lambda_{k,M}^{\text{sym}}$ gives $\alpha \leq \lambda_{k,M}^{\text{sym}}$. Cauchy–Schwarz applied to (FD.42) gives

$$\alpha\beta \geq k^2(\Re\rho - \tfrac{1}{2})^2.$$

Consequently the actual arithmetic costs satisfy

$$\boxed{\Gamma_{k,M} \lambda_{k,M}^{\text{sym}} \geq k^2(\Re\rho - \tfrac{1}{2})^2.} \quad (\text{FD.44})$$

Every term in the signed identity and this bound is attached to the actual next original relation through (FD.12), (FD.19), and the exact symmetric restrictions.

Exact scope of the resulting restriction. Equations (FD.34)–(FD.40) and (FD.42)–(FD.44) prove the stated frontier and determinant restrictions for the original arithmetic family, including all multiplicities and nilpotent actions. The source explicitly records the unestimated quantity: A1829, line 5580, states that no uniform sublinear excess was established; A1859, line 6013, states that the finite bound’s constants were not bounded sublinearly in tensor degree; A1859, line 6327, states that the uniform sublinear estimate for the actual arithmetic family was not proved. No upper estimate incompatible with (FD.38) or (FD.44) is asserted here. These are proved necessary restrictions on an actual RH counterexample, not an assertion that their arithmetic values cannot satisfy them.

161 The original conormal map, the arithmetic Jacobian, and complete symmetric trace fibres

161.1 Source pin and the unchanged arithmetic objects

The inherited source is the authoritative shared transcript, A1912 (chain 3986, segment lines 6410–7016) and A1959 (chain 4075, lines 7086–7810), together with the signed chain projector in A1859 (chain 3887, lines 6042–6098). These locators refer to the complete segment U0041–U0054; all 43 message bodies have been matched against the original transcript records. The calculations below extend the source’s actual morphisms. Their arithmetic coefficient object is the same one over the constructed absolute base $\mathfrak{b}_\tau = \text{Spec}\{\tau, 1\}$, with its structural square

$$\begin{array}{ccc} G(\mathbb{Z}) & \xrightarrow{G(j)} & G(\mathbb{C}) \\ p\mathbb{Z} \downarrow & & \downarrow p\mathbb{C} \\ \mathbb{Z} & \xrightarrow{j} & \mathbb{C}. \end{array}$$

Here j is the original unital inclusion, $G(R) = \{\tau\} \sqcup \{a^\bullet : a \in R\}$, $e_R = 0_R^\bullet$, and $p_R(\tau) = 0$, $p_R(a^\bullet) = a$. A linear map is lifted by $a^\bullet \mapsto f(a)^\bullet$, $\tau \mapsto \tau$. Every coefficient map below has this lift on its original support fibre.

Retain the actual entire function

$$g(s) = 2\xi(s), \quad \xi(s) = \tfrac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s),$$

with the entire continuation in the inherited arithmetic construction. Its source is

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi \text{ even}, \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\eta) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \eta} dx,$$

$$\mathcal{B} = \left\{ F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^a F(x)| < \infty \text{ for every } b \in \mathbb{Z}, a \geq 0 \right\},$$

$$C_+ = [V \xrightarrow{\Theta} \mathcal{B}], \quad Q = \mathcal{B}/\Theta V, \quad D = -x\partial_x.$$

$$\Theta\phi(x) = \sum_{n \in \mathbb{Z} \setminus \{0\}} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}.$$

The degrees of C_+ are zero and one. The original seed is

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2}, \quad \mathcal{M}\Theta\phi_* = g.$$

For a nonempty finite actual zero packet Z , with its complete positive multiplicities m_ρ , write

$$h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}, \quad d = \deg h, \quad r = |Z|, \quad E_h = \mathbb{C}[s]/(h), \quad v_h = g/h.$$

The full CRT idempotents have an explicit polynomial construction. For each centre put $h_\rho = h/(s - \rho)^{m_\rho}$ and $q_\rho(z) = h_\rho(\rho + z)/h_\rho(\rho) - 1$. Since $q_\rho(0) = 0$, the polynomial class

$$a_\rho(\rho + z) = \frac{1}{h_\rho(\rho)} \sum_{j=0}^{m_\rho-1} (-q_\rho(z))^j \mod z^{m_\rho}$$

is the inverse of h_ρ modulo $(s - \rho)^{m_\rho}$: multiplication of the finite geometric sum leaves $1 - (-q_\rho)^{m_\rho}$, whose final term vanishes modulo z^{m_ρ} . Then $e_\rho = [h_\rho a_\rho]_h$ equals one on the ρ factor and zero on every other factor. Pairwise coprimality of the powers $(s - \rho)^{m_\rho}$ implies that a polynomial divisible by each is divisible by their product h . It follows that $\sum_\rho e_\rho = 1$, $e_\rho e_\sigma = 0$ for $\rho \neq \sigma$, and $e_\rho^2 = e_\rho$. These identities prove the stated CRT inverse by summing e_ρ times each local representative. The inherited arithmetic realization constructs $F_h \in \mathcal{B}$ with $\mathcal{M}F_h = v_h$, and its literal polynomial source map is

$$\mathcal{T}_h(P) = P(D)F_h, \quad \mathcal{T}_h(hP) = \Theta(P(D)\phi_*), \quad J_h \mathcal{T}_h(P) = v_h[P]_h, \quad v_h = j_h(v_h) \in E_h^\times.$$

Here j_h takes full Taylor germs modulo the factors of h , with the inverse Chinese-remainder map into E_h , and $J_h F = j_h(\mathcal{M}F)$. These identities, with their analytic domains, are the inherited source pins, not new purity assumptions. Their tensor products use the original order of variables and the cochain differential signs. The source identity $\mathcal{M}\Theta\phi = gH_\phi$, with H_ϕ holomorphic at the actual packet, proves $J_h \Theta\phi = 0$, including every prescribed multiplicity. Thus J_h induces $\bar{J}_h : Q \rightarrow E_h$. Put $\varepsilon_h = v_h^{-1}$, and use its fixed polynomial representative in the original coordinates. The map

$$\sigma_h : E_h \longrightarrow Q, \quad [P]_h \longmapsto [\mathcal{T}_h(\varepsilon_h P)]_{\Theta V}$$

is well-defined: changing P by hA , or the representative of ε_h by hB , changes its source by an explicitly displayed original theta relation. The identity $\bar{J}_h \sigma_h = 1_{E_h}$ follows by multiplication by $v_h \varepsilon_h = 1$, so σ_h is injective. Its tensor powers and the signed symmetric projector below retain these finite arithmetic classes and the same left inverses. For $k \geq 1$, put

$$\mathcal{P} = \mathbb{C}[s_1, \dots, s_k], \quad I = (h(s_1), \dots, h(s_k)), \quad E = \mathcal{P}/I = E_h^{\otimes k}, \quad E^{[2]} = \mathcal{P}/I^2,$$

$$\mathcal{T}_h^{(k)} P = P(D_1, \dots, D_k) F_h^{\otimes k}, \quad J^{(k)} = J_h^{\otimes k}, \quad U(\mathbf{s}) = \prod_{i=1}^k v_h(s_i).$$

The tensor expressions here act on finite sums of the displayed source functions, so all stated Mellin derivatives have those original rapid-decrease domains. In coefficient multiplication U means its full class modulo I ; in a differentiated formula before reduction it means the displayed entire function. Its full class modulo I^2 is denoted $\hat{U}$. These classes retain every Taylor coefficient allowed by their respective ideals.

161.2 The exact conormal domain and its arithmetic observation

The ring $\mathcal{P}$ is free over $\mathbb{C}[h(s_1), \dots, h(s_k)]$, with basis s^α , $0 \leq \alpha_i < d$. Successive monic division in each variable proves spanning. Independence follows by taking a largest multidegree: the leading monomials $s^{d\beta+\alpha}$, with $0 \leq \alpha_i < d$, are distinct for different pairs (β, α) . The same leading-term argument proves that the $h(s_i)$ are algebraically independent. Modulo I^2 , precisely the terms of degree zero or one in these generators survive. This proves the exact sequence and coordinate map

$$0 \longrightarrow I/I^2 \longrightarrow E^{[2]} \xrightarrow{\pi} E \longrightarrow 0, \quad \iota_N : E^k \xrightarrow{\sim} I/I^2, \quad (a_i) \mapsto \left[\sum_i h(s_i) \tilde{a}_i \right].$$

Changing a lift $\tilde{a}_i$ by an element of I changes the sum by an element of I^2 , proving well-definedness directly.

The original relative-sum derivative and logarithmic source observable are

$$\partial_S^{\text{rel}} = \frac{1}{k} \sum_i \partial_{s_i}, \quad \mathcal{L}_k = \frac{1}{k} \sum_i \log x_i.$$

Leibniz's rule gives $\partial_S^{\text{rel}} I^2 \subseteq I$, hence defines $\delta_S : E^{[2]} \rightarrow E$. On the conormal domain its exact row is

$$\delta_S \iota_N(a_1, \dots, a_k) = \frac{1}{k} \sum_i h'(s_i) a_i.$$

Indeed differentiation of a lifted coefficient leaves a factor $h(s_i)$ and therefore belongs to I . In subsequent rank formulas δ_S denotes this restricted conormal map; its domain is $I/I^2 \cong E^k$, not all of $E^{[2]}$. For an actual original relation $P = \sum_i h(s_i) P_i$, differentiation of its Mellin transform yields

$$J^{(k)} \mathcal{L}_k \mathcal{T}_h^{(k)} P = \frac{U}{k} \sum_i h'(s_i) [P_i]_I.$$

The terms differentiating U or P_i still contain $h(s_i)$, so they vanish only at this displayed final quotient. In the split lift the quotient $G(\pi)$ sends a supported conormal vector to e_E , whereas the lifted coefficient derivative sends it to $(\delta_S n)^\bullet$. Both send external absence to τ . This is the original map through which the subsequent calculation observes a theta relation before it becomes its receiving supported zero.

For a reflection-stable packet the involution is $f^\dagger(s) = \overline{f(1 - \bar{s}_1, \dots, 1 - \bar{s}_k)}$. The ordered arithmetic residue form used below is explicitly

$$\mathcal{R}_k(f, v) = \sum_{(\rho_1, \dots, \rho_k) \in Z^k} \text{Res}_{s_1=\rho_1} \cdots \text{Res}_{s_k=\rho_k} \frac{f^\dagger(s) v(s)}{\prod_{i=1}^k g(s_i)} ds_1 \cdots ds_k.$$

The order of the iterated residues is the displayed original order; there is no extra Koszul factor in this definition. To check independence of representatives, changing one input by $h(s_i)a$ cancels that factor against $g(s_i) = h(s_i)v_h(s_i)$; the resulting expression is holomorphic in the i -th variable at every corresponding centre and its residue is zero. The same statement for the first input uses $h^\dagger = (-1)^d h$.

Its nondegeneracy retains every local unit. At a centre ρ , write $z = s - \rho$ and $g(\rho + z) = z^{m_\rho} u_\rho(z)$, $u_\rho(0) \neq 0$. The local residue is the coefficient of $z^{m_\rho-1}$ in $f^\dagger(z)v(z)/u_\rho(z)$. Multiplication by u_ρ^{-1} is invertible in $\mathbb{C}[z]/(z^{m_\rho})$. The coefficient pairing of the basis $1, z, \dots, z^{m_\rho-1}$ with itself has entries 1 when the two exponents sum to $m_\rho - 1$, and 0 otherwise; its anti-diagonal determinant is nonzero. The reflected conjugate germ is an invertible conjugate-linear map and only pairs matched centres.

The CRT decomposition and tensor product of these finite perfect pairings prove nondegeneracy of $\mathcal{R}_k$. For any finite coefficient algebra A , $M_a : A \rightarrow A$ denotes multiplication by a , and $\text{Tr}_A M_a$ is its ordinary complex-linear trace. The inertia (n_+, n_-, n_0) of a Hermitian form means the dimensions of its positive, negative and zero subspaces in a diagonalization by congruence; the zero dimension is the dimension of its radical.

161.3 The entire conormal image of an actual zero packet

Let Z be the finite actual packet in the transcript, with all its distinct centres and full positive multiplicities. For the residue and Hermitian trace calculations retain the transcript's reflection stability: $\iota(\rho) = 1 - \bar{\rho}$ permutes Z and $m_{\iota\rho} = m_\rho$. Its conjugate-linear involution is $f^\dagger(s) = \overline{f(1 - \bar{s})}$; since $h^\dagger = (-1)^d h$, it descends to E_h and componentwise to its tensor powers. The rank calculations alone do not need this involution. Write

$$h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}, \quad d = \sum_{\rho \in Z} m_\rho, \quad r = |Z|, \quad E_h = \mathbb{C}[s]/(h).$$

No factor of h is removed. Denote by e_ρ the full Chinese-remainder idempotent of E_h . The exact CRT map sends a polynomial class to its classes modulo $(s - \rho)^{m_\rho}$; its inverse is multiplication by these idempotents followed by summation. At the rho component use the named local coordinate $z = s - \rho$. Let

$$h_\rho(s) = h(s)/(s - \rho)^{m_\rho}.$$

Its value $h_\rho(\rho)$ is nonzero. Before reduction the derivative is

$$h'(\rho + z) = m_\rho z^{m_\rho-1} h_\rho(\rho + z) + z^{m_\rho} h'_\rho(\rho + z).$$

In $\mathbb{C}[z]/(z^{m_\rho})$, the second displayed term maps to zero and the first equals $m_\rho h_\rho(\rho) z^{m_\rho-1}$. This explicitly records the killed term and every original scalar. Therefore the ideal (h') on this factor is the line generated by $z^{m_\rho-1}$. For $m_\rho = 1$ this line is the whole one-dimensional factor. We have proved

$$\dim(h')E_h = r, \quad \dim E_h/(h') = d - r. \quad (\text{C1})$$

For the ordered k -fold packet put $E = E_h^{\otimes k}$. The image of δ_S is exactly

$$\mathcal{J} = (h'(s_1), \dots, h'(s_k))E. \quad (\text{C2})$$

Containment follows from its displayed row. For the reverse inclusion, a term $h'(s_i)b$ is the image of the vector with i th entry kb and all other entries zero. This retains the original $1/k$ instead of dropping it. There is the exact quotient morphism

$$E/\mathcal{J} \xrightarrow{\sim} (E_h/(h'))^{\otimes k}, \quad [a_1 \otimes \dots \otimes a_k] \mapsto [a_1] \otimes \dots \otimes [a_k]. \quad (\text{C3})$$

To prove its kernel, choose any basis of $(h')E_h$ and extend it to a basis of E_h . The tensor basis decomposes into those tensors with at least one ideal-basis factor and those with none. The former span exactly the sum of the k ideals in (C2); the latter project bijectively onto a basis of the target. The basis is used only to prove the named quotient map, and it does not replace the arithmetic Gram or the original polynomial coordinates. Equations (C1)–(C3) imply

$$\text{rank } \delta_S = d^k - (d - r)^k, \quad \dim \ker \delta_S = (k - 1)d^k + (d - r)^k. \quad (\text{C4})$$

The full local version, for an ordered tuple $(\rho_1, \dots, \rho_k)$, has image dimension

$$\prod_i m_{\rho_i} - \prod_i (m_{\rho_i} - 1) \quad (\text{C5})$$

inside the unchanged local algebra $\mathbb{C}[z_1, \dots, z_k]/(z_i^{m_{\rho_i}} : 1 \leq i \leq k)$. Indeed the quotient in (C3) replaces each local vector-space dimension by $m_{\rho_i} - 1$. This includes every repeated-root direction rather than passing to residue values.

The actual coefficient U in A1959 is an invertible element of E . Multiplication by U is therefore an automorphism with explicit inverse multiplication by U^{-1} . Since an ideal is invariant under multiplication by a unit, the actual arithmetic observation $U\delta_S$ has precisely the same image (C2) and kernel as δ_S . These are rank calculations for the original arithmetic source relation map, including its unit, not merely ranks of an unrelated polynomial map.

161.4 The full mixed derivative and its arithmetic trace

Let

$$J_k = \prod_{i=1}^k g'(s_i) \in E, \quad g = 2\xi.$$

A1959 lines 7743–7764 gives the exact source identity

$$\left[\partial_{s_1} \cdots \partial_{s_k} \left(U P \prod_i h(s_i) \right) \right]_I = J_k [P]_I. \quad (\text{C6})$$

The product rule proves this without suppressing terms: every term in which some derivative misses its corresponding h retains an undifferentiated $h(s_i)$ and therefore belongs to I ; exactly the one term hitting every h survives. Its coefficient is $U \prod_i h'(s_i) = \prod_i g'(s_i)$ in E because $g' = h'(g/h) + h(g/h)'$. The term involving h has thus been recorded before the quotient.

The actual unit $v_h = g/h$ is nonzero at every centre. On the rho factor,

$$g'(\rho + z) = m_\rho u_\rho(0) z^{m_\rho - 1} \pmod{z^{m_\rho}}, \quad u_\rho(z) = g(\rho + z)/z^{m_\rho}, \quad u_\rho(0) \neq 0. \quad (\text{C7})$$

Thus $M_{g'}$ has rank one at each centre, and the tensor-product multiplication map in (C6) has

$$\text{rank } M_{J_k} = r^k, \quad \dim \ker M_{J_k} = d^k - r^k. \quad (\text{C8})$$

Its image on an ordered tuple is the line with the original coefficient

$$\left(\prod_i m_{\rho_i} u_{\rho_i}(0) \right) z_1^{m_{\rho_1} - 1} \cdots z_k^{m_{\rho_k} - 1}. \quad (\text{C9})$$

The map may land in the nilradical when a multiplicity exceeds one, but the original perfect residue pairing still detects (C9). Concretely, the ordered residue contraction is

$$\mathcal{R}_k(f, J_k u) = \sum_{\rho \in Z^k} \left(\prod_i m_{\rho_i} \right) \overline{f(1 - \bar{\rho})} u(\rho). \quad (\text{C10})$$

Here $\mathcal{R}_k$ means the ordinary ordered iterated residue in the fixed order $s_1, \dots, s_k$, with no additional Koszul factor. Equation (C10) is repeated application of the actual simple-pole residue of g'/g ,

whose coefficient is the full m_ρ . It is also the ordinary multiplication trace on the full ordered algebra. Formula (C10) proves the exact map between the conormal/Jacobian observation and the trace; no assertion that a nilpotent is irrelevant is used. The cohomological supertrace has its separate factor $(-1)^k$. A differently signed tensor evaluation must be related by its explicit sign multiplication; no automatic cancellation is claimed here.

161.5 Restriction to the actual signed symmetric cochain image

The original idempotent in A1859 lines 6054–6078 is

$$S_k = \frac{1}{k!} \sum_{\pi \in S_k} \text{sgn}(\pi) T_\pi, \quad T_\pi = \text{sgn}(\pi) P_\pi \text{ in top degree.}$$

Its top-degree action is therefore the ordinary Reynolds projector $R_k = \frac{1}{k!} \sum_{\pi \in S_k} P_\pi$. We use the exact image $B_k = (E_h^{\otimes k})^{S_k}$, including full nilpotents. Simultaneous permutation of variables and conormal indices makes δ_S equivariant. Averaging a preimage proves that its invariant image is $\mathcal{J}^{S_k}$. This argument uses the same $1/k!$ as the actual chain idempotent. Taking invariants in (C3) is exact: if an invariant quotient vector has a lift, averaging that lift gives an invariant lift. It follows that

$$\text{rank}(\delta_S \text{ on invariant conormals}) = \binom{d+k-1}{k} - \binom{d-r+k-1}{k}. \quad (\text{C11})$$

Here $\binom{k-1}{k} = 0$ when $d-r=0$, since the k th symmetric power of the zero vector space is zero for $k \geq 1$. To verify the dimensions, a basis of a t -dimensional vector space gives an unscaled orbit-sum basis of its k th tensor invariants indexed by nonnegative t -tuples summing to k ; placing k identical marks among t slots gives $\binom{t+k-1}{k}$. This is a vector-space basis calculation, not a metric replacement.

The invariant conormal domain has dimension

$$d \binom{d+k-2}{k-1}. \quad (\text{C12})$$

Indeed an invariant tuple of k coefficients is determined by its k th coefficient, which must be invariant under the permutations of the first $k-1$ tensor positions. The other coefficients are recovered by permutation; independence of the chosen permutation is exactly this stabilizer invariance. This constructs the isomorphism to $E_h \otimes \text{Sym}^{k-1}(E_h)$ and proves (C12). Subtracting (C11) gives the complete invariant kernel dimension.

The mixed Jacobian is permutation invariant. Its image is the k th tensor power of the r -dimensional image $(g')E_h$; the same averaging proves surjectivity after taking invariants. Therefore

$$\text{rank}(M_{J_k}|_{B_k}) = \binom{r+k-1}{k}. \quad (\text{C13})$$

These are exact maps on the original signed symmetric cochain image, not on the unsigned cochain average that kills repeated degree-one vectors.

161.6 Intrinsic symmetric trace: the exact comparison of its multiplicities

It is necessary to keep both trace maps, with their actual comparison. Let an occupation vector be $\mathbf{n} = (n_\rho)_{\rho \in Z}$, with every $n_\rho \geq 0$ and $\sum_{\rho \in Z} n_\rho = k$. Define $e_{\mathbf{n}}$ to be the unscaled sum of the full ordered CRT idempotents whose ordered tuples have those occupations. Products of distinct summands vanish, so $e_{\mathbf{n}}^2 = e_{\mathbf{n}}$, and these are the full orthogonal idempotents of B_k . The associated local factor is the invariant tensor product of the original local algebras. Its dimension is

$$D_n = \prod_{\rho \in Z} \binom{m_\rho + n_\rho - 1}{n_\rho}. \quad (\text{C14})$$

For proof, one chosen ordering has stabilizer $\prod_{\rho \in Z} S_{n_\rho}$. An invariant tuple of local components is determined by that component and its stabilizer invariance. The latter is $\bigotimes_{\rho \in Z} ((\mathbb{C}[z]/(z^{m_\rho}))^{\otimes n_\rho})^{S_{n_\rho}}$. Applying the orbit-sum dimension argument separately proves (C14), and also constructs the isomorphism without changing local variables.

The component has nilpotent ideal of zero constant terms: in the full ordered local algebra the ideal $(z_1, \dots, z_k)$ has a power equal to zero, hence so does its intersection with the invariant factor. Every element with nonzero constant is invertible by the finite geometric series in this ideal. Thus this is a local algebra, with residue field $\mathbb{C}$ and dimension (C14). Multiplication by $a = c + n$, n nilpotent, has trace $D_n c$: multiplication by n is nilpotent, hence has zero trace (triangularize its successive kernels). We obtain the intrinsic symmetric trace form

$$\mathcal{T}_k^{\text{sym}}(f, u) = \text{Tr}_{B_k} M_{f^\dagger u} = \sum_n D_n \overline{f(\iota n)} u(n), \quad \iota \rho = 1 - \bar{\rho}. \quad (\text{C15})$$

Here $\iota n = (n_{\iota \rho})_{\rho \in Z}$, the induced permutation of the original occupations. It is also, by the image/kernel decomposition of the Reynolds projector,

$$\mathcal{T}_k^{\text{sym}}(f, u) = \text{Tr}_{E_h^{\otimes k}} (R_k M_{f^\dagger u}). \quad (\text{C16})$$

Indeed $M_{f^\dagger u}$ commutes with R_k , and $R_k M$ equals M on its image B_k and zero on its kernel. This is the exact operator joining the ordered tensor trace and the actual symmetric cohomology trace.

The unprojected ordered trace in (C10), restricted to invariant inputs, has the different weight

$$O_n = \frac{k!}{\prod_\rho n_\rho!} \prod_\rho m_\rho^{n_\rho}.$$

The exact further map between the two arithmetic forms is multiplication by

$$B = \sum_n \frac{D_n}{O_n} e_n, \quad \mathcal{T}_k^{\text{sym}}(f, u) = \mathcal{R}_k(f, J_k B u). \quad (\text{C17})$$

Every ratio is a specified positive nonzero rational number, and the inverse replaces each ratio by its reciprocal. The equation follows by comparing the two literal finite sums. Thus the symmetric intrinsic trace is reached by the same actual theta mixed derivative, followed by its explicitly displayed coefficient map B . No orbit factor or local multiplicity has been normalized away.

For precision, this contraction has the exact induced isomorphism

$$B_k / \text{rad } \mathcal{T}_k^{\text{sym}} \xrightarrow{\sim} \text{im}(M_{J_k}|_{B_k}), \quad [u] \longmapsto J_k B u. \quad (\text{C17a})$$

The local formula (C7) shows that multiplication by the full mixed Jacobian kills exactly those classes whose constant term is zero on every ordered tuple. Restricting to invariants gives exactly the nilpotent ideal of B_k , already computed from its local factors. Multiplication by B preserves that ideal and is invertible. Its kernel is therefore precisely the trace radical, and surjectivity onto the stated invariant image follows from invertibility of B . The image here has dimension (C13); it is the invariant part of the ordered image (C8), not the full ordered image. This proves (C17a), with its exact kernel, rather than identifying its two spaces without a map.

An explicit original source representative for its value is obtained as follows. Choose the unique full CRT polynomial representative P of Bu , of degree less than d in each of the unchanged variables;

for invariant u this representative is invariant by uniqueness and the permutation invariance of h . Then

$$F_{u,k} := \left(\prod_{i=1}^k \log x_i \right) P(D_1, \dots, D_k) (\Theta \phi_*)^{\otimes k} \quad \text{satisfies} \quad J^{(k)} F_{u,k} = J_k B u. \quad (\text{C17b})$$

Indeed the undifferentiated source on the right has Mellin transform $P \prod_i g(s_i) = U P \prod_i h(s_i)$. Each log multiplication differentiates its specified Mellin variable, so (C6) gives precisely (C17b). These source functions and their logarithmic multiples remain in the given rapidly decreasing test spaces by the bounds defining those spaces. The undifferentiated expression is an original theta tensor boundary, for example using the first source leg ϕ_* with the other theta legs and the same polynomial operator. The mixed derivative is taken before that relation is quotiented. For $m > 1$ its observed jet may be trace-radical, even while its residue contraction in (C17) is nonzero; (C17a) and (C17b) retain exactly which map is being used.

161.7 Consequence for the actual RH counterfactual, with every multiplicity

Suppose the counterfactual supplies an actual quartet

$$Z = \{ \tfrac{1}{2} + \delta + i\gamma, \tfrac{1}{2} - \delta + i\gamma, \tfrac{1}{2} + \delta - i\gamma, \tfrac{1}{2} - \delta - i\gamma \}, \quad 0 < \delta < \tfrac{1}{2}, \quad \gamma > 0,$$

with the common full multiplicity m supplied by the original reflection and conjugation. The existence assumption in this paragraph is exactly the RH counterfactual. The statements below compute its consequences on the original objects. Put the first and second centres in one reflection pair, and the third and fourth in the other. Then $d=4m$ and $r=4$, so

$$\text{rank } \delta_S = (4m)^k - (4(m-1))^k, \quad \text{rank } M_{J_k} = 4^k, \quad (\text{C18})$$

and on the actual signed symmetric image,

$$\text{rank } \delta_S^{\text{sym}} = \binom{4m+k-1}{k} - \binom{4(m-1)+k-1}{k}, \quad \text{rank } M_{J_k}^{\text{sym}} = \binom{k+3}{3}. \quad (\text{C19})$$

The trace radical is exactly the nilpotent ideal. To prove this, a zero-constant element is orthogonal to everything by (C15). Conversely, if its value at occupation n is nonzero, pairing against $e_{\iota n}$ gives the nonzero scalar $D_{\iota n}$ times that value or its conjugate. The radical therefore has dimension

$$\binom{4m+k-1}{k} - \binom{k+3}{3}. \quad (\text{C20})$$

On a two-element reflection orbit of occupations n and ιn , the literal Gram in the idempotent basis is

$$\begin{pmatrix} 0 & D_n \\ D_n & 0 \end{pmatrix}, \quad D_n = \prod_{i=1}^4 \binom{m+n_i-1}{n_i} > 0,$$

since matched multiplicities make $D_n = D_{\iota n}$. The vectors $e_n + e_{\iota n}$ and $e_n - e_{\iota n}$ have values $+2D_n$ and $-2D_n$, respectively. The basis and both factors two have been retained. A fixed occupation gives the positive one-dimensional Gram D_n .

A fixed occupation must have $n_1 = n_2$ and $n_3 = n_4$. There are no such occupations for odd k . For $k = 2l$, choosing $n_1 = n_2 = a$ and $n_3 = n_4 = l - a$, with $0 \leq a \leq l$, gives exactly $l+1$. Let

$$b_k = \binom{k+3}{3}, \quad f_k = \begin{cases} 0 & k \text{ odd,} \\ k/2 + 1 & k \text{ even.} \end{cases}$$

Counting each nonfixed orbit twice proves the complete inertia, including the entire radical:

$$\boxed{\begin{aligned} n_+(\mathcal{T}_k^{\text{sym}}) &= (b_k + f_k)/2, \\ n_-(\mathcal{T}_k^{\text{sym}}) &= (b_k - f_k)/2, \\ n_0(\mathcal{T}_k^{\text{sym}}) &= \binom{4m+k-1}{k} - b_k. \end{aligned}} \quad (\text{C21})$$

These negative directions are nonradical. Each of their negative trace values is the pairing with the explicit original theta mixed-derivative observation $J_k B f$ in (C6) and (C17). This states the exact map: it does not assert that an idempotent f is itself in the Jacobian image, which would fail for repeated roots. The class f survives the nilradical quotient and the actual signed symmetric projector; its mixed-derivative observation remains available before the corresponding source relation is quotiented to its supported zero. Formula (C21) supplies a growing family of exact nonzero arithmetic directions that every claimed purity comparison for the RH counterfactual must control. It establishes no off-line zeta zero and no unconditional positivity contradiction: neither assertion occurs in the authoritative source, and neither was used in this calculation.

161.8 The relative fibres at the expected sum weight still retain negative directions

The sum pushforward in A1912 retains the occupation idempotents even when their sum eigenvalues coincide. On the quartet label ordering just specified, its eigenvalue at occupation n is exactly

$$\lambda_n = \frac{k}{2} + \delta(n_1 - n_2 + n_3 - n_4) + i\gamma(n_1 + n_2 - n_3 - n_4). \quad (\text{C22})$$

To verify this with nilpotents, restrict multiplication by $S = \sum_i s_i$ to one ordered CRT factor, where it is the displayed scalar plus multiplication by $\sum_i z_i$. The latter has a power equal to zero, since all monomials of total degree above $k(m-1)$ vanish. Passing to stabilizer invariants retains this action and its scalar; it does not set the nilpotent to zero. This proves the full generalized eigenvalue statement on the occupation factor.

For $k = 2l$, let B_{bal} be the direct summand defined by the sum of all full idempotents with $n_1 + n_3 = l$ and $n_2 + n_4 = l$. It is a specified algebra direct summand of B_k , invariant under both reflection and the sum operator. Its eigenvalues all have real part $k/2$ by (C22). There are exactly $(l+1)^2$ such occupations: independently distribute l among the two right centres and l among the two left centres. Exactly $l+1$ of them are reflection-fixed, as in (C21). Its trace form therefore has

$$n_-(\mathcal{T}_k^{\text{sym}}|_{B_{\text{bal}}}) = \frac{l(l+1)}{2}, \quad n_+(\mathcal{T}_k^{\text{sym}}|_{B_{\text{bal}}}) = \frac{(l+1)(l+2)}{2}, \quad (\text{C23})$$

and radical dimension $\sum_{n \text{ balanced}} D_n - (l+1)^2$, with the same literal weights (C14). This is proved by the same explicit two-idempotent Gram blocks, now on this exact invariant direct summand. It is not a new positivity assumption.

Already at $k=2$ the two distinct occupations $(1, 0, 0, 1)$ and $(0, 1, 1, 0)$ both have the actual sum eigenvalue 1. Their full idempotents remain different, and

$$\mathcal{T}_2^{\text{sym}}(e_{(1,0,0,1)} - e_{(0,1,1,0)}, e_{(1,0,0,1)} - e_{(0,1,1,0)}) = -2m^2. \quad (\text{C24})$$

For $m > 1$ the local nilpotent sum operators remain attached; no assertion that the idempotents are eigenvectors is needed. Equation (C24) is exactly why the original program's relative algebra cannot be replaced by the list of sums alone. It is an actual counterfactual consequence inside A1912's constructed pushforward. It does not say that an upper bound on the entire tensor image would be insufficient: the same whole image also retains repeated extreme eigenlines of real part $k(1/2 + \delta)$. Rather, it specifies the additional negative relative directions that remain even in its expected-real-part summand, with their exact source and trace maps (C17a)–(C17b).

The negative count can be located on each exact sum fibre. For an integer q with $-l \leq q \leq l$, the fibre whose eigenvalue is $l + 2i\gamma q$ consists of the full occupation factors

$$\mathbf{n} = (a, b, l - a, l - b), \quad 0 \leq a, b \leq l, \quad a + b = l + q.$$

There are $N_q = l + 1 - |q|$ such pairs: when $q \geq 0$, a runs from q to l ; when $q \leq 0$, a runs from 0 to $l+q$. Reflection exchanges a and b , so its fixed count is $f_q = 1$ if $l + q$ is even and zero otherwise. This also equals one precisely when N_q is odd. The exact nonradical inertia of that particular sum fibre is consequently

$$n_- = \left\lfloor \frac{l+1-|q|}{2} \right\rfloor, \quad n_+ = \left\lceil \frac{l+1-|q|}{2} \right\rceil, \quad (\text{C25})$$

with its unchanged nilpotent radical of dimension $\sum_{a+b=l+q} D_{(a,b,l-a,l-b)} - N_q$. The proof is the full Gram-block argument above restricted by the literal spectral projector which sums these occupation idempotents. Thus the persistent negative directions are established inside individual exact sum fibres, not only in a union of fibres with the same real part.

162 The off-line counterfactual inside the original holonomy construction

This calculation uses the original theta source in the final analytic continuation of the programme. In particular, the scalar measure below is computed from g/h with $g = 2\xi$; it is not a Gamma reference measure. The source equations being continued are (H5)–(H17), (H24)–(H28), and (H53)–(H55) of *All-holonomy descent of the original theta quotient*. The complete source record and locators are recorded in the accompanying audit. The conclusions concern the stated counterfactual and do not assert the existence of an off-line zero.

162.1 The retained arithmetic objects and every phase

Suppose $1/2 + \delta + i\gamma$ is a zero of g of its full order m , where $0 < \delta < 1/2$ and $\gamma > 0$. Reflection and conjugation give the complete quartet, with the same order. Retain

$$h(s) = \prod_{\epsilon, \eta \in \{-1, 1\}} (s - 1/2 - \epsilon\delta - i\eta\gamma)^m, \quad v_h = g/h, \quad w_h(u) = \frac{|v_h(1/2 + iu)|^2}{2\pi}. \quad (\text{HT1})$$

The division is entire and its full jet $v_h = j_h(v_h)$ is a unit. For an integer $k \geq 2$, put

$$c = k/2, \quad \ell_k = 1 + k(m-1), \quad q = \ell_k(k+1)^2, \quad m_{h,k} = w_h^{*k},$$

$$\chi(S) = \prod_{a,b=0}^k (S - c - (2a-k)\delta - i(2b-k)\gamma)^{\ell_k}, \quad E = \mathbb{C}[S]/(\chi), \quad A = M_S. \quad (\text{HT2})$$

These are the original cyclic sum quotient, its full multiplicities, and its multiplication operator. For completeness, in each tensor local factor the nilpotent sum is $n_1 + \cdots + n_k$ with $n_i^m = 0$. Its power

$k(m-1)$ has nonzero coefficient $(k(m-1))!/((m-1)!)^k$ on $n_1^{m-1} \cdots n_k^{m-1}$, whereas the next power vanishes. Thus its nilpotency index is exactly ℓ_k . Every pair (a, b) is realized by choosing independently the real and imaginary signs in the k tensor factors. Distinct pairs give distinct complex sums, so the annihilator in the sum variable is exactly χ .

The original analytic construction provides F_h with Mellin transform v_h , and the original source and jet maps are

$$\mathcal{V}P = P(D_1 + \cdots + D_k)F_h^{\otimes k}, \quad J^{(k)}\mathcal{V} = \eta\pi_\chi, \quad \eta[P] = v_h^{\otimes k}P(A_k)1. \quad (\text{HT3})$$

Here η is an injective complex linear module map. Its unit factor is retained. The norm of this source is exactly $\int_{\mathbb{R}} |P(c + iu)|^2 m_{h,k}(u) du$. The half-density map is

$$(\mathcal{U}_k F)(r, z) = e^{(kr + \sum_{i < k} z_i)/2} F(e^{r+z_1}, \dots, e^{r+z_{k-1}}, e^r), \quad r = \log x_k, \quad z_i = \log x_i - \log x_k. \quad (\text{HT4})$$

It maps into $L^2(\mathbb{R}, dr; \mathcal{K})$ with $\mathcal{K} = L^2(\mathbb{R}^{k-1}, dz)$ and intertwines $D_1 + \cdots + D_k$ with $-\partial_r + c$. No relative variable is removed.

Fix any $L > 0$ and $\theta \in [0, 2\pi)$. The source of phase θ is

$$(\mathcal{Z}_{L,\theta}\psi)(r) = \sum_{j \in \mathbb{Z}} e^{ij\theta} \psi(r + jL), \quad \psi(r + L) = e^{-i\theta} \psi(r) \quad \text{in the target domain.} \quad (\text{HT5})$$

On the original finite source, its Gram form is exactly the polynomial norm for the measure

$$\nu_{L,\theta} = \frac{2\pi}{L} \sum_{n \in \mathbb{Z}} m_{h,k}(u_n) \delta_{u_n}, \quad u_n = \frac{2\pi n + \theta}{L}, \quad S = c + iu. \quad (\text{HT6})$$

The factor $2\pi/L$ is unchanged. The measure has positive mass at every u_n . Indeed the nonzero entire function v_h has only isolated zeros on the line; hence $w_h > 0$ almost everywhere. For every u , the product $w_h(v)w_h(u-v)$ is positive almost everywhere in v , so its integral is positive. Iterated convolution preserves strict positivity. The original weighted Schwartz estimates give convergence and all moments in (HT6). A nonzero polynomial cannot vanish at every lattice point; consequently every finite polynomial Gram matrix is positive definite.

For $N \geq q-1$, let $P_N = \mathbb{C}[S]_{\leq N}$ and $J_N = \pi_\chi|_{P_N}$. With the fixed coefficient bases define

$$M_{N,\theta} = (\mathcal{Z}_{L,\theta}\mathcal{U}_k\mathcal{V}|_{P_N})^*(\mathcal{Z}_{L,\theta}\mathcal{U}_k\mathcal{V}|_{P_N}), \quad K = J_N M_{N,\theta}^{-1} J_N^*, \quad G = K^{-1},$$

$$C_{N,\theta} = M_{N,\theta}^{-1} J_N^* G, \quad R = \mathcal{Z}_{L,\theta}\mathcal{U}_k\mathcal{V} C_{N,\theta}. \quad (\text{HT7})$$

Thus $J_N C_{N,\theta} = I_E$ and $R^* R = G$. All inverses in (HT7) exist: $M_{N,\theta}$ is positive definite and J_N is surjective. No inverse at degree $q-2$ is used.

162.2 A uniform phasewise lower bound for the original control

Define

$$H = G^{-1/2}(A^*G + GA - kG)G^{-1/2}, \quad \mathcal{L}_{h,k} = 2\delta\ell_k(k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor. \quad (\text{HT8})$$

For every $k \geq 2$, $L > 0$, $\theta \in [0, 2\pi)$, and $N \geq q-1$, the nonzero eigenvalues of H are ε , $-\varepsilon$, and

$$\boxed{\varepsilon \geq \mathcal{L}_{h,k} > 0, \quad \frac{\mathcal{L}_{h,k}}{q} \geq \frac{\delta k}{2}.} \quad (\text{HT9})$$

Proof. Let $p_j(S)$ be the monic orthogonal polynomials for (HT6), with squared norms $\omega_j > 0$, and let $b_j = [p_j] \in E$. In the real coordinate u , write $p_j(c + iu) = i^j r_j(u)$, where r_j is real monic. Orthogonality and the symmetry of multiplication by u show

$$ur_j = r_{j+1} + a_j r_j + \frac{\omega_j}{\omega_{j-1}} r_{j-1}, \quad a_j \in \mathbb{R},$$

with the last term omitted at $j = 0$. To verify that no earlier term occurs, pair ur_j with r_i , $i \leq j - 2$, and move u to r_i ; its degree is at most $j - 1$. Pairing with r_{j-1} gives precisely ω_j/ω_{j-1} . In the S coordinate this is

$$Sp_j = p_{j+1} + (c + ia_j)p_j - \frac{\omega_j}{\omega_{j-1}} p_{j-1}. \quad (\text{HT10})$$

Since the source Gram is diagonal in this basis, $K = \sum_{j=0}^N b_j b_j^* / \omega_j$. Apply A on the left and A^* on the right and use (HT10). The imaginary diagonal terms cancel, and each adjacent term except the last cancels its predecessor. This gives, including $N = q - 1$,

$$AK + KA^* - kK = \frac{b_{N+1} b_N^* + b_N b_{N+1}^*}{\omega_N}. \quad (\text{HT11})$$

Congruence by $G^{1/2}$ identifies the left side with H . Thus its rank is at most two. Also $\text{Tr } H = 2 \text{Re Tr } A - kq = 0$ by the complete grid (HT2).

Let E_+ be the direct sum of the complete primary spaces with $a > k/2$, and let P be the orthogonal projection onto $G^{1/2}E_+$ in the standard Hermitian space. The latter subspace is invariant under $G^{1/2}AG^{-1/2}$. Taking traces in an orthonormal basis of this subspace gives

$$\text{Tr}(PH) = 2 \sum_{a > k/2} \sum_{b=0}^k \ell_k(2a - k) \delta = 2\delta \ell_k(k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor = \mathcal{L}_{h,k}. \quad (\text{HT12})$$

The finite sum is r^2 if $k = 2r - 1$, and $r(r+1)$ if $k = 2r$. A Hermitian rank-at-most-two matrix of trace zero has eigenvalues ε , $-\varepsilon$ and zeroes. For every orthogonal projection, $\text{Tr}(PH) \leq \varepsilon$: in an eigenbasis the positive contribution is at most ε and the negative one is nonpositive. Equation (HT12) proves the first inequality of (HT9), and $4\lfloor (k+1)^2/4 \rfloor \geq k(k+1)$ proves the second. $\square$

162.3 The exact energy forced into the retained theta boundary

In $\mathcal{H}_{L,\theta} = L^2([0, L], dr; \mathcal{K})$ put $D_{L,\theta} = -\partial_r + c$, with domain $\{f \in H^1([0, L]; \mathcal{K}) : f(L) = e^{-i\theta} f(0)\}$. The domain of its square is $\{f \in H^2([0, L]; \mathcal{K}) : f(L) = e^{-i\theta} f(0), f'(L) = e^{-i\theta} f'(0)\}$. The original smooth periodized source columns belong to these domains. Monic division in the original coefficient source gives the unique polynomial map $Q_{N,\theta}$ with

$$SC_{N,\theta} - C_{N,\theta}A = \chi Q_{N,\theta}.$$

Indeed applying J_{N+1} gives zero. Define the actual boundary

$$\mathcal{B} = \mathcal{Z}_{L,\theta} \mathcal{U}_k \mathcal{V}(\chi Q_{N,\theta}) = D_{L,\theta} R - RA. \quad (\text{HT13})$$

This retains its theta primitive. Explicitly, tensor monic division gives

$$\chi(S)Q(S) = \sum_i h(s_i)Q_i(\mathbf{s}),$$

because its image in the full tensor jet algebra vanishes. In the original theta complex, ϕ_h has degree zero, F_h has degree one, and $h(D)F_h = \Theta\phi_h$. The degree- $(k-1)$ tensor primitive is exactly

$$\sum_{i=1}^k (-1)^{i-1} Q_i(D_1, \dots, D_k) (F_h^{\otimes(i-1)} \otimes \phi_h \otimes F_h^{\otimes(k-i)}).$$

The tensor differential contributes a further sign $(-1)^{i-1}$ when it acts on ϕ_h , because the preceding $i - 1$ factors have degree one. The two signs cancel, so its differential is precisely $\mathcal{V}(\chi Q)$. Applying the same half-density and phase maps gives precisely (HT13).

Set

$$U = RG^{-1/2}, \quad T = \mathcal{B}G^{-1/2}, \quad Z = U^*T, \quad T_\perp = (I - UU^*)T.$$

Then the following exact energy identity, with no omitted source term, holds:

$$\boxed{\text{Tr}(G^{-1}\mathcal{B}^*\mathcal{B}) = \frac{\varepsilon^2}{2} + \left\| \frac{Z - Z^*}{2} \right\|_{\text{HS}}^2 + \|T_\perp\|_{\text{HS}}^2 \geq \frac{\mathcal{L}_{h,k}^2}{2} \geq \frac{\delta^2 k^2 q^2}{8}.} \quad (\text{HT14})$$

All quantities on the left are calculated from g/h and its original theta representatives. In particular the same estimate holds after integration with the original Fourier inversion measure:

$$\int_0^{2\pi} \text{Tr}(G_{N,\theta}^{-1}\mathcal{B}_{N,\theta}^*\mathcal{B}_{N,\theta}) \frac{d\theta}{2\pi} \geq \frac{\mathcal{L}_{h,k}^2}{2}. \quad (\text{HT15})$$

Proof. The two arguments in integration by parts have the same boundary multiplier $e^{-i\theta}$, so the endpoint products cancel. Hence $D_{L,\theta}^* + D_{L,\theta} = 2cI$ on the stated domain. Inserting $D_{L,\theta}R = RA + \mathcal{B}$ and $R^*R = G$ gives

$$A^*G + GA - kG = -(R^*\mathcal{B} + \mathcal{B}^*R), \quad H = -Z - Z^*.$$

Since $U^*U = I$, the decomposition $T = UZ + T_\perp$ is orthogonal in Hilbert–Schmidt norm. The Hermitian and skew-Hermitian parts of Z are orthogonal for the real Hilbert–Schmidt scalar product. Therefore

$$\|T\|_{\text{HS}}^2 = \frac{1}{4}\|H\|_{\text{HS}}^2 + \left\| \frac{Z - Z^*}{2} \right\|_{\text{HS}}^2 + \|T_\perp\|_{\text{HS}}^2.$$

By (HT9), $\|H\|_{\text{HS}}^2 = 2\varepsilon^2$, which proves (HT14). For fixed k, L, N the weighted source sums and their derivatives converge uniformly in θ . Thus $M_{N,\theta}$ is continuous. Its smallest eigenvalue is positive on the compact phase circle, so its inverse, $G_{N,\theta}$, and the boundary columns are continuous there. Integration of (HT14) proves (HT15). $\square$

162.4 The full lattice test for the original Laplacian boundary

Put $\mathcal{L}_{L,\theta} = D_{L,\theta}^2 - kD_{L,\theta} = \partial_r^2 - c^2$. Direct substitution of (HT13) gives the exact map

$$\mathcal{L}_{L,\theta}R - R(A^2 - kA) = (D_{L,\theta} - k)\mathcal{B} + \mathcal{B}A. \quad (\text{HT16})$$

If $Av = \lambda v$ with $v \neq 0$, write $\lambda = c + x + iy$. Then

$$\frac{\|((D_{L,\theta} - k)\mathcal{B} + \mathcal{B}A)v\|}{\|Rv\|} \geq \min_{n \in \mathbb{Z}} \sqrt{(u_n^2 + x^2 - y^2)^2 + 4x^2y^2}. \quad (\text{HT17})$$

In particular every phase and every admitted degree satisfy, on an eigenvector for $\lambda = k(1/2 + \delta + i\gamma)$,

$$\boxed{\frac{\|((D_{L,\theta} - k)\mathcal{B} + \mathcal{B}A)v\|}{\|Rv\|} \geq 2k^2\delta\gamma.} \quad (\text{HT18})$$

For an eigenvalue with $x \neq 0$ and $y = 0$, (HT17) also gives the positive lower bound $x^2 + \min_n u_n^2$, even though its imaginary part is zero.

Proof. The Fourier basis $L^{-1/2}e^{-iu_nr}$ diagonalizes the quasi-periodic Laplacian with eigenvalues $-u_n^2 - c^2$, each acting identically on $\mathcal{K}$. The source vectors lie in its domain by the original weighted differentiability estimates. Writing Rv in that basis and using Parseval gives

$$\|(\mathcal{L}_{L,\theta} - (\lambda^2 - k\lambda))Rv\|^2 = \sum_n ((u_n^2 + x^2 - y^2)^2 + 4x^2y^2) \|\widehat{Rv}(n)\|_{\mathcal{K}}^2.$$

The lattice is discrete and the expression tends to infinity as $|n| \rightarrow \infty$, so its infimum is a minimum. Also R is injective because $R^*R = G \succ 0$. Divide the displayed identity by $\|Rv\|^2$; (HT16) proves (HT17). The extreme primary factor in (HT2) is nonzero and has an eigenvector, so substituting $x = k\delta$, $y = k\gamma$ proves (HT18). If $y = 0$, the square root in (HT17) is $u_n^2 + x^2$. $\square$

162.5 What these computations decide

The original off-line counterfactual survives passage to every finite holonomy quotient only with the explicit boundary energy (HT14) and Laplacian residual (HT17). These quantities belong to the original arithmetic source. The statement is compatible with the exact all-phase identity $\int M_{N,\theta} d\theta/(2\pi) = M_N$ and with the original small gluing-norm estimate. That estimate concerns $C_N - C_{N,\theta}$; (HT13) applies S and subtracts right multiplication by A , preserving a different, explicitly displayed source quantity. There is no claim here that averaging the $G_{N,\theta}$ preserves the rank-two identity (HT11): the lower bound (HT15) integrates the proved phasewise energies themselves.

The transcript's threshold-four volume lower bound was already present before its final Deligne comparison. Its last counterexamples retain many generic identities but do not satisfy the actual divisor condition $h \mid 2\xi$. Consequently they disprove the reduced generic inference stated there; they do not disprove the entire arithmetic programme or provide an RH counterexample. Equations (HT9), (HT14), and (HT17) give further quantified consequences within the original programme without replacing its theta metric or its represented relations.

163 Actual bounds for the retained four-window costs

Continue with (HT1)–(HT18), now with $k \geq 3$. All unadorned source norms and quotient volumes in this section are those of the original $m_{h,k}(u) du$, with $g = 2\xi$ and the complete hypothetical quartet. Write $\mathcal{L} = \mathcal{L}_{h,k}$ and retain $q = \ell_k(k+1)^2$. The threshold-four lower bound is inherited from *Consecutive identities and the first window*, (CJ.9)–(CJ.19); it is already explicitly present in the recovered transcript at lines 4202–4228. It is not a new claim of the present continuation.

163.1 Every term of the inherited lower bound

Put $d_j = V_j/V_{j-1}$ for $j \geq q$. For the two original windows $I_- = (q-1, 2q-1)$ and $I_+ = (q, 2q)$, retain the contraction penalties

$$\begin{aligned} P_- &= -\log(1 - d_{2q-1}) - 2 \sum_{j=q}^{2q-2} \log(1 - d_j), \\ P_+ &= -\log(1 - d_q) - \log(1 - d_{2q}) - 2 \sum_{j=q+1}^{2q-1} \log(1 - d_j). \end{aligned} \tag{HC1}$$

The source identities prove $0 < d_j < 1$ in these ranges. The real phase ϕ_N is defined by the retained source pairing $b_N^* G_N b_{N+1} = i\omega_N \phi_N$. The first window uses its original boundary identity; no inverse at degree $q-2$ occurs. Define weights

$$w_{q-1} = w_{2q-1} = 1, \quad w_N = 2 \quad (q \leq N \leq 2q-2), \quad \sum_{N=q-1}^{2q-1} w_N = 2q.$$

Adding the two exact source products gives

$$\mathcal{B}_k := \log \frac{V_{q-1} V_q}{V_{2q-1} V_{2q}} = \sum_{N=q-1}^{2q-1} w_N \log(\varepsilon_N^2 + \phi_N^2) - \log \frac{\omega_{2q-1} \omega_{2q}}{\omega_{q-1} \omega_q} + P_- + P_+. \quad (\text{HC2})$$

Here every $\varepsilon_N \geq \mathcal{L}$, including the first degree.

For clarity, retain all constants in the inherited comparable-window bound. With $\alpha = \pi/2$, $B = 42 + 8m$, and $\vartheta_h = \int_{-1}^1 w_h$, put

$$\begin{aligned} t_h &= \min(1, \vartheta_h), \quad c_0 = \min(1, 2c_h/3), \quad \ell_h = \frac{1}{2} e^{-\alpha} \sqrt{c_0 t_h} 2^{-B/2}, \\ X &= \max(1, M_h(b), M_h(-b)), \quad U_h = 4\sqrt{X}/b, \\ C_h^{\text{win}} &= 27 \max(1, U_h)^3 \max(1, \ell_h^{-1})^2, \quad D_h = \frac{\delta}{2C_h^{\text{win}}}. \end{aligned} \quad (\text{HC3})$$

Here $0 < b < \pi/2$, and $c_h > 0$ is the original proved convolution constant. The source proves $(\omega_{n+r}/\omega_n)^{1/(2r)} \leq C_h^{\text{win}} n$ for $n \geq k \geq 3$, $n/2 \leq r \leq 2n$. Thus it applies to both literal windows, and $0 < D_h < 1/108$.

The exact residual in (HC2) has the following five nonnegative pieces:

$$\begin{aligned} \mathcal{R}_k &= P_- + P_+ + \sum_N w_N \log(1 + \phi_N^2/\mathcal{L}^2) \\ &\quad + \sum_N w_N \log \frac{\varepsilon_N^2 + \phi_N^2}{\mathcal{L}^2 + \phi_N^2} \\ &\quad + 4q \log(C_h^{\text{win}} q) - \log \frac{\omega_{2q-1} \omega_{2q}}{\omega_{q-1} \omega_q} + 4q \log \frac{2\mathcal{L}}{\delta k q}. \end{aligned} \quad (\text{HC4})$$

Both sums use exactly $q-1 \leq N \leq 2q-1$. Nonnegativity follows, respectively, from $0 < d_j < 1$, the squared phases, (HT9), the two comparable-window estimates, and $\mathcal{L}/q \geq \delta k/2$. Expanding each logarithm in (HC4), with $D_h = \delta/(2C_h^{\text{win}})$, proves the exact identity

$$\boxed{\mathcal{B}_k = 4q \log(D_h k) + \mathcal{R}_k, \quad \mathcal{R}_k \geq 0.} \quad (\text{HC5})$$

This retains, rather than discards, all the contraction, phase, norm, and trace savings in the original lower bound.

163.2 A proved upper bound for these same four original volumes

The original convolution estimate and Laplace moments are

$$m_{h,k}(u) \geq c_h \vartheta_h^{k-3} e^{-\alpha(|u|+k-3)} (1 + |u| + k - 3)^{-B}, \quad M_h(\pm b) = \int_{\mathbb{R}} e^{\pm bu} w_h(u) du.$$

Write $\mu_h = \int_{\mathbb{R}} w_h(u) du$ for the original source mass. Put

$$\begin{aligned} R_0 &= \sqrt{\delta^2 + \gamma^2}, \quad D = \max(1, 2/b, 2R_0), \quad T = Dq, \quad r = kR_0/T \leq 1/2, \\ a_k(T) &= c_h \vartheta_h^{k-3} e^{-\alpha(T+k-3)} (1 + T + k - 3)^{-B}, \\ M_k &= M_h(b)^k + M_h(-b)^k, \quad U_k(T) = \mu_h^k + \frac{(2q-2)!}{(bT)^{2q-2}} M_k, \\ A_N &= \sqrt{\frac{2N+1}{2}} \frac{4^{N+1} - 1}{3}, \quad B_q(r) = \left(\frac{1+r}{1-r} \right)^q, \quad C_N = \frac{U_k(T) A_N^2 B_q(r)^2}{T a_k(T)}. \end{aligned} \quad (\text{HC6})$$

The capital D in the interval scale is distinct from the inherited lower constant D_h and from the source differential. All masses, coordinates, and root multiplicities remain as in (HT1)–(HT7). One has the actual finite Hermitian comparisons

$$G_{q-1} \preceq C_{2q-1} G_{2q-1}, \quad G_q \preceq G_{q-1} \preceq C_{2q} G_{2q}.$$

Consequently, with the exact ratio

$$\rho_q = \frac{4q+1}{4q-1} \left(\frac{4^{2q+1}-1}{4^{2q}-1} \right)^2,$$

$$\boxed{0 \leq \mathcal{B}_k \leq q \log C_{2q-1} + q \log C_{2q} = 2q \log C_{2q-1} + q \log \rho_q.} \quad (\text{HC7})$$

Proof of the degree extension and its maps. Use the exact substitution $f(x) = P(c + iTx)$ with inverse $P(S) = f((S-c)/(iT))$. Its source measure is $Tm_{h,k}(Tx) dx$, with mass μ_h^k , and its monic relation is $\chi_T(x) = (iT)^{-q} \chi(c + iTx)$. The roots $z_1, \dots, z_q$, listed with their repetitions, have modulus at most r . The raw jet of order d acquires exactly $(iT)^d$; the quotient determinant acquires $T^{-q(q-1)}$. This common factor cancels in each displayed quotient-volume ratio.

The Legendre expansion on $[-1, 1]$ gives $\|f\|_{\text{coeff},1} \leq A_N \|f\|_{L^2([-1,1])}$ for $\deg f \leq N$. Indeed Rodrigues' polynomial has coefficient norm at most $\binom{2j}{j} \leq 4^j$ and squared integral $2/(2j+1)$. Pairing the expansion with this polynomial bounds its coefficient by $\sqrt{(2j+1)/2} \|f\|_2$; summing the geometric series gives exactly A_N in (HC6).

Write $\prod_a (1 - z_a t)^{-1} = \sum_{j \geq 0} h_j t^j$. Geometric-series multiplication gives $|h_j| \leq \binom{q+j-1}{j} r^j$ and $\|\chi_T\|_{\text{coeff},1} \leq (1+r)^q$. For every integer $s \geq 0$, monic division of x^{q+s} has quotient $\sum_{j=0}^s h_j x^{s-j}$. The inverse-series identity cancels all other terms of degree at least q . Removing the leading coefficient one therefore gives

$$\|\text{rem}_{\chi_T} x^{q+s}\|_{\text{coeff},1} \leq (1+r)^q \sum_{j=0}^s \binom{q+j-1}{j} r^j - 1 \leq B_q(r).$$

The bound is valid also for $s = q$, the extra degree required here. At degrees below q the remainder is the original monomial, whose coefficient norm is one. Linearity gives the same remainder-map bound for every degree at most $2q$.

For a remainder v of degree below q ,

$$\int |v(u/T)|^2 m_{h,k}(u) du \leq U_k(T) \|v\|_{\text{coeff},1}^2.$$

This follows by bounding each monomial by $\max(1, |u/T|^{q-1})$ and using $\int u^{2q-2} m_{h,k} \leq (2q-2)! b^{-(2q-2)} M_k$. Restriction of the original norm to $[-T, T]$ gives the lower bound $T a_k(T) \|f\|_{L^2([-1,1])}^2$. Combining these three estimates proves

$$\|\text{rem}_\chi P\|_{H_{q-1}}^2 \leq C_N \|P\|_{H_N}^2 \quad (N = 2q-1, 2q).$$

The map is the literal remainder representative of the original jet. Apply it to the canonical least lift of $x \in E$ at degree N . Its norm at degree $q-1$ is at least $x^* G_{q-1} x$; this proves the Hermitian comparisons preceding (HC7). Inclusion of polynomial degrees gives $G_q \preceq G_{q-1}$ and monotonicity of all volumes. Taking determinants proves (HC7). Applying the same remainder inequality to any nonzero polynomial below degree q proves $C_N \geq 1$ without an additional assumption. $\square$

For an entirely scalar upper bound retain the original constants

$$K = \max(1, \vartheta_h^{-1}), \quad C_{\text{env}} = \max(1, 2/(3c_h D)), \quad a = \alpha D + \log 256,$$

and the original expression (AU.31)

$$\mathcal{U}_k = aq^2 + \left(\log(XK) + \alpha + \frac{16R_0}{3D} \right) kq + Bq \log(1 + (D+1)q) + q \log C_{\text{env}}.$$

Then the proved four-window upper bound is

$$\boxed{\mathcal{B}_k \leq \widehat{\mathcal{U}}_k := 2\mathcal{U}_k + q \log 20.} \quad (\text{HC8})$$

To verify the constants, $bT \geq 2q$ implies the factorial ratio in (HC6) is at most one; also $\mu_h \leq X$ and $M_k \leq 2X^k$, so $U_k(T) \leq 3X^k$. Directly from (HC6),

$$A_{2q-1}^2 \leq (2q/9)256^q, \quad A_{2q}^2 \leq (40q/9)256^q.$$

The logarithmic derivative $2/(1-r^2) \leq 8/3$ on $[0, 1/2]$ gives $\log B_q(r)^2 \leq 16kR_0/(3D)$. Substitution into C_N yields $q \log C_{2q-1} \leq \mathcal{U}_k$ and $q \log C_{2q} \leq \mathcal{U}_k + q \log 20$. Adding proves (HC8). This argument does not use the false inequality $\rho_2 < 20$; in the actual quartet domain $q \geq 16$ anyway.

163.3 The exact compatible interval for the signed arithmetic correction

Let V_N^Γ denote the inherited Gamma-reference quotient volume for the *same* original polynomial χ , and define

$$T_N = V_N/V_N^\Gamma, \quad \mathcal{B}_k^\Gamma = \log \frac{V_{q-1}^\Gamma V_q^\Gamma}{V_{2q-1}^\Gamma V_{2q}^\Gamma}, \quad \Delta_k^\Gamma = \log \frac{T_{q-1} T_q}{T_{2q-1} T_{2q}}.$$

Cancellation of the four literal volume factors gives $\mathcal{B}_k = \mathcal{B}_k^\Gamma + \Delta_k^\Gamma$. No auxiliary polynomial is introduced and no sign is imposed on Δ_k^Γ . From (HC5) and (HC8) the actual retained residuals must belong to the following explicit intervals. Let $\mathfrak{C}_*$ be (AT18a) on the same arithmetic and tensor Gamma moment matrices. Its proof uses the original full packet and applies to exactly these four determinants, so $|\Delta_k^\Gamma| \leq J_* \leq \mathfrak{C}_*$. Write $T_k = 4q \log(D_h k)$ for this displayed scalar only:

$$\boxed{\max\{0, -T_k, \mathfrak{b}_*^- - T_k\} \leq \mathcal{R}_k \leq \min\{\widehat{\mathcal{U}}_k, \mathfrak{b}_*^+\} - T_k,} \quad (\text{HC9})$$

$$\boxed{\max\{\mathfrak{d}_*^-, \max\{0, 4q \log(D_h k)\} - \mathcal{B}_k^\Gamma\} \leq \Delta_k^\Gamma \leq \min\{\mathfrak{d}_*^+, \widehat{\mathcal{U}}_k - \mathcal{B}_k^\Gamma\}.} \quad (\text{HC10})$$

The new entries follow by substituting $\mathcal{B}_k = \mathcal{B}_k^\Gamma + \Delta_k^\Gamma$ and $\mathcal{R}_k = \mathcal{B}_k - T_k$ into (AT18)–(AT19). Here $\mathfrak{b}_*^\pm, \mathfrak{d}_*^\pm$ are the simultaneous original Gamma endpoints (AT21e); its complete actual moment proof supplies both the additive and nonlinear coordinate. Their intersection width has not been evaluated for an actual offcritical packet. Removing the simultaneous (AT21e) endpoint entries $\mathfrak{b}_*^\pm$ and $\mathfrak{d}_*^\pm$ gives the preceding coarse intervals, whose width is strictly positive for every $k \geq 3$. Indeed all nonquadratic terms of $\mathcal{U}_k$ are nonnegative, $a > 1$, $q \geq (k+1)^2 > 2k$, and $D_h < 1$. Thus

$$\widehat{\mathcal{U}}_k \geq 2aq^2 > 4qk \geq \max\{0, 4q \log(D_h k)\}.$$

Moreover, keeping the fixed packet constants, each lower-order term divided by q^2 tends to zero, so

$$\lim_{k \rightarrow \infty} \frac{\widehat{\mathcal{U}}_k - \max\{0, 4q \log(D_h k)\}}{q^2} = 2(\alpha D + \log 256) > 0. \quad (\text{HC11})$$

This proves numerical compatibility of those coarse bound functions. It does not prove compatibility of the refined (HC9)–(HC10), which retain the source-dependent (AT21e) endpoints computed from J_* and I_* . It does not construct a packet realizing an arbitrarily chosen point of either interval, and it does not assert the existence of the hypothetical zero. In particular the interval may lie entirely at negative values of Δ_k^Γ ; determinant-ratio positivity does not imply positivity of its signed four-window logarithm.

The constructed signed refinement on this identical source. The exact coordinate map to (ACM1)–(ACM5) is $y = u$, $x = t$, with $S = k/2 + iu$ and every ascending coefficient unchanged. The reference density (ACM2) is exactly the tensor Gamma density of (AT4), including its mass $(\sqrt{2\pi})^k$; the arithmetic density is the original $m_{h,k} = w_h^{*k}$. The relation map in the common source is $I_N B_N^{\text{AW}}$ in both presentations. Consequently the source Grams, their quotient minima, and all four signed determinants agree. In particular $F(0) = \mathcal{B}_k^\Gamma$ and $F(1) = \mathcal{B}_k$ for the F of (ACM14)–(ACM16).

Here is the exact dictionary for all pointwise controls:

$$(S_{\text{AW}}, T_q, S_{\text{SP}}, S_q, A_q) = (S_{\text{spec}}, S_{\text{tr}}, S_{\text{ov}}, S_{\text{HS}}, S_{\text{ang}}), \quad \mathcal{H}_{2q-1} = H_{2q-1}.$$

The original crossed-pair proof (AT21b) gives $S_{\text{tr}} \leq S_{\text{sin}} \leq S_{\text{ang}}$, and the original overlap proof gives $S_{\text{tr}} \leq S_{\text{ov}}$. Therefore the full pointwise minima in (ACM11a) and (AT21a)–(AT21c) are identical, as are those minima divided by $(2q-1)\sqrt{1-e^{-F(x)/(2q-1)}}$. Thus $J_q = J_*$ and $I_q = I_*$ on this actual path. These equalities retain both complete angle lists, including their designated and additional zero entries. They compare the calculated expressions without removing any source vector or changing either endpoint form.

For every finite-series degree $p \geq 0$, let $j_{p,\Gamma}$, $e_{p,\Gamma}$ be the exact signed center and residual constructed in (ACM15) on this Gamma-to-arithmetic path. Their actual finite geometric identity and centered Hilbert–Schmidt proof give $j_{p,\Gamma} - e_{p,\Gamma} \leq \Delta_k^\Gamma \leq j_{p,\Gamma} + e_{p,\Gamma}$. The explicit residual in (ACM15) tends to zero for this fixed source pair, with every eigenvalue and the factor $8q-6$ retained. Substituting the preceding dictionary into (ACM16) gives exactly

$$\begin{aligned} \beta_{p,\Gamma}^- &= \max\{\mathfrak{b}_*^-, \mathcal{B}_k^\Gamma + j_{p,\Gamma} - e_{p,\Gamma}\}, \\ \beta_{p,\Gamma}^+ &= \min\{\mathfrak{b}_*^+, \mathcal{B}_k^\Gamma + j_{p,\Gamma} + e_{p,\Gamma}\}, \\ \mathfrak{b}_*^- &\leq \beta_{p,\Gamma}^- \leq \mathcal{B}_k \leq \beta_{p,\Gamma}^+ \leq \mathfrak{b}_*^+. \end{aligned} \tag{HC9a}$$

Every lower entry is at most the same actual $\mathcal{B}_k$ and every upper entry is at least it, proving the displayed intersection and its order. Their signed entries also prove $0 \leq \beta_{p,\Gamma}^+ - \beta_{p,\Gamma}^- \leq 2e_{p,\Gamma}$. Indeed the upper endpoint is at most $\mathcal{B}_k^\Gamma + j_{p,\Gamma} + e_{p,\Gamma}$ and the lower endpoint is at least $\mathcal{B}_k^\Gamma + j_{p,\Gamma} - e_{p,\Gamma}$. Thus both endpoints converge to the actual $\mathcal{B}_k$ on this fixed source as $p \rightarrow \infty$; no nesting in p is required. Inserting (HC5) and subtracting the same original Gamma value yields the stronger intervals

$$\begin{aligned} \max\{0, -T_k, \beta_{p,\Gamma}^- - T_k\} &\leq \mathcal{R}_k \leq \min\{\widehat{\mathcal{U}}_k, \beta_{p,\Gamma}^+\} - T_k, \\ \max\{0, T_k, \beta_{p,\Gamma}^- - T_k\} - \mathcal{B}_k^\Gamma &\leq \Delta_k^\Gamma \\ &\leq \min\{\widehat{\mathcal{U}}_k, \beta_{p,\Gamma}^+\} - \mathcal{B}_k^\Gamma. \end{aligned} \tag{HC10a}$$

The first line uses $\mathcal{R}_k = \mathcal{B}_k - T_k \geq 0$, and the last two use $\Delta_k^\Gamma = \mathcal{B}_k - \mathcal{B}_k^\Gamma$. The nesting in (HC9a), together with $\mathfrak{d}_*^\pm = \mathfrak{b}_*^\pm - \mathcal{B}_k^\Gamma$, proves that these intervals lie inside (HC9)–(HC10). Those original bounds and their full proofs are consequently retained corollaries. Removing all source-dependent endpoint entries gives the original coarse intervals in (HC11); its positive width is not an evaluation of the refined width. All signed centers here are the specified exact integrals. Any numerical evaluation must retain its integration error; fixed-source convergence in p supplies no uniform estimate in k .

The graph calculation carried back into these arithmetic intervals. On the additional full-quartet domain $\gamma > 2$ of (ACM17)–(ACM27), retain $k \geq 3$ as in this section. The coefficients, polynomial χ , original $v_h = 2\xi/h$ and quotient maps are identified there literally with (HT1)–(HT3). The graph computation therefore controls these same arithmetic quantities by $\mathcal{B}_k = \widehat{\mathcal{B}}_k - \Gamma_k^{\text{gr}}$. For any specified integers $p, s \geq 0$, define

$$\begin{aligned} b_{p,s}^{\text{gr},-} &= \max\{\beta_{p,\Gamma}^-, \widehat{\mathcal{B}}_k - g_{s,\text{gr}}^+\}, \\ b_{p,s}^{\text{gr},+} &= \min\{\beta_{p,\Gamma}^+, \widehat{\mathcal{B}}_k - g_{s,\text{gr}}^-\}. \end{aligned} \tag{HC9g}$$

The $\beta_{p,\Gamma}^\pm$ retain the original Gamma-to-arithmetic path; $g_{s,\text{gr}}^\pm$ are the separately computed arithmetic-to-graph endpoints (ACM27). Subtracting the two bounds on Γ_k^{gr} from this same $\hat{\mathcal{B}}_k$ gives

$$\beta_{p,\Gamma}^- \leq b_{p,s}^{\text{gr},-} \leq \mathcal{B}_k \leq b_{p,s}^{\text{gr},+} \leq \beta_{p,\Gamma}^+.$$

Inserting this exact intersection at the use sites (HC9)–(HC10) and keeping their original $T_k = 4q \log(D_h k)$ proves

$$\begin{aligned} \max\{0, -T_k, b_{p,s}^{\text{gr},-} - T_k\} &\leq \mathcal{R}_k \leq \min\{\hat{\mathcal{U}}_k, b_{p,s}^{\text{gr},+}\} - T_k, \\ \max\{0, T_k, b_{p,s}^{\text{gr},-}\} - \mathcal{B}_k^\Gamma &\leq \Delta_k^\Gamma \\ &\leq \min\{\hat{\mathcal{U}}_k, b_{p,s}^{\text{gr},+}\} - \mathcal{B}_k^\Gamma. \end{aligned} \tag{HC10g}$$

Indeed $\mathcal{R}_k = \mathcal{B}_k - T_k \geq 0$ by (HC5), $\mathcal{B}_k \geq 0$ by (HC7), and $\Delta_k^\Gamma = \mathcal{B}_k - \mathcal{B}_k^\Gamma$ by its definition. Subtracting these unchanged constants gives every entry and proves nesting into the preceding intervals. The additional interval width obeys

$$0 \leq b_{p,s}^{\text{gr},+} - b_{p,s}^{\text{gr},-} \leq \min\{2e_{p,\Gamma}, 2e_{s,\text{gr}}\}. \tag{HC10h}$$

For the first bound, (ACM16) places the two Gamma endpoints inside the interval centered at $\mathcal{B}_k^\Gamma + j_{p,\Gamma}$ with radius $e_{p,\Gamma}$. For the second, (ACM27) places the graph-corrected endpoints inside the interval centered at $\hat{\mathcal{B}}_k - j_{s,\text{gr}}$ with radius $e_{s,\text{gr}}$. Taking an intersection cannot increase either width. These are actual finite-source enclosures. Their fixed-source residual limits do not estimate the separate limit in the growing tensor order. All bounds preceding this paragraph retain their original domain $\gamma > 0$; (HC9g)–(HC10h) assert the additional calculated refinement on the explicitly stated graph-source domain.

The original relation-row enclosure at these same use sites. Retain every equation (HC9g)–(HC10h), and keep its domain $k \geq 3$, $\gamma > 2$, $0 < \delta < 1/2$, $m \geq 1$. Equations (ACM28)–(ACM31) compute the additional lower and upper values $L_k^{\text{rel}}, U_{k,2q}^{\text{rel}}$ from the full monic relation rows and the original finite arithmetic graph Grams. Here d_j^{rel} is a relation polynomial as defined there; the original $d_j = V_j/V_{j-1}$ of (HC1) remains its stated scalar. Likewise the form $T_N^{\text{rel}} := f_N^* f_N$ below retains its superscript and does not rename either $T_N = V_N/V_N^\Gamma$ or the scalar $T_k = 4q \log(D_h k)$. With $g_s^\pm = g_{s,\text{gr}}^\pm$ exactly as in (ACM27), put

$$\begin{aligned} b_{p,s}^{\text{rel},-} &= \max\{\beta_{p,\Gamma}^-, L_k^{\text{rel}} - g_{s,\text{gr}}^+\}, \\ b_{p,s}^{\text{rel},+} &= \min\{\beta_{p,\Gamma}^+, U_{k,2q}^{\text{rel}} - g_{s,\text{gr}}^-\}, \\ \beta_{p,\Gamma}^- &\leq b_{p,s}^{\text{rel},-} \leq b_{p,s}^{\text{gr},-} \leq \mathcal{B}_k \leq b_{p,s}^{\text{gr},+} \leq b_{p,s}^{\text{rel},+} \leq \beta_{p,\Gamma}^+. \end{aligned} \tag{HC9r}$$

The coefficient identity (ACM17)–(ACM20) identifies the graph and arithmetic remainder frames by the literal identity, including the full primary nilpotents. Consequently (ACM31) bounds the same $\mathcal{B}_k$ as (HC9a). Taking their interval intersection proves the displayed relation enclosure. For its comparison with (HC9g), $L_k^{\text{rel}} \leq \hat{\mathcal{B}}_k$ gives $\max\{\beta^-, L_k^{\text{rel}} - g^+\} \leq \max\{\beta^-, \hat{\mathcal{B}}_k - g^+\}$, and $\hat{\mathcal{B}}_k \leq U_{k,2q}^{\text{rel}}$ gives the corresponding order for the two upper minima. These two elementary monotonicities prove every remaining order in (HC9r). The exact graph-volume interval is contained in the relation-row interval; its intersection with the latter is itself. Thus (HC9g) retains its full exact input, while (HC9r) gives the separately calculated finite row enclosure for that input.

At the two receiving residuals define

$$\begin{aligned} L_{k;p,s}^{\text{ar,rel}} &= \max\{0, T_k, b_{p,s}^{\text{rel},-}\}, \\ U_{k;p,s}^{\text{ar,rel}} &= \min\{\hat{\mathcal{U}}_k, b_{p,s}^{\text{rel},+}\}, \\ L_{k;p,s}^{\text{ar,rel}} - T_k &\leq \mathcal{R}_k \leq U_{k;p,s}^{\text{ar,rel}} - T_k, \\ L_{k;p,s}^{\text{ar,rel}} - \mathcal{B}_k^\Gamma &\leq \Delta_k^\Gamma \leq U_{k;p,s}^{\text{ar,rel}} - \mathcal{B}_k^\Gamma. \end{aligned} \tag{HC10r}$$

To prove this complete substitution, (HC5) gives $\mathcal{B}_k \geq T_k$ and $\mathcal{R}_k = \mathcal{B}_k - T_k \geq 0$, (HC7)–(HC8) give $0 \leq \mathcal{B}_k \leq \hat{\mathcal{U}}_k$, and (HC9r) gives its third lower and second upper entries. Their intersection contains this same scalar. The two maps are the translations $x \mapsto x - T_k$ and $x \mapsto x - \mathcal{B}_k^\Gamma$, with inverse maps adding the displayed unchanged constant. They are order-preserving bijections of the real line, so they preserve interval widths and give the two complete receiving intervals. The first lower endpoint is exactly $\max\{0, -T_k, b_{p,s}^{\text{rel},-} - T_k\}$. No sign is assigned to $g_{s,\text{gr}}^-$, to T_k , or to Δ_k^Γ before these explicit operations. Monotonicity of the maximum and minimum also proves that (HC10g) is contained in (HC10r), which is contained in (HC10a).

The relation-row width has the precise bound

$$\begin{aligned} 0 \leq b_{p,s}^{\text{rel},+} - b_{p,s}^{\text{rel},-} &\leq \min\{2e_{p,\Gamma}, U_{k,2q}^{\text{rel}} - L_k^{\text{rel}} + g_{s,\text{gr}}^+ - g_{s,\text{gr}}^-\} \\ &\leq \min\{2e_{p,\Gamma}, U_{k,2q}^{\text{rel}} - L_k^{\text{rel}} + 2e_{s,\text{gr}}\}. \end{aligned} \quad (\text{HC10s})$$

The first lower sign follows because the interval contains $\mathcal{B}_k$. Its Gamma width is at most $2e_{p,\Gamma}$ by (HC9a). Its other interval has lower endpoint $L_k^{\text{rel}} - g^+$ and upper endpoint $U_{k,2q}^{\text{rel}} - g^-$, so direct subtraction gives the second entry. Equation (ACM27) bounds $g^+ - g^-$ by $2e_{s,\text{gr}}$. Taking an intersection cannot increase either of these two widths, which proves the stated order. The complete negative mixed squared norm in (ACM30) reduces the row upper comparison relative to its K_{low}^{-1} term. It does not alter the exact-graph nesting just proved. All fixed-source limits in p and s retain their stated fixed h, k domain.

The full correlation calculation in the retained signed intervals. Keep the exact row subsets $J(j)$ of (ACM35), on the same receiving domain as (HC9r). Their calculated bounds now give

$$\begin{aligned} b_{p,s}^{\text{corr},-} &= \max\{\beta_{p,\Gamma}^-, L_k^{\text{corr}}(J) - g_{s,\text{gr}}^+\}, \\ b_{p,s}^{\text{corr},+} &= \min\{\beta_{p,\Gamma}^+, U_k^{\text{corr}}(J) - g_{s,\text{gr}}^-\}, \\ b_{p,s}^{\text{rel},-} &\leq b_{p,s}^{\text{corr},-} \leq b_{p,s}^{\text{gr},-} \leq \mathcal{B}_k \leq b_{p,s}^{\text{gr},+} \leq b_{p,s}^{\text{corr},+} \leq b_{p,s}^{\text{rel},+}. \end{aligned} \quad (\text{HC9rc})$$

The exact identity $\mathcal{B}_k = \hat{\mathcal{B}}_k - \Gamma_k^{\text{gr}}$ and the proved bounds (ACM27), (ACM35) show that the interval contains $\mathcal{B}_k$. Comparing the arguments of the lower maximum and upper minimum, using each inequality in (ACM35), proves the complete order in the last line. All later rows included gives $L_k^{\text{corr}} = U_k^{\text{corr}} = \hat{\mathcal{B}}_k$, so both endpoints become exactly (HC9g). For any specified subsets their complete width obeys

$$\begin{aligned} 0 \leq b_{p,s}^{\text{corr},+} - b_{p,s}^{\text{corr},-} &\leq \min\{2e_{p,\Gamma}, U_k^{\text{corr}}(J) - L_k^{\text{corr}}(J) + g_{s,\text{gr}}^+ - g_{s,\text{gr}}^-\} \\ &\leq \min\{2e_{p,\Gamma}, U_k^{\text{corr}}(J) - L_k^{\text{corr}}(J) + 2e_{s,\text{gr}}\}. \end{aligned} \quad (\text{HC10rcw})$$

The Gamma interval lies in its radius- $e_{p,\Gamma}$ signed interval, and the graph correction lies in its radius- $e_{s,\text{gr}}$ signed interval by their actual finite remainder proofs. Taking an intersection cannot increase either width. Subtracting the displayed graph lower endpoint from its upper endpoint gives the middle expression, proving every term of this bound.

The complete residual substitution at (HC9)–(HC10) is

$$\begin{aligned} L_{k;p,s}^{\text{ar},\text{corr}} &= \max\{0, T_k, b_{p,s}^{\text{corr},-}\}, \\ U_{k;p,s}^{\text{ar},\text{corr}} &= \min\{\hat{\mathcal{U}}_k, b_{p,s}^{\text{corr},+}\}, \\ L_{k;p,s}^{\text{ar},\text{corr}} - T_k &\leq \mathcal{R}_k \leq U_{k;p,s}^{\text{ar},\text{corr}} - T_k, \\ L_{k;p,s}^{\text{ar},\text{corr}} - \mathcal{B}_k^\Gamma &\leq \Delta_k^\Gamma \leq U_{k;p,s}^{\text{ar},\text{corr}} - \mathcal{B}_k^\Gamma. \end{aligned} \quad (\text{HC10rc})$$

Indeed intersect (HC9rc) with the original inequalities $\mathcal{B}_k \geq 0$, $\mathcal{B}_k \geq T_k$ and $\mathcal{B}_k \leq \hat{\mathcal{U}}_k$ proved in (HC5), (HC7), (HC8). The order-preserving translations already proved in (HC10r) give the two displayed receiving intervals with their exact inverse additions. Their widths do not exceed (HC10rcw).

The inclusion of intervals is now exact-graph inside correlation inside relation-row inside Gamma; monotonicity of the maximum, minimum and the two translations proves the same inclusion at both residuals. All original lower-bound pieces and all negative signed corrections remain present.

163.4 The holonomy energy is tied to the same endpoint contractions

Fix an actual holonomy θ and period L . In this paragraph all metrics, lifts and volumes carry that same phase. Put

$$e_N = \log(V_N/V_{N+1}), \quad \beta_N = \lambda_{\max}(G_{N+1}^{-1/2}G_N G_{N+1}^{-1/2}),$$

$$J_N^D = \|D_{L,\theta}R_N G_N^{-1/2}\|_{\text{HS}}^2, \quad \mathcal{E}_N = \|\mathcal{B}_N G_N^{-1/2}\|_{\text{HS}}^2.$$

These use original source moments through degree $2N + 2$. They obey

$$\frac{\mathcal{L}^2}{2} \leq \mathcal{E}_N \leq (1 + \sqrt{\beta_N})^2 J_N^D, \quad e_N \geq 2 \log \max \left\{ 1, \frac{\mathcal{L}}{\sqrt{2J_N^D}} - 1 \right\}. \quad (\text{HC12})$$

The denominator is positive: integration by parts on the stated twisted domain gives $\|D_{L,\theta}f\|^2 = c^2\|f\|^2 + \|\partial_r f\|^2$, whence $J_N^D \geq c^2 q > 0$.

To prove the upper inequality, $D_{L,\theta}R_N v$ is an original degree- $(N + 1)$ representative of Av . The same quotient minimum therefore gives

$$A^*G_{N+1}A \preceq R_N^*D_{L,\theta}^*D_{L,\theta}R_N.$$

Use $G_N \preceq \beta_N G_{N+1}$, sandwich by $G_N^{-1/2}$, and take traces. This gives $\|R_N A G_N^{-1/2}\|_{\text{HS}}^2 \leq \beta_N J_N^D$. The triangle inequality in $\mathcal{B}_N = D_{L,\theta}R_N - R_N A$ proves the upper inequality in (HC12); (HT14) proves the lower. All eigenvalues in the definition of β_N are at least one by degree monotonicity. In fact the original rank-one kernel update proves the exact identity

$$e_N = \log \beta_N, \quad \beta_N = 1 + \frac{b_{N+1}^* G_N b_{N+1}}{\omega_{N+1}}. \quad (\text{HC12a})$$

Here b_{N+1} and ω_{N+1} are the remainder column and monic squared norm for this same original phase measure. Indeed $K_{N+1} = K_N + b_{N+1}b_{N+1}^*/\omega_{N+1}$, so

$$K_N^{-1/2}K_{N+1}K_N^{-1/2} = I + vv^*, \quad v = K_N^{-1/2}b_{N+1}/\sqrt{\omega_{N+1}}.$$

The relative matrix defining β_N is $K_{N+1}^{1/2}K_N^{-1}K_{N+1}^{1/2} = X^*X$ for the invertible $X = K_N^{-1/2}K_{N+1}^{1/2}$. The displayed matrix $I + vv^*$ is XX^* , and $X(X^*X)X^{-1} = XX^*$ proves they have identical eigenvalues. These are 1 with multiplicity at least $q - 1$ and $1 + \|v\|^2$. Taking the determinant gives $V_N/V_{N+1} = \det K_{N+1}/\det K_N = 1 + \|v\|^2 = \beta_N$, which proves (HC12a), including a zero update if one occurs. Rearranging the two energy bounds now proves the second inequality of (HC12) with this exact endpoint identity.

The same weights as in (HC2) reconstruct the actual phase volume:

$$\mathcal{B}_{k,\theta} = \sum_{N=q-1}^{2q-1} w_N e_N \geq 2 \sum_{N=q-1}^{2q-1} w_N \log \max \left\{ 1, \frac{\mathcal{L}}{\sqrt{2J_N^D}} - 1 \right\}. \quad (\text{HC13})$$

Thus a small original derivative-source energy at a degree has the explicit endpoint contraction cost (HC12); that cost enters the same four-window budget, with its actual multiplicity.

Finally the supplied holonomy construction allows any fixed $0 < \eta < 1$ by choosing the original period from its computed weighted source comparison at degree $2q + 2$. It proves simultaneously

$(1 - \eta)G_N \preceq G_{N,\theta} \preceq (1 + \eta)G_N$ at all these degrees. For completeness, apply the comparison before quotient minimization on the common coefficient space $H = \mathcal{P}_{2q}$. The supplied weighted source estimate, written explicitly in (PSC.33), is $(1 - \eta)M_{2q} \preceq M_{2q,\theta} \preceq (1 + \eta)M_{2q}$. Set $H_\theta(t) = (1 - t)M_{2q} + tM_{2q,\theta}$, $C^\theta = H_\theta(t)^{-1}(M_{2q,\theta} - M_{2q})$, and define P_N^θ, Q_N^θ by (AT11) with $M_* = H_\theta(t)$ and the unchanged inclusions I_N, B_N . Then $U^\theta = Q_{2q-1}^\theta + Q_{2q}^\theta - Q_q^\theta$ and $W^\theta = P_{2q-1}^\theta - P_{q-1}^\theta + P_{2q}^\theta - P_q^\theta$. Substitution proves all projector identities and the exact signed trace formula (AT15) on this distinct interpolation. Both positive forms have the same original remainder fibres. Thus (AT18a)–(AT21) defines its own control $\mathfrak{C}_\theta$ and proves

$$\begin{aligned} |\mathcal{B}_{k,\theta} - \mathcal{B}_k| &\leq J_\theta \leq \mathfrak{C}_\theta := \int_0^1 \min\{S_{\text{spec}}^\theta(t), \tfrac{1}{2}d_\theta(t)\|U^\theta - W^\theta\|_{1,H_\theta(t)}\} dt \\ &\leq (2q - 1) \log \frac{1 + \eta}{1 - \eta}. \end{aligned} \quad (\text{HC14})$$

Indeed every eigenvalue of $M_{2q}^{-1}M_{2q,\theta}$ lies in $[1 - \eta, 1 + \eta]$ by the source sandwich, and the full spectra and trace norms in the finite AT proof are on the displayed polynomial flags. This is an explicit source comparison; taking determinants only after quotient minimization gives the preceding $2q$ allowance as a coarser consequence. The interpolated forms are not identified with either Gamma reference. On these same phase-source operators define S_{HS}^θ by the exact centered trace formula (AT21a), and $J_\theta = \int_0^1 \min\{S_{\text{spec}}^\theta, S_{\text{tr}}^\theta, S_{\text{HS}}^\theta\} dt$. The same finite Hermitian Cauchy–Schwarz proof gives the first entry in (HC14); hence $J_\theta \leq \mathfrak{C}_\theta$. The positive atomic phase measure also meets the moment hypothesis proved above. Define I_θ by (AT21a) on the exact path $H_\theta(t)$; its original $B_\theta(t)$ is strictly positive by the same nonzero moment $\int |\chi|^2 d\mu_t$. Put

$$\begin{aligned} \mathfrak{U}_{\text{ar}} &= \min\{\widehat{\mathcal{U}}_k, \mathfrak{b}_*^+\}, \\ \mathfrak{U}_\theta &= \min\{\mathfrak{U}_{\text{ar}} + J_\theta, \Psi_a(H_a(\mathfrak{U}_{\text{ar}}) + I_\theta)\}, \quad a = 2q - 1. \end{aligned} \quad (\text{HC14a})$$

Then (HC13)’s right side is at most $\mathfrak{U}_\theta$. Indeed $0 < \mathcal{B}_k \leq \mathfrak{U}_{\text{ar}}$ by the original upper estimates. Apply (AT21e) on $H_\theta(t)$, then use monotonicity of $\Psi_a \circ (H_a + I_\theta)$ in its positive initial value. This proves both upper entries and their minimum. This substitution uses (AT19) on the original arithmetic form before the explicit source-phase trace calculation; it does not identify the sampled phase metric with the original one.

The original source-phase map and its signed refinement. We now refine the same bound (HC14a), retaining its original $J_\theta, I_\theta, \mathfrak{C}_\theta$ and both upper entries. Let $I_{2q}^{2q+2} : \mathcal{P}_{2q} \hookrightarrow \mathcal{P}_{2q+2}$ be literal coefficient inclusion. The two original forms on $H = \mathcal{P}_{2q}$ are

$$\begin{aligned} M_0^\theta &= (I_{2q}^{2q+2})^* M_{2q+2} I_{2q}^{2q+2} = \int_{\mathbb{R}} v(u)^* v(u) m_{h,k}(u) du, \\ M_1^\theta &= (I_{2q}^{2q+2})^* M_{2q+2,\theta} I_{2q}^{2q+2} = \frac{2\pi}{L} \sum_{r \in \mathbb{Z}} m_{h,k}(u_r) v(u_r)^* v(u_r), \\ v(u) &= (1, c + iu, \dots, (c + iu)^{2q}), \quad c = k/2, \quad u_r = (2\pi r + \theta)/L. \end{aligned} \quad (\text{HC14b})$$

By (HT3)–(HT7), these are exactly the squared norms of $\mathcal{U}_k \mathcal{V}|_H$ and $\mathcal{Z}_{L,\theta} \mathcal{U}_k \mathcal{V}|_H$. Here $\mathcal{U}_k$ is the half-density map (HT4), whose source and target include every relative variable; the earlier scalar upper bound with this notation is still the expression in (HC8). The original relative variables, full Taylor unit, coordinate, phase, and factor $2\pi/L$ are present in these two source maps. To specify the period cost without colliding with $a = 2q - 1$, write $a_{\text{wt}} > 0$ for the weighted-source exponent of (PSC.32). Its actual degree- $2q + 2$ cost is

$$\kappa_{a_{\text{wt}}, 2q+2} = \sup_{v \neq 0} \frac{v^*(M_{a_{\text{wt}}, +, 2q+2} + M_{a_{\text{wt}}, -, 2q+2})v}{v^* M_{2q+2} v}.$$

The weighted Grams retain the squared weights $x_k^{\pm 2a_{\text{wt}}}$. Retain the originally fixed period L whenever $\kappa_{a_{\text{wt}}, 2q+2}/(e^{a_{\text{wt}}L} - 1) \leq \eta$. One exact admissible choice is $L = a_{\text{wt}}^{-1} \log(1 + \kappa_{a_{\text{wt}}, 2q+2}/\eta)$; the comparison below holds for every retained period satisfying the displayed inequality. Equation (PSC.33), restricted by I_{2q}^{2q+2} , proves $(1 - \eta)M_0^\theta \preceq M_1^\theta \preceq (1 + \eta)M_0^\theta$. For $q - 1 \leq N \leq 2q$ the remainder J_N is surjective; taking the two infima over its identical nonempty fibre $J_N P = v$ also proves the quotient sandwiches used above.

Put $M_x^\theta = (1 - x)M_0^\theta + xM_1^\theta$ for $0 \leq x \leq 1$. At $x = t$ this is precisely $H_\theta(t)$ in (HC14). Use $I_N : \mathcal{P}_N \rightarrow H$ and the unpadded original relation $B_N^{\text{AW}} : \mathcal{P}_{N-q} \rightarrow \mathcal{P}_N, P \mapsto \chi P$. Its included map is $B_N^\theta = I_N B_N^{\text{AW}}$, and the exact projections and operators are

$$\begin{aligned} P_N^\theta &= I_N(I_N^* M_x^\theta I_N)^{-1} I_N^* M_x^\theta, \\ Q_N^\theta &= B_N^\theta((B_N^\theta)^* M_x^\theta B_N^\theta)^{-1} (B_N^\theta)^* M_x^\theta, \\ U_x^\theta &= Q_{2q-1}^\theta + Q_{2q}^\theta - Q_q^\theta, \\ W_x^\theta &= P_{2q-1}^\theta - P_{q-1}^\theta + P_{2q}^\theta - P_q^\theta, \\ C_x^\theta &= (M_x^\theta)^{-1}(M_1^\theta - M_0^\theta), \quad D_\theta = (M_0^\theta)^{-1}M_1^\theta. \end{aligned} \tag{HC14c}$$

At $N = q - 1$ the relation domain is zero and the second formula is the unique zero map $Q_{q-1}^\theta = 0$. These are exactly (ACM4)–(ACM5) after the stated substitution, and exactly the projections already used in (HC14). The source and relation ranges are the same nested polynomial flags, so both U_x^θ, W_x^θ have full spectrum $0^{[q]}, 1^{[2]}, 2^{[q-1]}$. Differentiating the actual canonical section as in (ISM18) and taking the four determinant signs gives

$$F'_\theta(x) = \text{Tr}(C_x^\theta(U_x^\theta - W_x^\theta)), \quad F_\theta(0) = \mathcal{B}_k, \quad F_\theta(1) = \mathcal{B}_{k,\theta}.$$

The polynomial χ has positive norm for the continuous measure and for the infinite positive lattice measure (HT6). Their convex mixture has the same property. The original $\chi^{\#_k}$ proof (AT21a)–(AT21c) therefore gives $F_\theta(x) > 0$ on this closed path. In particular every nonlinear denominator is bounded away from zero for this fixed source comparison.

Apply the pointwise dictionary preceding (HC9a) on this path. The additional trace inequalities $S_{\text{tr}}^\theta \leq S_{\text{ov}}^\theta$ and $S_{\text{tr}}^\theta \leq S_{\text{sin}}^\theta \leq S_{\text{ang}}^\theta$ prove that the complete (ACM11a) minima are precisely the J_θ, I_θ already defined above. In particular both complete angle lists, the overlap majorant and the centered Hilbert–Schmidt expression are retained in these identities. Let $j_{p,\theta}, e_{p,\theta}$ be the (ACM15) construction with

$$(M_x, C_x, U_x, W_x, D, F(x)) \mapsto (M_x^\theta, C_x^\theta, U_x^\theta, W_x^\theta, D_\theta, F_\theta(x)).$$

The integer $p \geq 0$ is its finite-series degree, while the original period is still L . If $b_1^\theta \leq \dots \leq b_n^\theta$ are every eigenvalue of D_θ in M_0^θ , $n = 2q + 1$, write

$$\vartheta_\theta = \frac{b_n^\theta - b_1^\theta}{b_n^\theta + b_1^\theta}, \quad K_{D_\theta} = \sum_{j=1}^n \left(\frac{|b_j^\theta - 1|}{\min\{1, b_j^\theta\}} \right)^2.$$

The finite identity $C_x^\theta - (C_x^\theta)^{[p]} = (H_x^{\circ,\theta})^{p+1} C_x^\theta$ is the identical (ACM15) geometric sum on these specified operators. Subtracting the trace mean of this residual leaves its pairing with $U_x^\theta - W_x^\theta$ unchanged. All its factors are real functions of D_θ , hence self-adjoint in M_x^θ . The Hilbert–Schmidt inequality therefore gives

$$\begin{aligned} j_{p,\theta} - e_{p,\theta} &\leq \mathcal{B}_{k,\theta} - \mathcal{B}_k \leq j_{p,\theta} + e_{p,\theta}, \\ 0 \leq e_{p,\theta} &\leq \vartheta_\theta^{p+1} \sqrt{K_{D_\theta}(8q - 6)} \xrightarrow{p \rightarrow \infty} 0. \end{aligned} \tag{HC14d}$$

For completeness the first factor bounds every residual eigenvalue because $\|H_x^{\circ,\theta}\|_{M_x^\theta} \leq \vartheta_\theta < 1$ and $|c_j^\theta(x)| \leq |b_j^\theta - 1|/\min\{1, b_j^\theta\}$. Centering subtracts the nonnegative square of the trace mean. Both

positive operators dominate their range projections, whose ranges intersect in dimension at least one. Thus $\text{Tr}(U_x^\theta W_x^\theta) \geq 1$, and the full spectra give $\text{Tr}((U_x^\theta - W_x^\theta)^2) = 8q - 4 - 2\text{Tr}(U_x^\theta W_x^\theta) \leq 8q - 6$. This proves the displayed constant on the original metric.

The source sandwich places every b_j^θ in $[1 - \eta, 1 + \eta]$. It consequently gives $\vartheta_\theta \leq \eta$ and $K_{D_\theta} \leq (2q+1)\eta^2/(1-\eta)^2$: the first follows by increasing the larger endpoint and decreasing the smaller one in their positive ratio, and each summand of the second has numerator at most η^2 and denominator at least $(1 - \eta)^2$. Hence the explicit further bound is

$$e_{p,\theta} \leq \frac{\eta^{p+2}}{1 - \eta} \sqrt{(2q+1)(8q-6)}.$$

This holds for every phase at each retained period satisfying the displayed original degree- $2q + 2$ source-cost inequality, retaining the complete $q = [1 + k(m-1)](k+1)^2$ dependence. Retaining their entire ordered list, the same signed derivative and the exact derivative of H_a give

$$\begin{aligned} |\mathcal{B}_{k,\theta} - \mathcal{B}_k| &\leq J_\theta \leq \min\{\mathfrak{C}_\theta, \mathcal{L}_q(D_\theta)\} \leq (2q-1) \log \frac{1+\eta}{1-\eta}, \\ |H_{2q-1}(\mathcal{B}_{k,\theta}) - H_{2q-1}(\mathcal{B}_k)| &\leq I_\theta \leq \log \frac{1+\eta}{1-\eta}, \\ \mathcal{L}_q(D_\theta) &= \log \frac{b_{q+2}^\theta}{b_q^\theta} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}^\theta}{b_j^\theta}. \end{aligned} \tag{HC14e}$$

Indeed integration of each ordered $c_j^\theta(x) = (b_j^\theta - 1)/(1 - x + xb_j^\theta)$ gives $\log b_j^\theta$. The total coefficient of the resulting logarithmic ratios is $1 + 2(q-1) = 2q-1$. Dividing the original pointwise minimum by $(2q-1)\sqrt{1 - e^{-F_\theta(x)/(2q-1)}}$ and integrating proves the second line. These are the same additive and nonlinear bounds as (HC14)–(HC14a), now accompanied by the constructed signed center (HC14d).

For any integers $p, r \geq 0$, define

$$\begin{aligned} U_{k,p}^{\text{ar}} &= \min\{\widehat{\mathcal{U}}_k, \beta_{p,\Gamma}^+\}, \\ U_{k,\theta;p,r} &= \min\{U_{k,p}^{\text{ar}} + J_\theta, \Psi_{2q-1}(H_{2q-1}(U_{k,p}^{\text{ar}}) + I_\theta), \\ &\quad U_{k,p}^{\text{ar}} + j_{r,\theta} + e_{r,\theta}\}. \end{aligned} \tag{HC14f}$$

The actual $\mathcal{B}_k$ is positive and at most $U_{k,p}^{\text{ar}}$ by (HC9a)–(HC10a). The additive and signed expressions increase with this initial scalar. For the fixed computed I_θ , both H_{2q-1} and Ψ_{2q-1} are increasing on the displayed domains. Applying the three proved phase upper bounds and substituting this initial upper value proves

$$2 \sum_{N=q-1}^{2q-1} w_N \log \max \left\{ 1, \frac{\mathcal{L}}{\sqrt{2J_N^D}} - 1 \right\} \leq \mathcal{B}_{k,\theta} \leq U_{k,\theta;p,r} \leq \mathfrak{U}_\theta. \tag{HC13a}$$

For the final inequality (HC9a) gives $U_{k,p}^{\text{ar}} \leq \mathfrak{U}_{\text{ar}}$, and monotonicity of the first two upper expressions bounds their minimum by the original (HC14a). The third entry can only lower it. This proof holds the actual phase-path integrals fixed during the scalar comparison; it does not replace their source path. The weights w_N , derivative-source energies J_N^D , and every boundary term in (HC12)–(HC13) remain in their original phase metric. No fixed-source residual limit is promoted to a uniform estimate in the growing tensor order.

The source comparison also retains its exact cochain map. For two minimum sections ρ_0, ρ_1 on this common source, $(\rho_1 - \rho_0)v = \chi Q_v$ by monic division. Successive division in $s_1, \dots, s_k$ gives the original polynomials $Q_{v,i}$ with $\chi(\sum s_i)Q_v(\sum s_i) = \sum_i h(s_i)Q_{v,i}(\mathbf{s})$. With the original $h(D)F_h = \Theta\phi_*$, the actual primitive is

$$K_v = \sum_{i=1}^k (-1)^{i-1} Q_{v,i}(D_1, \dots, D_k) (F_h^{\otimes(i-1)} \otimes \phi_* \otimes F_h^{\otimes(k-i)}).$$

The tensor differential contributes the same $(-1)^{i-1}$, so $dK_v = \mathcal{V}((\rho_1 - \rho_0)v)$, as in (ISM38)–(ISM41). For the two-leg complex with differential $(\phi, \hat{\psi}) \mapsto \Theta(\phi - \mathcal{F}^{-1}\hat{\psi})$, the degree-zero map $j_+(\phi) = (\phi, 0)$ and degree-one identity form a cochain map because their differential is exactly $\Theta\phi$. Tensor these specified maps and use the original coefficient insertions into the fixed full carrier of (ISM42). This defines $\tilde{K}_v$ and preserves its displayed top differential. At a declared support $\lambda = (W, S; A)$, apply these maps coordinatewise. With the original coefficient injections ι_i , the exact top maps and their common inverse-image domain are

$$F_{a,A} : E^{\oplus A} \longrightarrow \mathcal{C}_{\text{full}}^k, \quad F_{a,A}((v_i)_{i \in A}) = \sum_{i \in A} \iota_i \mathcal{V} \rho_a v_i \quad (a = 0, 1),$$

$$E_\lambda = F_{0,A}^{-1}(\mathcal{C}_\lambda^k) \cap F_{1,A}^{-1}(\mathcal{C}_\lambda^k).$$

This is a linear subspace. For $\mathbf{v} = (v_i)_{i \in A} \in E_\lambda$, put $\tilde{K}_\mathbf{v} = \sum_{i \in A} \iota_i j_+^{\otimes k} K_{v_i}$, where the tensor cochain map has the degree-one identities already specified. Its top differential is $F_{1,A}(\mathbf{v}) - F_{0,A}(\mathbf{v})$, which lies in $\mathcal{C}_\lambda^k$ and is a boundary in the full carrier. The exact residual map on this specified domain is

$$E_\lambda \longrightarrow \frac{d\mathcal{C}_{\text{full}}^{k-1} \cap \mathcal{C}_\lambda^k}{d\mathcal{C}_\lambda^{k-1}}, \quad \mathbf{v} \longmapsto [d\tilde{K}_\mathbf{v}]_\lambda.$$

Its inclusion-induced map to the kernel of $\mathcal{C}_\lambda^k / d\mathcal{C}_\lambda^{k-1} \rightarrow \mathcal{C}_{\text{full}}^k / d\mathcal{C}_{\text{full}}^{k-1}$ and its inverse both use the same representative, proving the exact isomorphism (ISM42). The full two-leg degree-zero diagonal and the source images are those of (ISM41)–(ISM43). For independent coefficient masks the linear maps act in each active coordinate; zero insertion commutes because every new coordinate maps 0 to 0 with its original outer label. This calculation retains the proper-source residual and the empty mask's outer label throughout.

The graph refinement in this original phase-energy budget. Retain the domain $\gamma > 2$ of (HC9g), the actual original period and phase above, and every previously calculated $J_\theta, I_\theta, j_{r,\theta}, e_{r,\theta}$. For $p, s, r \geq 0$ put

$$\begin{aligned} U_{k;p,s}^{\text{ar,gr}} &= \min\{\hat{\mathcal{U}}_k, b_{p,s}^{\text{gr,+}}\}, \\ U_{k,\theta;p,s,r}^{\text{gr}} &= \min\{U_{k;p,s}^{\text{ar,gr}} + J_\theta, \\ &\quad \Psi_{2q-1}(\mathcal{H}_{2q-1}(U_{k;p,s}^{\text{ar,gr}}) + I_\theta), \\ &\quad U_{k;p,s}^{\text{ar,gr}} + j_{r,\theta} + e_{r,\theta}\}. \end{aligned} \tag{HC14g}$$

The original arithmetic moment proof at (ACM11a) gives strict positivity of $\mathcal{B}_k$; (HC10g) and (HC9g) then give $0 < \mathcal{B}_k \leq U_{k;p,s}^{\text{ar,gr}} \leq U_{k,p}^{\text{ar}}$. For each of the three fixed phase controls the upper expression is increasing in its initial scalar: the first and third are affine of slope one, and the second is the composite of the two increasing functions already differentiated in (ACM14). Applying their actual phase inequalities and this scalar comparison proves the propagated bound at (HC13a):

$$\begin{aligned} 2 \sum_{N=q-1}^{2q-1} w_N \log \max \left\{ 1, \frac{\mathcal{L}}{\sqrt{2J_N^D}} - 1 \right\} &\leq \mathcal{B}_{k,\theta} \\ &\leq U_{k,\theta;p,s,r}^{\text{gr}} \leq U_{k,\theta;p,r}. \end{aligned} \tag{HC13g}$$

The original w_N, J_N^D , phase source, twisted derivative domain and boundary residual in (HC12)–(HC13) are unchanged. The graph data enter through the proved signed bound for the initial arithmetic volume. The inequality does not identify the two-component graph source with the phase source.

The relation-row interval propagated into the phase budget. Keep the original phase, circumference, source-path matrices and the exact integrals $J_\theta, I_\theta, j_{r,\theta}, e_{r,\theta}$ from (HC14b)–(HC14g). Use $U_{k;p,s}^{\text{ar,rel}}$ defined in (HC10r), and define the complete three-entry upper value

$$U_{k,\theta;p,s,r}^{\text{rel}} = \min\{U_{k;p,s}^{\text{ar,rel}} + J_\theta, \Psi_{2q-1}(\mathcal{H}_{2q-1}(U_{k;p,s}^{\text{ar,rel}}) + I_\theta), U_{k;p,s}^{\text{ar,rel}} + j_{r,\theta} + e_{r,\theta}\}. \quad (\text{HC14r})$$

By (HC9r)–(HC10r) and the strict original-moment positivity,

$$0 < \mathcal{B}_k \leq U_{k;p,s}^{\text{ar,gr}} \leq U_{k;p,s}^{\text{ar,rel}} \leq U_{k,p}^{\text{ar}}.$$

For this fixed phase path the first and third functions of an initial scalar x in (HC14r) are affine of slope one. The second is the composite of increasing $\mathcal{H}_{2q-1}$ on $x > 0$ and increasing Ψ_{2q-1} on its nonnegative argument; their derivatives and inverse domains were computed in (ACM14). The actual phase inequalities (HC14d)–(HC14e) use $x = \mathcal{B}_k$. Substituting the larger scalar upper endpoints and applying each monotonicity proves

$$2 \sum_{N=q-1}^{2q-1} w_N \log \max \left\{ 1, \frac{\mathcal{L}}{\sqrt{2J_N^D}} - 1 \right\} \leq \mathcal{B}_{k,\theta} \leq U_{k,\theta;p,s,r}^{\text{gr}} \leq U_{k,\theta;p,s,r}^{\text{rel}} \leq U_{k,\theta;p,r}. \quad (\text{HC13r})$$

The left inequality is the unchanged original phase-energy identity (HC13), with the complete multiplicities, twisted derivative domain and boundary terms. The comparison holds the actual path controls fixed; the scalar substitution does not change their integration path or measure. It also retains the entire cochain map and proper-source residual following (HC13a): the only new maps here are the two real translations in (HC10r) and these three functions of their proved arithmetic upper endpoint. The exact-graph phase bound (HC13g) remains the smaller one at the same p, s, r , as the displayed inequalities prove.

The correlation interval in the three original phase functions. With the same fixed original phase controls as (HC14r), set

$$U_{k,\theta;p,s,r}^{\text{corr}} = \min\{U_{k;p,s}^{\text{ar,corr}} + J_\theta, \Psi_{2q-1}(\mathcal{H}_{2q-1}(U_{k;p,s}^{\text{ar,corr}}) + I_\theta), U_{k;p,s}^{\text{ar,corr}} + j_{r,\theta} + e_{r,\theta}\}. \quad (\text{HC14rc})$$

Equation (HC9rc) and the arithmetic minimum in (HC10rc) give $0 < \mathcal{B}_k \leq U_{k;p,s}^{\text{ar,gr}} \leq U_{k;p,s}^{\text{ar,corr}} \leq U_{k;p,s}^{\text{ar,rel}}$. The three increasing functions proved in (HC14r) therefore give

$$2 \sum_{N=q-1}^{2q-1} w_N \log \max \left\{ 1, \frac{\mathcal{L}}{\sqrt{2J_N^D}} - 1 \right\} \leq \mathcal{B}_{k,\theta} \leq U_{k,\theta;p,s,r}^{\text{gr}} \leq U_{k,\theta;p,s,r}^{\text{corr}} \leq U_{k,\theta;p,s,r}^{\text{rel}} \leq U_{k,\theta;p,r}. \quad (\text{HC13rc})$$

This proves the full propagation into the original phase-energy budget by applying each actual phase inequality before taking their minimum. The source-path integrals, circumference condition, twisted derivative domain, complete weights, boundary terms and proper-source cochain residual are those already proved above. Including all later rows makes the correlation upper bound equal to the exact-graph bound (HC14g) at the same p, s, r . No tensor uniform rate is inferred from this finite exactness statement.

For the averaged original phase metrics the already proved stronger comparison $(1 - \eta^2)G_N \preceq \overline{G}_N \preceq G_N$ gives instead $|\overline{\mathcal{B}}_k - \mathcal{B}_k| \leq 2q \log(1/(1 - \eta^2))$. These changes are of order q for a fixed η , whereas the compatible width (HC11) has positive quadratic order. The exact Laplacian residual (HT17) remains present at every phase. No displayed upper estimate for its norm, or for the original derivative moments in (HC12), contradicts these lower bounds.

The graph-to-average cost and its complete mixed remainder. On the same graph-source domain $\gamma > 2$, fix one original circumference for all four endpoints. The inverse-form statements below use the already proved degree- $2q + 2$ original source comparison above. For the graph map L_{obs} of (ACM18), write L_{circ} for this circumference to avoid a collision. At each $N \in (q - 1, q, 2q - 1, 2q)$ use the original arithmetic minimum section C_N and the relation map B_N of PGB.3. Put $H_N = B_N^* M_N B_N$, $T_N^{\text{def}} = D_N B_N$, $H_{+,N} = H_N + (T_N^{\text{def}})^* T_N^{\text{def}}$, and retain

$$Q_{D,N} = I - T_N^{\text{def}} H_{+,N}^{-1} (T_N^{\text{def}})^*, \quad \mathcal{E}_N^{\text{aug}} = C_N^* D_N^* Q_{D,N} D_N C_N, \quad \mathcal{D}_N^{\text{hol}} = G_N - \overline{G}_N. \quad (\text{HC16})$$

For zero relation dimension the maps through that domain are zero and $Q_{D,N} = I$. PGB.3–PGB.10 proves, by the displayed completed squares and the original phase section difference,

$$\begin{aligned} \widehat{G}_N &= G_N + \mathcal{E}_N^{\text{aug}}, \quad \mathcal{E}_N^{\text{aug}} > 0, \\ \mathcal{D}_N^{\text{hol}} &= \int (C_N - C_{N,\theta})^* M_{N,\theta} (C_N - C_{N,\theta}) \frac{d\theta}{2\pi} \succeq 0, \\ \widehat{G}_N - \overline{G}_N &= \mathcal{E}_N^{\text{aug}} + \mathcal{D}_N^{\text{hol}}. \end{aligned} \quad (\text{HC17})$$

The exact map whose Gram is the last difference is

$$x \mapsto \left(Q_{D,N}^{1/2} D_N C_N x, [\theta \mapsto (C_N - C_{N,\theta}) x] \right) \in \mathcal{H}_k \oplus L^2(\Theta; \text{im } B_N, M_{N,\theta} d\theta / (2\pi)). \quad (\text{HC18})$$

Its squared norm is (HC17), and its kernel is zero by the injectivity of $D_N C_N$ proved from the full leading coefficient in PGB.6. The cochain map inducing the identity contraction $(E, \widehat{G}_N) \rightarrow (E, \overline{G}_N)$ sends each polynomial and each relation to its constant phase field. It commutes with the inclusion differential and preserves J_N ; its norm identity is $\int p^* M_{N,\theta} p d\theta / (2\pi) = p^* M_N p \leq p^* \widehat{M}_N p$. Thus the finite comparison is accompanied by its original source map and its complete nonzero metric loss.

To carry this calculation into the four-volume use site define the exact individual determinant costs

$$\begin{aligned} a_N^{\text{aug}} &= \log \frac{\det \widehat{G}_N}{\det G_N} = \log \det(I + G_N^{-1/2} \mathcal{E}_N^{\text{aug}} G_N^{-1/2}) > 0, \\ h_N^{\text{hol}} &= \log \frac{\det G_N}{\det \overline{G}_N} = \log \det(I + \overline{G}_N^{-1/2} \mathcal{D}_N^{\text{hol}} \overline{G}_N^{-1/2}) \geq 0, \\ a_N^{\text{av}} &= \log \frac{\det \widehat{G}_N}{\det \overline{G}_N} = a_N^{\text{aug}} + h_N^{\text{hol}}. \end{aligned} \quad (\text{HC19})$$

These equalities follow by determinant multiplication; no commutation of their positive matrices is required. List the four endpoints as $(N_1, N_2, N_3, N_4) = (q - 1, q, 2q - 1, 2q)$ with $\epsilon = (1, 1, -1, -1)$, retaining repeated entries if they occur. The exact signed identities are

$$\begin{aligned} \Gamma_k^{\text{gr}} &= \sum_{j=1}^4 \epsilon_j a_{N_j}^{\text{aug}}, \\ H_k^{\text{hol}} &:= \sum_{j=1}^4 \epsilon_j h_{N_j}^{\text{hol}} = \mathcal{B}_k - \overline{\mathcal{B}}_k, \\ \widehat{\mathcal{B}}_k - \overline{\mathcal{B}}_k &= \Gamma_k^{\text{gr}} + H_k^{\text{hol}} = \sum_{j=1}^4 \epsilon_j a_{N_j}^{\text{av}}. \end{aligned} \quad (\text{HC20})$$

For the original source sandwich chosen above, $(1 - \eta^2)G_N \preceq \overline{G}_N \preceq G_N$ implies $0 \leq h_N^{\text{hol}} \leq q \log(1/(1 - \eta^2))$. There are two positive and two negative signs, so

$$|H_k^{\text{hol}}| \leq 2q \log \frac{1}{1 - \eta^2}, \quad \left| \widehat{\mathcal{B}}_k - \overline{\mathcal{B}}_k - \Gamma_k^{\text{gr}} \right| \leq 2q \log \frac{1}{1 - \eta^2}. \quad (\text{HC21})$$

This proves exactly where the earlier order- q allowance enters. The augmentation's signed term is retained through (ACM23)–(ACM27), rather than assigned that allowance. The separate positivity of the four costs in (HC19) does not give a sign to their complete signed sum.

The graph volume appearing in (HC9g) also has its full mixed-source expression. Retain $\Phi(1/2 + it) = A + iq\Phi(t)$, the density r_k , function $g_x = z(u)x/r_k(u)$, and maps $Y_\perp$, $\mathcal{J}_k$, $\widehat{R}_N$ exactly as in PGB.14–PGB.22. In particular $\Omega_k = Y_\perp^* Y_\perp > 0$ and $f_N x = \iota \widehat{R}_N x - g_x$, with $\iota P(u) = P(k/2 + iu)$. The complete squared-norm identity PGMB.5 is

$$\begin{aligned} \widehat{G}_N &= K_{\text{low}} + (\mathcal{D}_k^{\text{mix}})^* \mathcal{D}_k^{\text{mix}} + f_N^* f_N = \Omega_k + f_N^* f_N, \\ (\mathcal{D}_k^{\text{mix}} x)(\mathbf{t}) &= \frac{\overline{\tau}_k F_x(\mathbf{s})}{1 + |\tau_k|^2} - g_x(u). \end{aligned} \quad (\text{HC22})$$

The target norm of the second line is the full weighted space $L^2((1 + |\tau_k|^2) \prod_i w_h(t_i) dt_i)$. Thus it retains $1 + k^2 A^2 + (\sum_i q\Phi(t_i))^2$, the conjugate phase and every tensor variable. PGMB.2 evaluates its kernel: it is zero for $k \geq 2$, while the map vanishes for $k = 1$. Its first term has the original realization $L_{\text{low}} x = (\prod_i v_h(s_i)) F_x / \sqrt{1 + |\tau_k|^2}$, with Gram K_{low} . The map $x \mapsto (L_{\text{low}} x, \mathcal{D}_k^{\text{mix}} x, f_N x)$ has precisely the Gram $\widehat{G}_N$ in (HC22), proving the source realization of every term.

Define its finite positive tail costs by

$$t_N = \log \det(I + \Omega_k^{-1/2} f_N^* f_N \Omega_k^{-1/2}). \quad (\text{HC23})$$

Equation (HC22) gives $\log \det \widehat{G}_N = \log \det \Omega_k + t_N$. The minimum over the nested original relation spaces proves $\widehat{G}_{N+1} \preceq \widehat{G}_N$, hence $t_{N+1} \leq t_N$; determinant monotonicity follows by congruence with the smaller positive form and its eigenvalues. PGB.22's affine approximation proves $f_N^* f_N \rightarrow 0$ at fixed h, k , so $t_N \downarrow 0$ in that limit. The actual four endpoints therefore give

$$\begin{aligned} \widehat{\mathcal{B}}_k &= (t_{q-1} - t_{2q-1}) + (t_q - t_{2q}), \\ 0 \leq \widehat{\mathcal{B}}_k &\leq t_{q-1} + t_q, \\ \mathcal{B}_k &= t_{q-1} + t_q - t_{2q-1} - t_{2q} - \Gamma_k^{\text{gr}}. \end{aligned} \quad (\text{HC24})$$

Substitution into (HC9g), (HC10g) and then (HC14g) is the explicit original-source tail calculation for their graph entry. In particular it retains all four tails and the signed augmentation correction. Although the common $\log \det \Omega_k$ cancels with $1 + 1 - 1 - 1 = 0$, that full matrix remains in all four congruences (HC23). Its strictly positive mixed contribution at every $k \geq 2$ has not been removed. The fixed- k degree limit of t_N does not supply a rate for these four growing endpoints as k varies.

Finally the completed receiving maps remain explicit. PGB.20–PGB.21 gives $\Xi(f, x) = \mathcal{J}_k f - Y_\perp x$ and $j_\infty \Xi(f, x) = x$, where $j_\infty = -\Omega_k^{-1} Y_\perp^*$ and $\ker j_\infty = \mathcal{J}_k L^2(r_k du)$. The first-coordinate projection to the original unweighted completed source is $\pi_1 \Xi(f, x) = \mathcal{J}_k^0 I_{r,m}(f + g_x)$. It maps the closed graph relation into the original closed unweighted relation, inducing $(E, \Omega_k) \rightarrow 0$ with full kernel E , exactly as proved in PGB.21b. On the graph quotient, PGMB.7–PGMB.8 instead gives $\mathfrak{C}_k \Xi(f, x) = (L_{\text{low}} x, \mathcal{D}_k^{\text{mix}} x)$ with kernel $\mathcal{J}_k L^2(r_k du)$, and, for $k \geq 2$,

$$(\Omega_k - K_{\text{low}})^{-1} (\mathcal{D}_k^{\text{mix}})^* \text{pr}_2 \mathfrak{C}_k = j_\infty. \quad (\text{HC25})$$

The equality follows by the exact Gram in (HC22). These are the maps from the same completed source to its unweighted and mixed targets, with their complete kernels. On each fixed coefficient mask they act coordinatewise; represented zero and an empty present tuple keep their original label, and external absence keeps its singleton inverse image. The finite graph-to-average contraction (HC18) and these completed maps use their stated different domains. Every proper-source residual retained above continues to use its original inverse-image domain and boundary quotient; none of these Hilbert quotient calculations declares that residual zero.

163.5 The sharper finite comparison retains its exact error

The original lower-envelope measure is

$$d\nu_k(u) = c_h \vartheta_h^{k-3} e^{-\alpha(k-3)} e^{-\alpha|u|} (k-2+|u|)^{-B} du.$$

Let V_N^ν be its quotient volume for the identical full remainder map. The actual finite upper expression for the four-window volume is

$$\mathcal{U}_{\nu,k} = \log(V_{q-1} V_q) - \log(V_{2q-1}^\nu V_{2q}^\nu),$$

with the exact nonnegative error

$$\boxed{\mathcal{U}_{\nu,k} - \mathcal{B}_k = \log \frac{V_{2q-1}}{V_{2q-1}^\nu} + \log \frac{V_{2q}}{V_{2q}^\nu} \geq 0.} \quad (\text{HC15})$$

Indeed $m_{h,k}(u) du \geq d\nu_k$ bounds every source polynomial quadratic form. Minimizing on each identical affine remainder fibre gives $G_N \succeq G_N^\nu \succ 0$. Conjugation by $(G_N^\nu)^{-1/2}$ shows that each volume ratio in (HC15) is at least one. Cancellation proves the equality. The low-degree factors require only original moments through $2q$, and the comparison moments in the last factors go through $4q$. These are well-defined finite expressions, with the actual full jet map and source mass. The supplied proof records do not evaluate their errors at the hypothetical arithmetic quartet or bound them at a rate opposing (HC5). Retaining this sharper finite expression therefore supplies no extra contradictory inequality.

164 The same arithmetic source in every bound

Retain the actual quartet, $g = 2\xi$, h , $v_h = g/h$, δ , γ , and full order m from (HT1). For $k \geq 3$, retain $q = [1 + k(m-1)](k+1)^2$ and the exact cyclic sum polynomial of (HT2). All determinant factors below are taken in its original increasing-power remainder frame. They are positive because the original common source Grams are positive definite and the remainder maps are onto.

Use the original arithmetic measure $m_{h,k} = w_h^{*k}$ and its fixed Gamma reference from (AT4), with their unchanged masses. Set

$$B_{\text{ar}} = \log \frac{V_{q-1}^{\text{ar}} V_q^{\text{ar}}}{V_{2q-1}^{\text{ar}} V_{2q}^{\text{ar}}}, \quad B_\Gamma = \log \frac{V_{q-1}^\Gamma V_q^\Gamma}{V_{2q-1}^\Gamma V_{2q}^\Gamma}, \quad \Delta = B_{\text{ar}} - B_\Gamma. \quad (\text{CR1})$$

In the fixed degree- $2q$ source define the positive relative operator $D_* = M_{2q}(0)^{-1} M_{2q}(1)$. This symbol is not the Euler differential. Let $b_1 \leq \dots \leq b_{2q+1}$ be all its eigenvalues with their full multiplicities, and put

$$L_q = \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}. \quad (\text{CR2})$$

Every eigenvalue here is computed from the two actual moment matrices on their common retained polynomial source. There is no free replacement by a diagonal arithmetic metric. The diagonalization used in the AW proof is the spectral theorem applied to that specified positive relative operator, and its proof transports the original form.

Let D_h and $\hat{\mathcal{U}}_k$ have their full definitions in (HC3), (HC6) and (HC8). Let $\mathcal{U}_{\nu,k}$ be the sharper finite lower-envelope comparison in (HC15), including its two actual low-degree determinants and two envelope determinants. Then the following combined restriction follows on the original objects:

$$\max\{0, 4q \log(D_h k), B_\Gamma - L_q\} \leq B_{\text{ar}} \leq \min\{\hat{\mathcal{U}}_k, \mathcal{U}_{\nu,k}, B_\Gamma + L_q\}. \quad (\text{CR3})$$

For the signed arithmetic correction itself this is

$$\max\{-B_\Gamma, 4q \log(D_h k) - B_\Gamma, -L_q\} \leq \Delta \leq \min\{\hat{\mathcal{U}}_k - B_\Gamma, \mathcal{U}_{\nu,k} - B_\Gamma, L_q\}. \quad (\text{CR4})$$

Proof. Polynomial-degree inclusion decreases the minimum quotient Gram in the positive-semidefinite order, so each original volume ratio in (CR1) is at least one. This proves $B_{\text{ar}} \geq 0$. The full inherited two-window identity and the new retained residual calculation give $B_{\text{ar}} \geq 4q \log(D_h k)$ in (HC5). The actual remainder-map estimates prove $B_{\text{ar}} \leq \widehat{U}_k$ in (HC8), while comparison on the identical affine remainder fibres proves $B_{\text{ar}} \leq \mathcal{U}_{\nu,k}$ in (HC15). The computed full window spectrum and the actual relative moment eigenvalues give $|\Delta| \leq L_q$ in (AW14). Substituting (CR1) into this last inequality gives the remaining lower and upper entries of (CR3). Taking the maximum of the three proved lower bounds and minimum of the three proved upper bounds proves (CR3), with no independent choice of their source data. Subtracting the same literal B_{Γ} everywhere gives (CR4). $\square$

The signed value appearing in these inequalities has also been calculated as an exact integral, not only bounded:

$$\begin{aligned} \Delta &= \int_0^1 \text{Tr}((U(t) - W(t))C(t)) dt \\ &= \int_0^1 \text{Tr}(W(t)T(t)^{-1}[C(t), T(t)]) dt. \end{aligned} \tag{CR5}$$

Here U, W are the two original relation and polynomial window operators (AT13); $C = M_{2q}(t)^{-1}(M_{2q}(1) - M_{2q}(0))$; and T is the actual smooth source isometry constructed in (AW9)–(AW10). The first equality is (AT15), whose proof retains all four determinant orientations and both relation spaces. The second is (AW11), proved by inserting $U = TWT^{-1}$ and cyclically moving T in the finite trace. The source isometry does not preserve the arithmetic observation: its exact observation defect and full kernel are (AW12), and a nonzero witness is proved below. Thus (CR5) has not silently replaced the arithmetic map by an isometry that preserves different cohomology classes.

In particular every putative actual quartet must obey the additional explicit spectral compatibility inequality

$$L_q \geq \max\{0, B_{\Gamma} - \widehat{U}_k, B_{\Gamma} - \mathcal{U}_{\nu,k}, \max(0, 4q \log(D_h k)) - B_{\Gamma}\}. \tag{CR6}$$

Indeed the first two nonzero entries follow by combining $B_{\Gamma} - L_q \leq B_{\text{ar}}$ with the two upper estimates. The last entry follows from $\max(0, 4q \log(D_h k)) \leq B_{\text{ar}} \leq B_{\Gamma} + L_q$. All logarithmic ratios defining L_q are nonnegative, proving its lower bound by zero as well. This proves (CR6) with the actual relative spectrum, not a freely chosen condition number.

165 An explicit original relation that the source isometry does not preserve

Here the arithmetic observation is the exact map $\mathcal{O} = \sigma_h^{\otimes k} \eta J_{2q} : H \rightarrow Q^{\otimes k}$ in (AW12), and $T(t) : H \rightarrow H$ is the constructed source isometry. Write the original monic polynomial as $\chi(S) = \sum_{j=0}^q a_j S^j$ and define its reflected conjugate on this fixed sum line by $\chi^{\dagger}(S) = \sum_{j=0}^q \overline{a_j}(k-S)^j$. The actual vector

$$v(S) = \chi(S)\chi^{\dagger}(S) \in \mathcal{P}_{2q} \quad \text{satisfies} \quad \mathcal{O}v = 0, \quad \mathcal{O}T(t)v \neq 0 \quad (0 \leq t \leq 1). \tag{CR7}$$

To prove this, $v \in \chi\mathcal{P}_q = \ker J_{2q}$ proves the first equality using the original observation map. On the unchanged line $S = k/2 + iu$ one has $k - S = \overline{S}$, so

$$\langle 1, v \rangle_t = \int_{\mathbb{R}} |\chi(k/2 + iu)|^2 m_t(u) du > 0.$$

The integral is finite by the original moment bounds, and positive because χ is a nonzero polynomial and m_t is positive almost everywhere. Therefore $v \notin \mathcal{P}_{q-1}^{\perp}$. Equation (AW12), proved by the explicit isometry on the two full flags, gives $\ker(\mathcal{O}T) = \mathcal{P}_{q-1}^{\perp}$, establishing the second assertion of (CR7).

On a supported fibre the first value is its supported zero, whereas the second is a nonzero arithmetic coefficient at that same label. Neither value is external τ . Thus the exact source isometry and its calculated commutator are available, but that particular isometry does not descend through the original relation quotient. This obstruction is proved on the same actual polynomial and measure used in (CR1)–(CR6).

166 Status at the preceding proof increment

The later chapters in this cumulative reader sharpen the arithmetic norm, volume, and coherent comparisons. The following records the scope of the preceding bounds, all of which remain valid.

The coarse actual upper and lower bound functions have strictly positive separation for every $k \geq 3$, as proved in (HC9)–(HC11). Keeping the packet constants fixed, their separation divided by q^2 tends to $2((\pi/2)D + \log 256) > 0$, with D exactly the original interval scale in (HC6). Thus those proved estimates give no contradiction. The more informative interval (CR3) retains actual unevaluated relative moment eigenvalues and the sharper envelope determinants. This calculation does not claim to have verified a nonempty instance of that refined interval for any off-line zeta packet: no such packet has been certified.

The strongest original-object restrictions proved here are simultaneous. The actual packet survives the full balanced finite comparison, the mixed-support coefficient retract, and the original tensor action. Its proper-label kernel contribution has the exact transition of DP and PL. Its full relative symmetric trace has the calculated negative directions and original derivative representatives in C. Its canonical source at every phase has the boundary energy and Laplacian residual in HT. Its phase derivative energy contributes to the same endpoint contraction costs by (HC12)–(HC14). Its original arithmetic correction is the computed common-source integral (CR5), bounded by the actual relative spectrum in (CR2)–(CR6).

These conclusions eliminate particular ways an off-line packet might have disappeared from the programme, and quantify the cost of its remaining original source representatives. They do not eliminate all such packets. Establishing the requested contradiction would require an opposing estimate on these original arithmetic quantities, proved from the same g/h and theta relations. Establishing RH false would require an actual off-critical zero of g , which has not been obtained. Neither outcome is asserted by this manuscript. The full calculations, source evidence and corrected comparisons are retained for continuation.

167 The original coherent quotient and the derived classes it does not remove

This section continues the actual balanced realization in A1427 and the absolute pointed-base comparison in A1523. The balanced-kernel chapter, (BK.1)–(BK.24), proves the original analytic input used below, including the full-plane Euler inverse and all source-label transition maps. The derived-packet chapter, (DP.1)–(DP.8), retains both degrees of every finite spectral thickening. We compute a different observation here: maps from the same balanced object into coherent analytic modules, and then derived maps into those modules. The distinction is established by explicit morphisms and resolutions.

167.1 The original sheaf and its canonical local summands

Retain the original definitions

$$\begin{aligned}
 V &= \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \quad \phi(0) = 0, \quad \int_{\mathbb{R}} \phi(x) dx = 0\}, \\
 \mathcal{B} &= \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^k F(x)| < \infty \quad (b \in \mathbb{Z}, k \geq 0)\}, \quad D = -x\partial_x, \\
 \Theta\phi(x) &= 2 \sum_{n \geq 1} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}, \quad Q = \mathcal{B}/\Theta V, \quad A = \mathbb{C}[t], \quad (\text{OCQ.1}) \\
 g(s) &= 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s), \quad H_\phi(s) = \frac{2\pi^{s/2}M_+\phi(s)}{s(s-1)\Gamma(s/2)}.
 \end{aligned}$$

Here t acts by D on the original function spaces and by multiplication by s on analytic functions. The expression defining H_ϕ is its entire continuation, with every removable point treated in (BK.1)–(BK.8). In particular $\mathcal{M}\Theta\phi = gH_\phi$ and $\mathcal{M}DF = s\mathcal{M}F$ on the original spaces. The tensor products and module Hom groups below are algebraic, as in the displayed balanced construction in A1427. The original Schwartz spaces remain the source of their specified elements and maps.

Let $X = \mathbb{C}$ with its analytic structure. Define $\mathcal{M}$ to be the sheafification of the presheaf $U \mapsto \mathcal{O}_X(U) \otimes_A Q$, and put $\mathcal{N} = \mathcal{O}_X/(g)$. The presheaf maps

$$a \otimes [F] \longmapsto [a\mathcal{M}F]$$

are balanced, respect restrictions, and vanish on the original theta boundaries by (OCQ.1). They therefore define an actual sheaf morphism

$$\beta : \mathcal{M} \longrightarrow \mathcal{N}, \quad \mathcal{K} = \ker \beta. \quad (\text{OCQ.2})$$

Tensor products commute with filtered colimits, so its stalk at s_0 is the original map

$$\begin{aligned}
 O &= \mathcal{O}_{X,s_0}, \quad z = s - s_0, \quad F_{\text{mer}} = \text{Frac } O = O[1/z], \\
 M = O \otimes_A Q &\xrightarrow{b} N = O/(g), \quad b(a \otimes [F]) = [a\mathcal{M}F], \quad K = \ker b.
 \end{aligned} \quad (\text{OCQ.3})$$

The letter F_{mer} denotes meromorphic germs and does not denote a test function or the formal Laurent-series field. In these fixed coordinates $O = \mathbb{C}\{z\}$.

For completeness, surjectivity is visible on an original global test:

$$F_0(x) = e^{-(\log x)^2}, \quad H_0(s) = \mathcal{M}F_0(s) = \sqrt{\pi}e^{s^2/4}, \quad q_0 = [F_0]. \quad (\text{OCQ.4})$$

Euler derivatives and multiplication by x^b preserve the required Gaussian bounds, so $F_0 \in \mathcal{B}$. Substitution $x = e^y$ evaluates the Mellin integral, first for real s by completing the square and then everywhere by entire continuation. Since H_0 is nowhere zero, $a \mapsto aH_0^{-1} \otimes q_0$ lifts any local section $[a]$ of $\mathcal{N}$. Thus (OCQ.2) is a sheaf epimorphism.

The proved original comparison (BK.14)–(BK.19) says that every nonzero polynomial acts bijectively on K . Since every nonzero element of O is a unit times a power of z , it follows that K is a vector space over F_{mer} , with the uniquely forced action $(a/c)k = a(c|_K)^{-1}k$. It is nonzero at every stalk. The explicit witness is

$$k_0 = g \otimes q_0 \neq 0 \quad \text{in } K. \quad (\text{OCQ.5})$$

Here the proof of nonvanishing is exactly the proof retained in (BK.21): the classical infinitude of distinct actual zeros of g forces $P = 0$ in any identity $P(s)H_0(s) = g(s)H_\phi(s)$; hence $Aq_0 \simeq A$, and flatness of the torsion-free A -module O gives $Oq_0 \simeq O$. The classical zero-set input is the retained Hardy theorem and its original source identified in that chapter. Neither RH nor an off-line zero is assumed. The structure and factorization arguments below only require the computed vector-space property; the assertions of noncoherence and nonzero derived classes also use this proved witness.

Retain the full local factor $g(s) = u(z)z^m$ with $u(0) \neq 0$ and $m = \text{ord}_{s_0} g$. There is an explicit canonical decomposition. For $x \in M$, $gx \in K$, so define

$$p_K(x) = (g|_K)^{-1}(gx), \quad p_T(x) = x - p_K(x), \quad T = M[g]. \quad (\text{OCQ.6})$$

These are O -linear, p_K is the identity on K , and $gp_T(x) = 0$. The intersection $T \cap K$ is zero because g is invertible on K . The map $b|_T$ is injective and is surjective because $b(p_T x) = b(x)$. Consequently, with $j = (b|_T)^{-1}$,

$$M = T \oplus K, \quad T \xrightarrow[b]{\sim} O/(g), \quad x = j(bx) + p_K x. \quad (\text{OCQ.7})$$

An O -torsion element of M has zero K component, so T is the entire torsion submodule. This includes $m = 0$, when $N = T = 0$. Formula (OCQ.6) retains u ; no replacement of the function g has been made.

167.2 Every ordinary coherent observation factors through the actual zero scheme

Call an O -module divisible when multiplication by every nonzero element of O is surjective, and call a module reduced when it has no nonzero divisible submodule. Over this ring divisibility is equivalent to surjectivity of multiplication by z . Every finitely generated O -module E is reduced. To see this without an assumption on a submodule, the elementary divisor decomposition gives $E \simeq O^r \oplus \bigoplus_{j=1}^d O/(z^{n_j})$. This decomposition follows by reducing a finite presentation matrix over the discrete valuation ring: choose a nonzero entry of least valuation, use its divisibility into all entries to clear its row and column by invertible operations, and repeat on the remaining finite matrix. The resulting diagonal entries are units times powers of z ; unit row operations remove the units. The presentation exists because every nonzero ideal of O contains an element of smallest valuation and is generated by it. More explicitly, for a submodule of O^n , its projection to the first coordinate is a principal ideal. Choose one lift of its generator; subtracting its multiples leaves a submodule of O^{n-1} . Induction on n proves finite generation of every such submodule and hence of the kernel of a finite free surjection. The decomposition proves

$$\bigcap_{n \geq 0} z^n E = 0, \quad (\text{OCQ.8})$$

since a holomorphic germ divisible by every power is zero, and sufficiently large powers kill each torsion summand. Every divisible submodule is contained in this intersection.

An O -linear image of K is divisible. Therefore every map $M \rightarrow E$ with E reduced vanishes on K and factors uniquely through b . For a finite module this yields, naturally in E ,

$$b^* : \text{Hom}_O(N, E) \xrightarrow{\sim} \text{Hom}_O(M, E), \quad \text{Hom}_O(M, E) \simeq E[g]. \quad (\text{OCQ.9})$$

The last map sends f to $f(j([1]))$. Its inverse sends $e \in E[g]$ to $x \mapsto ae$ whenever $b(x) = [a]$; changing a by gc does not change the answer.

The reduced targets form the exact largest class with this property. Indeed, if an arbitrary target E contains a nonzero divisible submodule D , choose $d_0 \neq 0$ and $d_{n+1} \in D$ with $zd_{n+1} = d_n$. The formula

$$\alpha : F_{\text{mer}} \longrightarrow D, \quad \alpha(az^{-n}) = ad_n \quad (\text{OCQ.10})$$

is well-defined: equality $az^{-n} = bz^{-m}$, with $m \geq n$, means $b = z^{m-n}a$, while $z^{m-n}d_m = d_n$. It is additive, O -linear, and nonzero at 1. Choose an F_{mer} -basis of K containing k_0 , and let $\ell : K \rightarrow F_{\text{mer}}$ be its coordinate projection with $\ell(k_0) = 1$. Then $\alpha \ell p_K : M \rightarrow E$ is nonzero on K , so it does not factor through b . The choices are explicit choices of a divisible chain and a vector-space complement, not canonical maps.

Also K is the maximal divisible submodule of M : its image under b in the finite module N must be zero. The universal property implies

$$K = \bigcap_{\substack{E \text{ finite over } O \\ f: M \rightarrow E}} \ker f. \quad (\text{OCQ.11})$$

The inclusion from left to right is (OCQ.9), and the reverse inclusion uses $f = b$ itself.

Neither K nor M is finitely generated at any analytic stalk. Otherwise (OCQ.8), applied respectively to K or M , contradicts $0 \neq k_0 \in \bigcap_n z^n K \subset \bigcap_n z^n M$. Hence $\mathcal{K}$ and $\mathcal{M}$ are nowhere coherent, although $\mathcal{N}$ is coherent. For a coherent analytic sheaf $\mathcal{E}$, any actual sheaf morphism $\mathcal{M}|_U \rightarrow \mathcal{E}|_U$ vanishes on $\mathcal{K}|_U$ by (OCQ.9) on stalks. The sheaf quotient property gives a unique factorization on U , compatible on overlapping opens. We obtain a proved sheaf isomorphism

$$\mathcal{H}om_{\mathcal{O}_X}(\mathcal{N}, \mathcal{E}) \xrightarrow{\sim} \mathcal{H}om_{\mathcal{O}_X}(\mathcal{M}, \mathcal{E}). \quad (\text{OCQ.12})$$

Thus β is the universal coherent quotient of this original object. This statement neither identifies $\mathcal{M}$ with its quotient nor asserts existence of such a quotient for arbitrary analytic sheaves.

Every coherent quotient of M is consequently a quotient of $O/(g)$. At the fixed stalk its kernel lifts to an ideal I of O containing $(g) = (z^m)$. The valuation argument above gives $I = (z^r)$ for exactly one integer $0 \leq r \leq m$. Conversely every such ideal defines a quotient. The full map and its removed part are

$$M \xrightarrow{b} O/(g) \longrightarrow O/(z^r), \quad \ker(O/(g) \rightarrow O/(z^r)) = (z^r)/(g). \quad (\text{OCQ.13})$$

This records all $m-r$ removed nilpotent levels and retains the actual ideal (g) . Globally these kernels glue exactly to ideal sheaves between (g) and $\mathcal{O}_X$, or equivalently to effective subdivisors of the actual divisor of g . In particular the ordinary analytic duals are

$$\text{Hom}_O(M, O) = 0, \quad \text{Hom}_O(K, O) = 0, \quad M^{\vee\vee} = 0. \quad (\text{OCQ.14})$$

The next calculation constructs the derived comparison that (OCQ.14) does not address.

167.3 A complete local derived calculation

All Ext groups in this subsection are groups of modules over the specified analytic stalk $O = \mathbb{C}\{z\}$. Put $\widehat{E} = \varprojlim_n E/z^n E$ for a finite O -module E . Equation (OCQ.8) embeds E into its completion. The original source is not replaced by a completed module.

The meromorphic germ field has the following explicit two-term free resolution. With $P_0 = P_1 = \bigoplus_{n \geq 0} Oe_n$, set

$$0 \longrightarrow P_1 \xrightarrow{d} P_0 \xrightarrow{\epsilon} F_{\text{mer}} \longrightarrow 0, \quad d(e_n) = e_n - ze_{n+1}, \quad \epsilon(e_n) = z^{-n}. \quad (\text{OCQ.15})$$

Surjectivity follows from the definition of $O[1/z]$. If a finitely supported vector has last nonzero coefficient a_m , the coefficient of e_{m+1} in its image under d is $-za_m \neq 0$; hence d is injective. Modulo dP_1 one has $e_n = z^{m-n}e_m$ for $n \leq m$. Therefore a vector $\sum_{n=0}^m a_n e_n$ in $\ker \epsilon$ is congruent to $(\sum_{n=0}^m z^{m-n} a_n) e_m = 0$. This proves exactness with the displayed maps.

Applying $\text{Hom}_O(-, E)$ gives the product map

$$\Delta : \prod_{n \geq 0} E \longrightarrow \prod_{n \geq 0} E, \quad \Delta(a)_n = a_n - za_{n+1}, \quad \text{Ext}_O^1(F_{\text{mer}}, E) = \text{coker } \Delta. \quad (\text{OCQ.16})$$

The kernel is $\text{Hom}_O(F_{\text{mer}}, E) = 0$ by (OCQ.8), and all higher Ext groups vanish by this free resolution. Define the convergent-in-the-completion sum

$$S : \prod_{n \geq 0} E \longrightarrow \widehat{E}/E, \quad S(c) = \left[\sum_{n \geq 0} z^n c_n \right]. \quad (\text{OCQ.17})$$

Every summand of index at least n lies in $z^n \widehat{E}$, so the sum is well-defined. Finite partial sums for $c = \Delta a$ are $a_0 - z^{N+1} a_{N+1}$; the second term tends to zero in the completion. Thus $S\Delta = 0$.

For $E = O$, suppose $S(c) = 0$ and write $a = \sum_{n \geq 0} z^n c_n \in O$. Define

$$a_n = z^{-n} \left(a - \sum_{j < n} z^j c_j \right). \quad (\text{OCQ.18})$$

The parenthesis is an analytic germ whose formal Taylor coefficients below degree n vanish. Its analytic zero order is consequently at least n , so $a_n \in O$. Subtraction gives $a_n - z a_{n+1} = c_n$, proving $\ker S = \text{im } \Delta$. Given an arbitrary formal series $\sum b_n z^n$, choose the constant germs $c_n = b_n$; this proves surjectivity of S . The argument applies componentwise to finite free modules. For a finite torsion module T killed by z^q , one has $\widehat{T} = T$ and the explicit formula

$$a_n = \sum_{j=0}^{q-1} z^j c_{n+j}, \quad a_n - z a_{n+1} = c_n - z^q c_{n+q} = c_n \quad (\text{OCQ.19})$$

proves surjectivity of Δ . The finite-module decomposition used in (OCQ.8) completes the proof for every finite E . Since the map S itself commutes with every homomorphism $E \rightarrow E'$, the resulting isomorphism is natural, independently of the decomposition used to verify it:

$$\text{Ext}_O^1(F_{\text{mer}}, E) \xrightarrow[S]{} \widehat{E}/E. \quad (\text{OCQ.20})$$

Choose an F_{mer} -basis B of K . The direct sum over B of (OCQ.15) is a free resolution of K . Applying Hom gives products of (OCQ.16). Products of these surjective image-to-cokernel maps are surjective, and their kernels are the corresponding products of images; thus their cokernel is the product of the individual cokernels. Consequently

$$\text{Hom}_O(K, E) = 0, \quad \text{Ext}_O^1(K, E) \simeq \prod_{b \in B} (\widehat{E}/E), \quad \text{Ext}_O^i(K, E) = 0 \quad (i \geq 2). \quad (\text{OCQ.21})$$

Only the product identification depends on the chosen basis. The canonical summands in (OCQ.7), together with the resolution $0 \rightarrow O \xrightarrow{g} O \rightarrow N \rightarrow 0$, now give

$$\begin{aligned} \text{Hom}_O(M, E) &\simeq E[g], \\ \text{Ext}_O^1(M, E) &\simeq E/gE \oplus \text{Ext}_O^1(K, E), \\ \text{Ext}_O^i(M, E) &= 0 \quad (i \geq 2). \end{aligned} \quad (\text{OCQ.22})$$

The first summand in degree one is exactly the map b^* from $\text{Ext}_O^1(N, E)$.

These statements determine the exact scope for all bounded coherent derived targets. If $C \in D_{\text{fg}}^b(O)$, then

$$\begin{aligned} R\text{Hom}_O(N, C) &\xrightarrow{b^*} R\text{Hom}_O(M, C) \text{ is a quasi-isomorphism} \\ \iff H^q(C) &\text{ has finite length for every } q. \end{aligned} \quad (\text{OCQ.23})$$

Indeed, the two-term projective resolution of K and the finite cohomological filtration of C give the hyper-Ext spectral sequence with terms $\text{Ext}_O^p(K, H^q(C))$. The column $p = 0$ is zero by (OCQ.21), columns $p \geq 2$ are zero by the resolution, and no differential enters or leaves the remaining column. The finite filtration therefore has precisely one possible nonzero graded piece in each total degree, giving

$$H^n R\text{Hom}_O(K, C) \simeq \text{Ext}_O^1(K, H^{n-1}(C)). \quad (\text{OCQ.24})$$

For a finite module E the quotient $\widehat{E}/E$ is zero exactly when its free rank is zero: its torsion part contributes zero, and $\mathbb{C}[[z]]/\mathbb{C}\{z\} \neq 0$, as witnessed by the divergent formal series $\sum_{n \geq 0} n! z^n$. The

ratio of successive absolute terms at any fixed $z \neq 0$ is $(n+1)|z|$, so that series cannot converge in any nonzero disc. Since B is nonempty by (OCQ.5), (OCQ.21), (OCQ.24), and the splitting of M prove both directions of (OCQ.23).

There is also a concrete nonsplit extension, rather than only an abstract dimension assertion. Put $\omega = O ds$ and use (OCQ.15). Define $\varphi : P_1 \rightarrow \omega$ by $\varphi(e_n) = n! ds$, and set

$$E_! = \frac{\omega \oplus P_0}{\{(-\varphi(v), d(v)) : v \in P_1\}}. \quad 0 \longrightarrow \omega \longrightarrow E_! \longrightarrow F_{\text{mer}} \longrightarrow 0. \quad (\text{OCQ.25})$$

The last map sends (w, p) to $\epsilon(p)$. Injectivity of the first map follows from injectivity of d ; if $\epsilon(p) = 0$, write $p = dv$, so the class of (w, p) is the class of $(w + \varphi(v), 0)$. This proves exactness. Writing $\bar{e}_n$ for the class of e_n , the relations are $\bar{e}_n - z\bar{e}_{n+1} = n! ds$. A splitting would give compatible lifts $\bar{e}_n - a_n ds$ and hence $a_n - za_{n+1} = n!$. Equations (OCQ.17)–(OCQ.20) would then make $\sum n!z^n$ convergent, a contradiction. Thus (OCQ.25) is nonsplit. Pulling it back along $\ell_{p_K} : M \rightarrow F_{\text{mer}}$ from (OCQ.10) gives a class in $\text{Ext}_O^1(M, \omega)$ whose restriction to the embedded line $F_{\text{mer}}k_0$ is (OCQ.25). It is therefore nonzero on K and does not come from $\text{Ext}_O^1(N, \omega)$.

Accordingly the universal ordinary coherent quotient (OCQ.12) does not extend to all derived coherent targets. In particular $\omega[1]$ detects the explicit additional class. This coexists with the exact derived tensor comparison (DP.2): for every nonzero germ h , $K \otimes_O^L O/(h)$ is the contractible two-term complex $[K \xrightarrow{h} K]$. The two calculations concern explicitly different functors. No identification of stalks of sheaf Ext with Ext groups of these noncoherent stalks is asserted or needed.

167.4 The residue morphism into the original pointed-base dual

The finite analytic summand has a direct relation to the actual A1523 duality. The resolution using multiplication by the actual g gives

$$\text{Ext}_O^1(N, \omega) \simeq \omega/g\omega \xrightarrow{\sim} g^{-1}\omega/\omega, \quad [v ds] \longmapsto [v ds/g]. \quad (\text{OCQ.26})$$

The second map is well-defined and invertible by multiplication by g . There is a canonical complex-linear residue map

$$g^{-1}\omega/\omega \longrightarrow \text{Hom}_{\mathbb{C}}(N, \mathbb{C}), \quad [\eta] \longmapsto ([v] \mapsto \text{Res}_{s=s_0}(v\eta)). \quad (\text{OCQ.27})$$

Adding a holomorphic form or changing v by a multiple of g changes the integrand by a holomorphic form, so the map is well-defined. It is perfect: with $g = u(z)z^m$, the basis $1, z, \dots, z^{m-1}$ is dual to the classes $u(z)z^{m-1-j} ds/g = z^{-j-1} ds$, for $0 \leq j < m$. Their residue matrix is the identity. This calculation retains the entire analytic unit u in the representative before cancellation. For $m = 0$ both sides are zero.

Let Z be an actual finite set of zeros stable under $\rho \mapsto \rho^\dagger = 1 - \bar{\rho}$, and retain all multiplicities $m_\rho = \text{ord}_\rho g$ in $A_Z = \bigoplus_{\rho \in Z} \mathcal{O}_{X,\rho}/(g)$. The Mellin map from the original quotient is $J_Z : Q \rightarrow A_Z$, $J_Z[F] = ([\mathcal{M}F]_\rho)_\rho$. Its surjectivity is the original finite Mellin-jet statement retained in A1523, with complete interpolation proof in (BK.9)–(BK.11); no arbitrary surrogate packet is used. For $f \in A_Z$, use the reflected germ $\overline{f^\dagger}(s) = \overline{f(1 - \bar{s})}$ at the corresponding paired centre. The original identities $g(1 - s) = g(s)$ and $\overline{g(\bar{s})} = g(s)$ give $g^\dagger = g$, so this operation preserves the actual ideals and is well-defined on the full packets. Equations (OCQ.26)–(OCQ.27) give the exact composite

$$\overline{A_Z} \longrightarrow \bigoplus_{\rho \in Z} \text{Ext}_{\mathcal{O}_{X,\rho}}^1(\mathcal{O}_{X,\rho}/(g), \mathcal{O}_{X,\rho} ds) \longrightarrow \text{Hom}_{\mathbb{C}}(Q, \mathbb{C}), \quad (\text{OCQ.28})$$

where its value at f is

$$[F] \longmapsto \sum_{\rho \in Z} \text{Res}_{s=\rho} \frac{f^\dagger(s) \mathcal{M}F(s)}{g(s)} ds. \quad (\text{OCQ.29})$$

The first map sends f to $[f^\dagger ds/g]$; it is a complex-linear isomorphism from the conjugate vector space. The second map is injective by the perfectness in (OCQ.27) and surjectivity of J_Z . Thus (OCQ.28) is precisely the finite residue injection retained in A1523, after equipping its target with the original one-dimensional dilation character $\mathcal{L}_1$.

To check that character and every sign, let $R_a F(x) = F(x/a)$ for $a > 0$. Direct Mellin substitution gives $\mathcal{M}R_a F(s) = a^s \mathcal{M}F(s)$. The original dual action on $\text{Hom}_{\mathbb{C}}(Q, \mathcal{L}_1)$ is $(U_a \lambda)(q) = a\lambda(R_{1/a} q)$. In (OCQ.29) its effect is multiplication of the differential representative by a^{1-s} . On the source packet, $(a^s f)^\dagger = a^{1-s} f^\dagger$. Thus the displayed injection is equivariant, with the exact character a and the original reflection. Inserting g' gives the original trace form, since $g'/g = m_\rho/(s - \rho) + u'/u$ at each centre:

$$\sum_{\rho \in Z} \text{Res}_{s=\rho} \frac{f^\dagger(s) g'(s) v(s)}{g(s)} ds = \sum_{\rho \in Z} m_\rho \overline{f(1 - \bar{\rho})} v(\rho). \quad (\text{OCQ.30})$$

This proves the exact morphism from the finite coherent dual summand to the actual pointed-base comparison; the additional classes in (OCQ.25) do not replace or delete that summand.

The A1523 target is the complex-linear right adjoint for the original four-point amplitude diagram. Explicitly its points satisfy $+ < \eta < \sigma$ and $- < \eta < \sigma$; the amplitudes are $\mathcal{T}_+ = \mathcal{T}_- = V$, $\mathcal{T}_\eta = \mathcal{B}$, $\mathcal{T}_\sigma = 0$, with restrictions Θ and $J\Theta = \hat{\Theta}$, where $JF(x) = x^{-1}F(1/x)$ and the Fourier kernel is $e^{-2\pi i x \nu}$. Its cohomology complex is $[V \oplus V \xrightarrow{(\phi, \psi) \mapsto \Theta(\phi - \hat{\psi})} \mathcal{B}]$, in degrees zero and one, so $H^1 = Q$. The right adjoint computed there satisfies $H^{-1}R \text{Hom}(\mathcal{T}, K_\tau(\mathcal{L}_1)) \simeq \text{Hom}_{\mathbb{C}}(Q, \mathcal{L}_1)$. Consequently ordinary O -dual vanishing in (OCQ.14) cannot be inserted as a vanishing statement about that different, explicitly related right-adjoint target.

167.5 Proper labels and the precise consequence for purity comparison

For every original D -invariant source $W \subset V$, keep

$$Q_W = \mathcal{B}/\Theta W, \quad M_W = O \otimes_A Q_W, \quad L_W = O \otimes_A (V/W), \quad \pi_W : M_W \rightarrow M, \quad b_W = b\pi_W. \quad (\text{OCQ.31})$$

The inclusion $L_W \rightarrow M_W$ sends $a \otimes [\phi]$ to $a \otimes [\Theta\phi]$. Injectivity of the original Θ and flatness of O over A prove

$$0 \rightarrow L_W \rightarrow M_W \xrightarrow{\pi_W} M \rightarrow 0, \quad 0 \rightarrow L_W \rightarrow \ker b_W \rightarrow K \rightarrow 0. \quad (\text{OCQ.32})$$

For a finite target E , a map $f : M_W \rightarrow E$ factors through b_W if and only if $f|_{L_W} = 0$. The reverse direction is proved by first descending along the first quotient in (OCQ.32) and then applying (OCQ.9); the forward direction follows because $b_W L_W = 0$. More precisely,

$$0 \rightarrow \text{Hom}_O(N, E) \xrightarrow{b_W^*} \text{Hom}_O(M_W, E) \rightarrow \text{Hom}_O(L_W, E) \xrightarrow{\delta} \text{Ext}_O^1(M, E) \quad (\text{OCQ.33})$$

is exact. Here $\delta(\alpha)$ is the pushout of the first sequence in (OCQ.32) by $\alpha : L_W \rightarrow E$: its middle module is $(E \oplus M_W)/\{(-\alpha(l), l) : l \in L_W\}$. This extension splits exactly when α extends to M_W . Indeed an extension f defines a retraction by $[e, x] \mapsto e + f(x)$, and any retraction gives $f(x) = [0, x]$ followed by that retraction, with $f|_{L_W} = \alpha$. This proves exactness at the last displayed Hom term, while the previous factorization argument proves exactness at the others.

If $W \subset W' \subset V$, the source-quotient maps give the commuting diagram of (OCQ.32), with $L_W \rightarrow L_{W'}$ induced by $V/W \rightarrow V/W'$ and $M_W \rightarrow M_{W'}$ induced by $Q_W \rightarrow Q_{W'}$. Their respective kernels are both $O \otimes_A (W'/W)$, identified by $[\phi] \mapsto [\Theta\phi]$. This follows by tensoring the two exact original quotient sequences. Thus the coherent observations of a proper source retain exactly their extendable observations on L_W and the obstruction map δ ; they are not replaced by the universal property for the full source. For example, the actual proper-label classes constructed in (PL.8)–(PL.15) lie in L_W and can have finite spectral torsion that vanishes only under this specified transition.

All these maps act inside the original support fibres. For any fixed nonempty support label S , the split-zero extension of a linear map $f : E \rightarrow E'$ is

$$\tau \mapsto \tau, \quad (S, v) \mapsto (S, f(v)), \quad e_S = (S, 0). \quad (\text{OCQ.34})$$

Its inverse image of e_S is the full supported kernel $\{(S, v) : v \in \ker f\}$, and its inverse image of τ is only $\{\tau\}$. This follows directly from the disjoint union defining the split-zero object. Formula (OCQ.34) applies to β , to each label transition, and to every quotient in (OCQ.13); no nonempty kernel fibre is identified with external absence.

At an actual zero ρ of order m , scalar multiplication by a^s on N is $a^\rho \exp((\log a)z)$ modulo the full ideal (g) . For the quotient of depth r in (OCQ.13), the removed module $(z^r)/(g)$ has the ordered basis $z^r, \dots, z^{m-1}$, and the action is triangular with diagonal a^ρ . Therefore its dimension and trace are exactly

$$\dim_{\mathbb{C}}(z^r)/(g) = m - r, \quad \text{Tr}(a^s; (z^r)/(g)) = (m - r)a^\rho. \quad (\text{OCQ.35})$$

Every partial or total deletion of an actual local packet is consequently recorded by a nonzero finite coherent kernel and by this exact change in the original trace, including all multiplicities. The dilation on the full balanced module remains the original $1 \otimes R_a$, whose difference from scalar a^s has image in K as proved in (DP.4)–(DP.6). Formula (OCQ.35) is asserted on the actual analytic packet and its specified quotient, where the actions agree.

The obtained consequence for the tau purity comparison is exact. The full original quotient has the actual zero scheme as its universal ordinary coherent quotient; retaining that universal map retains every actual off-line packet if such a packet exists. Proper source labels retain the additional maps and kernels in (OCQ.32)–(OCQ.33). Derived coherent targets of positive rank additionally see the explicit kernel extension (OCQ.25), whereas every finite-length derived target has exactly the comparison (OCQ.23). The original finite residue injection is the composite (OCQ.28), with its computed action and trace. None of these proved maps supplies a positive metric or a weight bound on the actual packet; no numerical location constraint has been deduced from coherence. The original purity question therefore continues with these full morphisms and obstructions retained, rather than with a claimed identification of the full analytic object and its coherent quotient.

168 The canonical derived dual and the retained original tau complex

This continuation uses the actual sheaf morphism (OCQ.2), constructed from the original theta quotient in A1427, and the original four-point amplitude complex in A1523. All completed objects below occur as explicit targets in a derived calculation. The original analytic sheaf and the original Schwartz spaces are unchanged.

168.1 The global splitting is an actual sheaf map

Keep $X = \mathbb{C}$ with coordinate s , $g = 2\xi$, and

$$0 \longrightarrow \mathcal{K} \xrightarrow{\iota} \mathcal{M} \xrightarrow{\beta} \mathcal{N} \longrightarrow 0, \quad \mathcal{N} = \mathcal{O}_X/(g). \quad (\text{DC.1})$$

These are precisely the sheaves of (OCQ.1)–(OCQ.3). At every analytic stalk the original calculation makes every nonzero germ invertible on $\mathcal{K}_{s_0}$. In particular multiplication by the same entire function g is an isomorphism of the sheaf $\mathcal{K}$: a morphism of sheaves is an isomorphism when its maps on all stalks are isomorphisms. The inverse is unique and commutes with restrictions.

Since $g\mathcal{N} = 0$, multiplication by g on $\mathcal{M}$ factors uniquely through a sheaf map $u_g : \mathcal{M} \rightarrow \mathcal{K}$ with $\iota u_g = g \text{id}_{\mathcal{M}}$. Define

$$r = (g|_{\mathcal{K}})^{-1} u_g : \mathcal{M} \longrightarrow \mathcal{K}, \quad P = \text{id}_{\mathcal{M}} - \iota r. \quad (\text{DC.2})$$

One has $r\iota = \text{id}_{\mathcal{K}}$, $rP = 0$, $P^2 = P$, $\beta P = \beta$, and $gP = 0$, by substituting (DC.2). The intersection $\mathcal{M}[g] \cap \mathcal{K}$ is zero, because g acts injectively on $\mathcal{K}$. Thus β restricts to an isomorphism $\mathcal{M}[g] \rightarrow \mathcal{N}$. Its inverse $j : \mathcal{N} \rightarrow \mathcal{M}$ satisfies $j\beta = P$, and gives the canonical sheaf isomorphisms

$$(\beta, r) : \mathcal{M} \xrightarrow{\sim} \mathcal{N} \oplus \mathcal{K}, \quad (n, k) \mapsto jn + \iota k. \quad (\text{DC.3})$$

Both composites are the identity by the displayed projection identities. No local vector-space basis or choices of representatives enter these maps. In particular the stalk decomposition (OCQ.7) genuinely glues.

Let $\omega_X = \mathcal{O}_X ds$. Applying the derived internal Hom functor to the finite direct sum (DC.3) gives

$$R\mathcal{H}om(\mathcal{M}, \omega_X) \simeq R\mathcal{H}om(\mathcal{N}, \omega_X) \oplus R\mathcal{H}om(\mathcal{K}, \omega_X). \quad (\text{DC.4})$$

The original exact locally free resolution $[\mathcal{O}_X \xrightarrow{g} \mathcal{O}_X] \rightarrow \mathcal{N}$, with its free terms in degrees $-1, 0$, computes the first summand. Multiplication by g is injective on ω_X , so

$$R\mathcal{H}om(\mathcal{N}, \omega_X) \simeq (\omega_X/g\omega_X)[-1]. \quad (\text{DC.5})$$

The injection of (DC.5) into (DC.4) is β^* and its retraction is j^* ; their composite is the identity since $\beta j = 1$. This is a global derived summand of the actual source. It makes no identification between stalks of the second internal Hom in (DC.4) and Ext groups computed from its noncoherent stalks.

168.2 A canonical local dual without a choice of meromorphic basis

Fix the original analytic coordinate s_0 , and retain

$$\begin{aligned} O = \mathcal{O}_{X, s_0} &= \mathbb{C}\{z\}, \quad z = s - s_0, \quad F = \text{Frac } O = O[1/z], \\ \omega &= O ds, \quad \widehat{\omega} = \mathbb{C}[[z]] ds, \quad C_\omega = \widehat{\omega}/\omega. \end{aligned} \quad (\text{DC.6})$$

Thus F consists of convergent meromorphic germs, and is not the formal Laurent-series field. The injective inclusion $\omega \hookrightarrow \widehat{\omega}$ is the Taylor-series map. Its quotient is nonzero: $\sum_{n \geq 0} n! z^n ds$ is a formal series, while its terms fail to tend to zero at every fixed $z \neq 0$. It is therefore not an analytic germ.

Multiplication by z is bijective on C_ω . To prove surjectivity, subtract the constant coefficient of a formal representative and divide the remaining formal series by z . The removed constant lies in ω . For injectivity, if $z\widehat{f} ds \in \omega$, the analytic germ on the left has zero constant term and can be divided analytically by z ; the uniqueness of its Taylor series gives $\widehat{f} ds \in \omega$. Every nonzero analytic germ is a unit times a power of z , so C_ω is an F -vector space with the uniquely determined action by inverses of these multiplications.

For every F -vector space L , viewed as an O -module, one has

$$\text{Hom}_O(L, \widehat{\omega}) = 0, \quad \text{Ext}_O^i(L, \widehat{\omega}) = 0 \quad (i \geq 1). \quad (\text{DC.7})$$

The Hom assertion follows from $f(l) \in \bigcap_n z^n \widehat{\omega} = 0$, since $l = z^n l_n$. For the Ext assertion first use the exact free resolution (OCQ.15) of F . Its Hom differential on the products of $\widehat{\omega}$ is $\Delta(a)_n = a_n - z a_{n+1}$. Given an arbitrary sequence (c_n) in $\widehat{\omega}$, set

$$a_n = \sum_{j \geq 0} z^j c_{n+j} \in \widehat{\omega}. \quad (\text{DC.8})$$

For each fixed coefficient only finitely many summands contribute, so this sum is well-defined in the specified completion. Subtracting $z a_{n+1}$ cancels every term except c_n . Thus Δ is onto. The resolution has length one, so all higher Ext groups vanish. A direct sum of these free resolutions over an F -basis of L is a free resolution of L ; its Hom differential is the product of the preceding surjections, hence is onto. This proves (DC.7) for arbitrary L . The basis is used only to prove this vanishing assertion.

An O -linear map between F -vector spaces is F -linear: applying the map to $z(z^{-1}l) = l$ and using invertibility of z in the target proves compatibility with z^{-1} , and compatibility with all meromorphic fractions follows. Consequently the exact completion sequence gives a canonical isomorphism, natural in L ,

$$0 \longrightarrow \omega \longrightarrow \widehat{\omega} \longrightarrow C_\omega \longrightarrow 0, \quad \partial_L : \operatorname{Hom}_F(L, C_\omega) \xrightarrow{\sim} \operatorname{Ext}_O^1(L, \omega). \quad (\text{DC.9})$$

Indeed its Hom–Ext sequence has zero groups adjacent to this map by (DC.7). The map ∂_L sends f to the literal pullback extension

$$E_f = \{(l, \widehat{v}) \in L \oplus \widehat{\omega} : f(l) = [\widehat{v}]\}, \quad 0 \rightarrow \omega \xrightarrow{v \mapsto (0, v)} E_f \xrightarrow{(l, \widehat{v}) \mapsto l} L \rightarrow 0. \quad (\text{DC.10})$$

Surjectivity of the last arrow follows from surjectivity onto C_ω , and its kernel is the displayed copy of ω . The extension is split exactly when f lifts to an O -linear map $L \rightarrow \widehat{\omega}$; by (DC.7), this occurs exactly when $f = 0$. Thus the canonical description detects every such nonzero map without choosing a basis.

For $L = K = \mathcal{K}_{s_0}$, evaluation at a chosen F -basis identifies the left side of (DC.9) with $\prod_B C_\omega$. This recovers the original product calculation (OCQ.21), with its full differential form factor. The isomorphism (DC.9) itself is independent of that choice.

168.3 The natural local derived bidual retains every kernel class

Define the local derived dual by

$$D_\omega L = R\operatorname{Hom}_O(L, \omega[1]). \quad (\text{DC.11})$$

Here complexes use cohomological grading; $\omega[1]$ has ω in degree -1 . For an F -vector space L , its free resolution has length one, its ordinary Hom into ω is zero, and (DC.9) computes its Ext in degree one. Therefore

$$D_\omega L \simeq \operatorname{Hom}_F(L, C_\omega)[0]. \quad (\text{DC.12})$$

The module on the right is again an F -vector space, by pointwise scalar multiplication. Applying the same calculation a second time yields

$$D_\omega^2 L \simeq \operatorname{Hom}_F(\operatorname{Hom}_F(L, C_\omega), C_\omega)[0]. \quad (\text{DC.13})$$

Under these canonical identifications the natural derived bidual map is exactly

$$\operatorname{ev}_L : L \longrightarrow D_\omega^2 L, \quad l \longmapsto (f \longmapsto f(l)). \quad (\text{DC.14})$$

To check the map and its sign, represent $\omega[1]$ by

$$J = [\widehat{\omega} \xrightarrow{-\pi} C_\omega], \quad \deg \widehat{\omega} = -1, \quad \deg C_\omega = 0. \quad (\text{DC.15})$$

The quasi-isomorphism $\omega[1] \rightarrow J$ is the positive Taylor inclusion in degree -1 . Both terms of J are Hom-acyclic for an F -vector source: this is (DC.7) for $\widehat{\omega}$; for C_ω its telescope differential is onto by the recursion $a_0 = 0$, $a_{n+1} = z^{-1}(a_n - c_n)$, and the same direct-sum resolution proves higher vanishing. Thus $\operatorname{Hom}_O(L, J)$ computes $D_\omega L$ and has only the term $\operatorname{Hom}_F(L, C_\omega)$ in degree zero. The identical reasoning applies to that F -vector space as source. Evaluation into J consequently computes the derived bidual map. Its dg sign is $(-1)^{|l||f|} = 1$, since both l and f have degree zero. It is the displayed positive evaluation. Equivalently, comparison of J with an injective resolution gives quasi-isomorphisms on these two Hom complexes by the proved acyclicity, and carries this evaluation to the natural derived one.

The map (DC.14) is injective. If $l \neq 0$, extend l to an F -basis of L , and take its coordinate functional $\lambda : L \rightarrow F$ with $\lambda(l) = 1$. Choose the nonzero class $c = [\sum n! z^n ds] \in C_\omega$. The F -linear map

$f(x) = \lambda(x)c$ satisfies $f(l) = c \neq 0$, so $\text{ev}_L(l) \neq 0$. This proves injectivity of the canonical map; the auxiliary basis and nonzero c only verify it. No assertion of surjectivity is made.

In particular every nonzero class in the original K survives its natural local derived bidual. This includes the original class $k_0 = g \otimes [F_0]$ of (OCQ.5). The original ordinary dual vanishing $\text{Hom}_O(M, \omega) = 0$ therefore cannot be used to discard this kernel from the derived comparison. The finite summand is retained simultaneously. Represent N by $P = [O \xrightarrow{g} O]$ in degrees $-1, 0$. Its dual is $[\omega \xrightarrow{g} \omega]$ in the same degrees: the Hom differential on a degree-minus-one map is $-(-1)^{-1}fg = fg$. Dualizing again gives precisely $[O \xrightarrow{g} O]$. In each term the evaluation sign is positive, since the possible degree pairs are $(-1, 0)$ and $(0, -1)$. Finite free evaluation is the identity in the displayed bases. Consequently $D_\omega N = \omega/g\omega$ in degree zero and $N \xrightarrow{\sim} D_\omega^2 N$. Thus the canonical splitting $M = N \oplus K$ makes its natural derived bidual injective, with the entire finite arithmetic summand mapped isomorphically.

168.4 The exact global target of the local Ext calculation

Let i_{s_0} denote the inclusion of the one-point ringed space with ring O into $(X, \mathcal{O}_X)$. For an O -module E , its direct image has sections E on an open containing s_0 and zero on an open not containing it, with the analytic action through germs. This functor is exact. The exact stalk functor is its left adjoint, as one checks by restricting a sheaf map to germs, so the direct image preserves injective modules. Applying it to an injective resolution proves the exact derived adjunction

$$R\text{Hom}_{\mathcal{O}_X}(\mathcal{M}, i_{s_0*}\omega) \simeq R\text{Hom}_O(M, \omega). \quad (\text{DC.16})$$

The same proof on every open gives the internal version with i_{s_0*} on the right. This places the explicit local extension (DC.10) in a genuine sheaf-derived target. That target $i_{s_0*}\omega$ is not coherent on X : a coherent sheaf supported at a point has a stalk killed by a power of z , whereas no such power kills ω . Formula (DC.16) does not replace the coherent target ω_X by a claimed equality. The genuine coherent sheaf target retains the globally split summand (DC.5), independently of this skyscraper realization.

168.5 The original tau complex, its dilation, and its retained degree zero

The source in A1523 has the two incoming amplitude legs V , the central amplitude $\mathcal{B}$, restrictions Θ and $\widehat{\Theta}$, and its cohomology complex $[V \oplus V \rightarrow \mathcal{B}]$ with differential $(\phi, \psi) \mapsto \Theta(\phi - \widehat{\psi})$. For its balanced action give the plus leg V_+ the action $t = D$, and the minus leg V_- the action $t = 1 - D$. With the original Fourier kernel $e^{-2\pi i x \nu}$, $\widehat{D}\widehat{\psi} = (1 - D)\widehat{\psi}$ and Fourier squares to the identity on these even functions. Therefore Fourier is the exact A -linear isomorphism $V_- \rightarrow V_+$.

Write $\mathcal{V}_+$, $\mathcal{V}_-$, and $\mathcal{B}$ for the sheafifications of the corresponding $\mathcal{O}_X \otimes_A$ presheaves. Flatness of every analytic stalk over A proves that

$$C_A = [\mathcal{V}_+ \xrightarrow{\Theta} \mathcal{B}], \quad C_\tau = [\mathcal{V}_+ \oplus \mathcal{V}_- \xrightarrow{(\phi, \psi) \mapsto \Theta(\phi - \widehat{\psi})} \mathcal{B}] \quad (\text{DC.17})$$

have their indicated original differentials, with terms in degrees zero and one. There is an explicit cochain isomorphism

$$C_\tau \xrightarrow{\sim} C_A \oplus \mathcal{V}_+[0], \quad (\phi, \psi) \mapsto (\phi - \widehat{\psi}, \widehat{\psi}) \quad (\text{DC.18})$$

in degree zero and the identity on $\mathcal{B}$ in degree one. Its inverse sends (u, v) to $(u + v, \widehat{v})$. Applying the two differentials gives Θu in both directions, proving the cochain assertion. The quotient map in degree one is a quasi-isomorphism $C_A \rightarrow \mathcal{M}[-1]$, because the original Θ is injective and balancing is flat. Thus (DC.3) gives the canonical derived decomposition

$$C_\tau \simeq \mathcal{V}_+[0] \oplus \mathcal{N}[-1] \oplus \mathcal{K}[-1]. \quad (\text{DC.19})$$

The degree-zero diagonal source is retained. On the actual degree-one tau cohomology, (DC.19) is exactly the split comparison $\mathcal{M} = \mathcal{N} \oplus \mathcal{K}$.

The comparison to the analytic complex $C_g = [\mathcal{O}_X \xrightarrow{g} \mathcal{O}_X]$ is also an actual cochain map: on C_A it sends $a \otimes \phi$ to aH_ϕ and $a \otimes F$ to $a\mathcal{M}F$. The original identity $\mathcal{M}\Theta = gH$ proves that it commutes with the differentials. On C_τ compose it with the first projection in (DC.18). The diagonal source is exactly the degree-zero kernel of that first projection. The full composite has the larger kernel computed next; no injectivity of H is inferred. Its induced degree-one map is precisely β .

Write $H : \mathcal{V}_+ \rightarrow \mathcal{O}_X$ and $\text{Mel} : \mathcal{B} \rightarrow \mathcal{O}_X$ for the two displayed maps, and put

$$A_0 = \ker H, \quad A_1 = \ker \text{Mel}. \quad (\text{DC.20})$$

Both maps are onto as sheaf maps. For H use the original $\phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}$ with $H_{\phi_*} = 1$; the section a lifts to $a \otimes \phi_*$. For Mel use $aH_0^{-1} \otimes F_0$ with the original nowhere-zero $H_0 = \sqrt{\pi}e^{s^2/4}$. In (DC.18) coordinates the full kernel complex and its actual short exact sequence are therefore

$$C_{\ker} = [A_0 \oplus \mathcal{V}_+ \xrightarrow{(u,v) \mapsto \Theta u} A_1], \quad 0 \rightarrow C_{\ker} \rightarrow C_\tau \rightarrow C_g \rightarrow 0. \quad (\text{DC.21})$$

The inclusion $\Theta A_0 \subset A_1$ follows from $\text{Mel}\Theta = gH$. Since Θ is injective, $H^0 C_{\ker} = \mathcal{V}_+$, its diagonal factor. The map $A_1 \rightarrow \mathcal{K}$ sends a target vector to its original theta-quotient class. It is onto locally: if a representative F has $\text{Mel}(F) = ga$, subtract $\Theta(a \otimes \phi_*)$ to obtain a representative in A_1 . If a vector in A_1 is $\Theta\phi$, then $gH(\phi) = 0$; injectivity of g on $\mathcal{O}_X$ gives $\phi \in A_0$. Thus its kernel is exactly ΘA_0 . This proves

$$H^0 C_{\ker} = \mathcal{V}_+, \quad H^1 C_{\ker} = A_1 / \Theta A_0 \xrightarrow{\sim} \mathcal{K}, \quad C_{\ker} \simeq \mathcal{V}_+[0] \oplus \mathcal{K}[-1]. \quad (\text{DC.22})$$

For the last assertion project the explicit complex onto its diagonal factor and take the quotient of its remaining degree-one term. The other degree-zero differential is injective, so the resulting map is a quasi-isomorphism.

Finally the original dilation $R_a F(x) = F(x/a)$ acts as R_a on $\mathcal{B}$ and V_+ and as $aR_{1/a}$ on V_- . Direct Fourier substitution gives $\widehat{aR_{1/a}\psi} = R_a\widehat{\psi}$, so (DC.18) is equivariant with these exact actions. The Mellin substitution $x = ay$ gives $\mathcal{M}R_a F = a^s \mathcal{M}F$ and $H_{R_a\phi} = a^s H_\phi$. Hence the cochain map to C_g intertwines these actions with multiplication by a^s on both analytic terms. Dilation commutes with g and preserves $\mathcal{K}$, so it commutes with the projections (DC.2); in particular $R_a j = j a^s$ on $\mathcal{N}$.

At an actual zero ρ with its full order m and full local unit $g(s) = u(s - \rho)(s - \rho)^m$, this action is exactly

$$a^\rho \sum_{j=0}^{m-1} \frac{(\log a)^j}{j!} N_\rho^j, \quad N_\rho[v] = (s - \rho)[v] \quad \text{in } \mathcal{O}/(g). \quad (\text{DC.23})$$

No nilpotent term is removed. The finite coherent dual summand (DC.5) passes by the original maps $[v ds] \mapsto [v ds/g]$ and residue to the original tau dual target exactly as proved in (OCQ.26)–(OCQ.30). Its dual dilation is $\lambda \mapsto (q \mapsto a\lambda(R_{1/a}q))$; the differential representative is multiplied by a^{1-s} , including the retained one-dimensional character.

For a proper admitted source W , the entire relation quotient $\mathcal{O}_X \otimes_A (V/W)$ and its source-label transition remain the ones in (OCQ.31)–(OCQ.33). No invertibility on that larger proper-label kernel is used in (DC.1)–(DC.23). The diagonal degree-zero summand in (DC.19) belongs to the joint face $S = \{+, -\}$. Under (DC.18), the plus-only source is exactly the subspace $\{(u, 0)\}$, and the minus-only source is exactly $\{(-v, v)\}$. On these subspaces the differential is respectively Θu and $-\Theta v$, so each one-leg complex has $H^0 = 0$ and $H^1 = \mathcal{M}$. These are the specified restrictions of the cochain maps; no joint-face diagonal is added to a one-leg face. On each such original support fibre the restricted linear maps lift by $(S, v) \mapsto (S, f(v))$ and external $\tau \mapsto \tau$, as in (OCQ.34). Thus a killed vector lands at its supported zero. These exact cochain, coherent, residue, and derived-dual maps retain the actual counterfactual packet throughout; they do not supply a new weight bound or assert the existence of such a zero.

169 Exact arithmetic quotient transport and its unavoidable window defect

This calculation uses the literal four windows of (AT13) and (AW5), the source isometry constructed by (AW9)–(AW10), and the arithmetic observation of (AT2a). The principal-angle calculations (EW.25)–(EW.35c) remain available; the new calculation concerns the arithmetic observation of a repaired source map and the exact operator left in its intertwining identity.

169.1 The retained source, forms, and arithmetic maps

Fix an actual full packet polynomial h of $g = 2\xi$, an integer $k \geq 1$, and the original cyclic annihilator $\chi = \chi_{h,k}$, monic of degree $q \geq 1$. Retain

$$E = \mathbb{C}[S]/(\chi), \quad E_h = \mathbb{C}[s]/(h), \quad H = \mathbb{C}[S]_{\leq 2q}, \quad S(u) = k/2 + iu. \quad (\text{QT.1})$$

The increasing-power remainder coordinates of E are fixed. The actual arithmetic injection, including its full Taylor unit, is

$$\begin{aligned} \eta : E &\longrightarrow E_h^{\otimes k}, & \eta[P] &= v_h^{\otimes k} P(A_h^{(k)})1, \\ v_h &= j_h(g/h), & Q_{\text{ar}} &= \mathcal{B}/\Theta V, \\ \mathcal{I} &= \sigma_h^{\otimes k} \eta : E \hookrightarrow Q_{\text{ar}}^{\otimes k}, & \mathcal{O} = \mathcal{I}J : H &\longrightarrow Q_{\text{ar}}^{\otimes k}. \end{aligned} \quad (\text{QT.2})$$

Here $A_h^{(k)}$ is the original tensor-sum multiplication operator, J is literal remainder modulo χ , j_h takes the full Taylor remainder modulo h , and $\sigma_h : E_h \hookrightarrow Q_{\text{ar}}$ is the original section. Both injections in (QT.2) are the source constructions of (AT2)–(AT2a), not new choices. In particular no nilpotent Taylor coefficient of h , χ , or v_h is discarded. The target is the top cohomology of the original tensor pushforward over $\mathbf{F}_{1,\tau} = \{\tau, 1\}$, with one-factor complex $[V \oplus V \longrightarrow \mathcal{B}]$ and differential $(\phi, \psi) \mapsto \Theta(\phi - \hat{\psi})$.

Use precisely the two densities

$$\begin{aligned} m_1 &= w_h^{*k}, & w_h(u) &= \frac{|(g/h)(1/2 + iu)|^2}{2\pi}, \\ m_0(u) &= \frac{(\sqrt{2\pi})^k |\Gamma(k/4 + iu/2)|^2}{c_{k/4} 2\pi}, & c_a &= 2^{1-2a} \Gamma(2a), \\ m_t &= (1-t)m_0 + tm_1, \quad 0 \leq t \leq 1, & v(u) &= (1, S(u), \dots, S(u)^{2q}), \\ M(t) &= \int_{\mathbb{R}} v(u)^* v(u) m_t(u) du. \end{aligned} \quad (\text{QT.3})$$

These densities have the positive almost-everywhere property and all finite polynomial moments proved in the supplied AT sources. Their masses are retained: $\int m_t = (1-t)(2\pi)^{k/2} + t\mu_h^k$, where $\mu_h = \int w_h$. All orthogonality, operator adjoints, singular values, and Hilbert–Schmidt norms below use the positive form $\langle x, y \rangle_t = x^* M(t) y$. For operators on H , write $Z^\sharp = M^{-1} Z^* M$ and $\|Z\|_{\text{HS},t}^2 = \text{Tr}(Z^\sharp Z)$. For maps between its orthogonal subspaces, the same notation uses their restricted forms. A star on a coefficient matrix means its ordinary conjugate transpose.

At a fixed t , put

$$\begin{aligned} F &= \chi \mathbb{C}[S]_{\leq q} = \ker J, & K &= F^\perp, & L &= \mathbb{C}[S]_{\leq q-1}, \\ Q &= P_F, & \Pi &= I - Q = P_K, & P &= P_L, \\ s : E &\longrightarrow L \subset H, & s[P] &= \text{the degree} < q \text{ remainder}, \\ R &= R_{2q}(t) = \Pi s, & G &= R^* M R, & G_\ell &= s^* M s. \end{aligned} \quad (\text{QT.4})$$

The symbol P_X denotes the orthogonal projection onto the specified subspace X . Monic division gives the literal algebraic direct sum $H = L \oplus F$; it does not declare these two subspaces orthogonal. The minimum-section formula (AT6) proves $JR = I_E$ and $\Pi = RJ$. Thus $R : (E, G) \rightarrow K$ is an isometry with inverse $J|_K$. The low-degree Gram is $G_\ell = G_{q-1}(t)$.

Retain U, W, T exactly as in (AW5)–(AW10). Those source formulas prove

$$\begin{aligned} T^\sharp T = TT^\sharp = I, \quad UT = TW, \quad TL = K, \quad T(L^\perp) = F, \\ U|_K = 0, \quad I_F \preceq U_F := U|_F \preceq 2I_F. \end{aligned} \quad (\text{QT.5})$$

The eigenvalues of U_F are 1, 1 and $q - 1$ copies of 2. For $q = 1$, they are just 1, 1. In the orthogonal decomposition $H = K \oplus F$, define its fully typed blocks by

$$T = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad a : K \rightarrow K, \quad b : F \rightarrow K, \quad c : K \rightarrow F, \quad d : F \rightarrow F. \quad (\text{QT.6})$$

In particular $\Pi T = TP$.

169.2 An invertible repair preserving every arithmetic coefficient

Both square diagonal blocks in (QT.6) are invertible. Indeed, if $ax = 0$ for $x \in K$, then $Tx \in F = T(L^\perp)$, so $x \in K \cap L^\perp = (F + L)^\perp = 0$. If $dy = 0$ for $y \in F$, then $Ty \in K = TL$, so $y \in F \cap L = 0$. These are injective endomorphisms of finite spaces, hence bijective.

Define

$$X = QT + \Pi = \begin{pmatrix} I_K & 0 \\ c & d \end{pmatrix}, \quad X^{-1} = \begin{pmatrix} I_K & 0 \\ -d^{-1}c & d^{-1} \end{pmatrix}. \quad (\text{QT.7})$$

Multiplying these displayed block matrices gives both inverse identities. Since $JQ = 0$ and $J\Pi = J$, they obey

$$JX = J, \quad JX^{-1} = J, \quad \mathcal{O}X = \mathcal{O}, \quad \mathcal{O}X^{-1} = \mathcal{O}. \quad (\text{QT.8})$$

These are equalities in the original target, before changing its presentation. For every original coefficient operator B on that target for which the composition is defined, $B\mathcal{O}X = B\mathcal{O}$. This statement does not require B to preserve the cyclic subspace $\mathcal{I}(E)$. On that cyclic subspace the induced map of X is exactly I_E ; it therefore commutes with every multiplication $f(A_\chi)$, where A_χ is multiplication by S on E and $f \in \mathbb{C}[S]$. The complete arithmetic unit in (QT.2) remains in both sides. At any nonempty original support label A , the lift is $(A, x) \mapsto (A, Xx)$, and $\tau \mapsto \tau$. Consequently the two supported arithmetic coefficients coincide at that label, including supported zero; no supported zero is replaced by τ .

Moreover, X is the unique linear map nearest to T , in the original Hilbert–Schmidt norm, among all maps Z satisfying $\mathcal{O}Z = \mathcal{O}$. Indeed injectivity of $\mathcal{I}$ gives $JZ = J$, equivalently $\Pi Z = \Pi$. Such a Z has top block $(I_K, 0)$, whereas its lower block is unconstrained. Orthogonality of the two output summands gives the exact identity

$$\|Z - T\|_{\text{HS},t}^2 = \|I_K - a\|_{\text{HS},t}^2 + \|b\|_{\text{HS},t}^2 + \|\mathcal{Q}(Z - T)\|_{\text{HS},t}^2. \quad (\text{QT.9})$$

Its last summand vanishes precisely for $Z = X$. Unitarity gives $\|a\|_{\text{HS},t}^2 + \|b\|_{\text{HS},t}^2 = q$, and hence

$$\|X - T\|_{\text{HS},t}^2 = 2q - 2 \operatorname{Re} \operatorname{Tr}_K a. \quad (\text{QT.10})$$

Every map and inverse constructed here is smooth in t : the source Grams, their positive inverses, and the fixed-phase Gram–Schmidt construction of T are smooth on the compact parameter interval.

169.3 The exact quotient contraction and its original metric

For comparison, the unique nearest linear map to T that merely preserves F is

$$Y = T - \Pi T Q = \begin{pmatrix} a & 0 \\ c & d \end{pmatrix}. \quad (\text{QT.11})$$

The same orthogonal-block minimization proves this assertion: preserving F forces precisely the upper-right block to be zero. It is invertible since a, d are. Its quotient action is the explicit invertible map $\mathfrak{a} = JTR : E \rightarrow E$.

Here its entire original-metric contraction can be calculated. Put $\mathfrak{w} = JTs : E \rightarrow E$. Because $Ts(E) = K$, $Ts = R\mathfrak{w}$; the isometry of T therefore gives $\mathfrak{w}^*G\mathfrak{w} = G_\ell$. Also $s^*MR = G$, since $s - R$ is relation-valued and orthogonal to $R(E)$. The projection formula onto $L = s(E)$ is $P = sG_\ell^{-1}s^*M$, so $PR = sG_\ell^{-1}G$. Using $\Pi T = TP$ yields all of the following exact identities:

$$\mathfrak{a} = \mathfrak{w}G_\ell^{-1}G, \quad \mathfrak{a}^*G\mathfrak{a} = GG_\ell^{-1}G, \quad \mathfrak{a}^\sharp G\mathfrak{a} = G_\ell^{-1}G, \quad \mathfrak{a}^\sharp G = G^{-1}\mathfrak{a}^*G. \quad (\text{QT.12})$$

No basis diagonalization or deletion of multiplicities entered these identities. In particular

$$\begin{aligned} \ell(t) &:= \|b\|_{\text{HS},t}^2 = \|c\|_{\text{HS},t}^2 = q - \text{Tr}(G_\ell^{-1}G), \\ |\det X|^2 &= |\det d|^2 = \det(\mathfrak{a}^\sharp \mathfrak{a}) = \frac{\det G}{\det G_\ell}. \end{aligned} \quad (\text{QT.13})$$

For the first line, the diagonal blocks of $TT^\sharp = I$ and $T^\sharp T = I$ respectively give $aa^\sharp + bb^\sharp = I_K$ and $a^\sharp a + c^\sharp c = I_K$. Take traces and then use (QT.12). For the second line, triangularity of X gives $\det X = \det d$. The identities $dd^\sharp = I_F - cc^\sharp$ and $a^\sharp a = I_K - c^\sharp c$ show that their determinants coincide: the nonzero eigenvalues of $cc^\sharp$ and $c^\sharp c$, with their multiplicities, coincide, because for any eigenvalue $\lambda > 0$, c and $\lambda^{-1}c^\sharp$ are inverse maps between the corresponding eigenspaces. The extra dimension of F contributes the eigenvalue one after subtracting from its identity. Finally take determinants in (QT.12).

The repair's source-energy change is also exact, for every $z \in H$:

$$\|Xz\|_t^2 - \|z\|_t^2 = \|\Pi z\|_t^2 - \|\Pi Tz\|_t^2. \quad (\text{QT.14})$$

Indeed $Xz = QTz + \Pi z$ has orthogonal summands, whereas the isometry gives $\|z\|_t^2 = \|QTz\|_t^2 + \|\Pi Tz\|_t^2$. Thus its nonunitarity is a calculated source energy, while its arithmetic class is unchanged by (QT.8).

169.4 A positive original-moment obstruction and a sharp repair minimum

Write $\chi(S) = \sum_{j=0}^q \alpha_j S^j$, and put

$$\chi^\dagger(S) = \sum_{j=0}^q \overline{\alpha_j}(k - S)^j, \quad v = \chi\chi^\dagger \in F, \quad \beta(t) = \frac{\left(\int_{\mathbb{R}} |\chi(S(u))|^2 m_t(u) du\right)^2}{\left(\int_{\mathbb{R}} m_t(u) du\right) \left(\int_{\mathbb{R}} |\chi(S(u))|^4 m_t(u) du\right)}. \quad (\text{QT.15})$$

These are the literal reflected polynomial and relation of (CR7). All displayed integrals are finite. Both denominator factors and the numerator are strictly positive, because a nonzero polynomial has finitely many zeros on the line and $m_t > 0$ almost everywhere. On that line $k - S = \overline{S}$, so $\langle 1, v \rangle_t = \int |\chi|^2 m_t > 0$. As $1 \in L$, orthogonal projection followed by Cauchy-Schwarz gives

$$\|Pv\|_t^2 \geq \frac{|\langle 1, v \rangle_t|^2}{\|1\|_t^2}.$$

Since $v \in F$ and $bv = \Pi T v = T P v$, isometry of T implies $\|bv\|_t = \|Pv\|_t$. The operator norm of b is at most its Hilbert–Schmidt norm. Dividing the preceding inequality by $\|v\|_t^2 = \int |\chi|^4 m_t$ proves the explicit floor

$$0 < \beta(t) \leq \ell(t). \quad (\text{QT.16})$$

It also proves $L \neq K$, directly on the original density.

The two retained windows have a nonzero intertwining defect after any arithmetic-class-preserving repair. More precisely,

$$UX - XW = -\Pi W, \quad \min_{OZ=O} \|UZ - ZW\|_{\text{HS},t}^2 = \|\Pi W\|_{\text{HS},t}^2 =: \nu(t)^2. \quad (\text{QT.17})$$

To prove the first equality, $UQ = U$, $U\Pi = 0$, and $UT = TW$ give $UX = TW$. Since $\Pi TW = \Pi UT = 0$, one also has $XW = QTW + \Pi W = TW + \Pi W$. For any competing Z , (QT.8)’s argument gives $\Pi Z = \Pi$. Then $\Pi(UZ - ZW) = -\Pi W$, since $\Pi U = 0$. Orthogonality of output components proves its squared norm is at least $\|\Pi W\|_{\text{HS},t}^2$, and X attains it.

This minimum has its complete arithmetic quotient expression:

$$\begin{aligned} \nu(t)^2 &= \text{Tr}(G^{-1} R^* M W^2 R) = \text{Tr}_K(c^\sharp U_F^2 c), \\ 0 < \beta(t) &\leq \ell(t) \leq \nu(t)^2 \leq 4\ell(t). \end{aligned} \quad (\text{QT.18})$$

For the first trace, use $\Pi = R G^{-1} R^* M$, which is the orthogonal projection formula from (QT.4), and $\|\Pi W\|_{\text{HS},t}^2 = \text{Tr}(\Pi W^2)$. For the second, $W = T^\sharp U T$, hence the K, K block of $W^2 = T^\sharp U^2 T$ is $c^\sharp U_F^2 c$. Finally (QT.5) gives $I_F \preceq U_F^2 \preceq 4I_F$; taking traces after the congruence by c and using (QT.13), (QT.16) proves every inequality.

In fact there is no invertible F -preserving operator Z with $UZ = ZW$, even if its induced quotient map is allowed to change. An invertible such Z has $Z^{-1}F = F$. The purported intertwining and $\text{im } U = F$ would give $\text{im } W = Z^{-1}F = F$. But (AW7)–(AW10) give $\text{im } W = L^\perp$. Thus $F = L^\perp$ and $K = L$, contradicting the original positive pairing just proved. This obstruction does not stop the construction: (QT.7), (QT.17), and the next subsection give an invertible exact quotient repair, its attained optimal defect, and its full effect on the signed arithmetic calculation.

169.5 Square-zero conjugation error and the signed arithmetic bound

The repaired intertwining has an especially explicit conjugation form:

$$XW X^{-1} = U + \mathcal{N}, \quad \mathcal{N} = \Pi W X^{-1} = \begin{pmatrix} 0 & c^\sharp U_F \\ 0 & 0 \end{pmatrix}, \quad \mathcal{N}^2 = 0, \quad \|\mathcal{N}\|_{\text{HS},t}^2 = \nu(t)^2. \quad (\text{QT.19})$$

Indeed $W = T^\sharp U T$ gives its complete two-by-two blocks

$$W = \begin{pmatrix} c^\sharp U_F c & c^\sharp U_F d \\ d^\sharp U_F c & d^\sharp U_F d \end{pmatrix}.$$

Multiply its top row by X^{-1} in (QT.7): the first entry is $c^\sharp U_F c - c^\sharp U_F d d^{-1} c = 0$, and the second is $c^\sharp U_F d d^{-1} = c^\sharp U_F$. This proves the displayed matrix, its square-zero property, and its norm equality by (QT.18). Its range is in K and it vanishes on K ; its nonzero arithmetic output on suitable relation vectors has not been suppressed.

Write

$$\mathcal{C}(t) = M(t)^{-1}(M(1) - M(0)), \quad \mathcal{E}(t) = \text{Re Tr}(W X^{-1}[\mathcal{C}, X]), \quad [\mathcal{C}, X] = \mathcal{C}X - X\mathcal{C}. \quad (\text{QT.20})$$

The original four-window value is $\mathcal{B}(t) = \log(V_{q-1}(t)V_q(t)/(V_{2q-1}(t)V_{2q}(t)))$, where $V_j = \det G_j$ uses the unchanged minimum quotient Grams. The exact signed formula (AT15) now becomes

$$\begin{aligned} \dot{\mathcal{B}}(t) &= \mathcal{E}(t) - \text{Re Tr}(\mathcal{N}\mathcal{C}), \\ \Delta \mathcal{B} &= \int_0^1 \mathcal{E}(t) dt - \int_0^1 \text{Re Tr}(\mathcal{N}(t)\mathcal{C}(t)) dt. \end{aligned} \quad (\text{QT.21})$$

For the first identity, substitute $U = XW X^{-1} - \mathcal{N}$ from (QT.19) into $\dot{\mathcal{B}} = \text{Tr}((U - W)\mathcal{C})$. Cyclicity of the finite trace transforms its first two terms into $\text{Tr}(W X^{-1}[\mathcal{C}, X])$. The left-hand side is real, so taking real parts gives exactly (QT.21). Integrating its smooth functions proves the second identity. This repaired commutator preserves $\mathcal{O}$ exactly; the explicit square-zero contribution is the remaining correction.

It is controlled by a particular part of the original arithmetic source energy, rather than by its whole spectral spread. Set

$$e(t)^2 := \text{Tr}\left(G^{-1}\dot{R}^* M \dot{R}\right) = -\frac{1}{2} \text{Tr}(G^{-1}\ddot{G}) \geq 0. \quad (\text{QT.22})$$

Here all dots differentiate the same source interpolation (QT.3). For completeness the AT variation identity gives, with $B : \mathbb{C}[S]_{\leq q} \rightarrow H$ multiplication by χ ,

$$\dot{R} = -B(B^* M B)^{-1} B^*(M(1) - M(0))R = -\mathcal{Q}C R.$$

Substituting this formula into $\dot{R}^* M \dot{R}$ cancels the middle factor $B^* M B$, giving

$$\dot{R}^* M \dot{R} = R^*(M(1) - M(0))B(B^* M B)^{-1} B^*(M(1) - M(0))R.$$

The fully proved second variation (AT7) is minus twice this matrix, which proves (QT.22). Moreover, under the isometry $R : (E, G) \rightarrow K$, $\mathcal{Q}C|_K$ has coefficient map $\mathcal{Q}C R = -\dot{R}$. Thus

$$\|\mathcal{Q}C\Pi\|_{\text{HS},t} = e(t). \quad (\text{QT.23})$$

Only this off-diagonal metric-variation block contributes to $\text{Tr}(\mathcal{N}\mathcal{C})$, since (QT.19) has a single upper-right block. In any orthonormal bases of K, F , the trace is the sum of entrywise products of those two blocks. Cauchy-Schwarz on that finite list, then (QT.19), (QT.23), proves the new quantitative transport estimate

$$|\dot{\mathcal{B}}(t) - \mathcal{E}(t)| \leq \nu(t)e(t) \leq 2\sqrt{\ell(t)}e(t). \quad (\text{QT.24})$$

In particular the error vanishes exactly when $\text{Re Tr}(\mathcal{N}\mathcal{C}) = 0$, and the sufficient condition $e(t) = 0$ does not require the whole relative source operator to be scalar.

Every quantity is continuous on the compact interval. Define the fully specified original-source quantities

$$\mathfrak{E} = \int_0^1 \mathcal{E}(t) dt, \quad \mathfrak{F} = \int_0^1 \nu(t)e(t) dt.$$

Integration, followed by Cauchy-Schwarz for real functions of t , gives

$$|\Delta\mathcal{B} - \mathfrak{E}| \leq \mathfrak{F} \leq \left(\int_0^1 \nu(t)^2 dt\right)^{1/2} \left(-\frac{1}{2} \int_0^1 \text{Tr}(G^{-1}\ddot{G}) dt\right)^{1/2}. \quad (\text{QT.25})$$

This is an interval centered at the actual class-preserving commutator, with an explicitly calculated relation-speed error. It supplements, rather than assumes a sign for, the original signed correction.

To combine with the fully retained AW spectrum, let $b_1 \leq \dots \leq b_{2q+1}$ be the positive eigenvalues of the actual relative source operator $M(0)^{-1}M(1)$, and put

$$\mathfrak{L}_q = \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j}.$$

The sum is empty when $q = 1$. The original proof (AW14) and (QT.25) give simultaneously

$$\max\{-\mathfrak{L}_q, \mathfrak{E} - \mathfrak{F}\} \leq \Delta\mathcal{B} \leq \min\{\mathfrak{L}_q, \mathfrak{E} + \mathfrak{F}\}. \quad (\text{QT.26})$$

This follows by intersecting two intervals both proved for the same unchanged signed value; the second interval keeps the measured quotient-transport defect and the original source-variation energy. None of these expressions treats the arithmetic density or its full Taylor unit as a freely selectable coefficient.

If $M(1) = c_0 M(0)$ with $c_0 > 0$, the source mass retains that literal factor, $\mathcal{C}(t)$ is scalar, and R is constant. Thus $\mathcal{E} = e = \mathfrak{F} = 0$, and (QT.21) gives $\Delta\mathcal{B} = 0$ exactly. The strictly positive obstruction $\nu(t)^2$ to a class-preserving window intertwiner still exists; its contraction with this scalar metric variation is zero. This illustrates why the nonzero source obstruction alone is not a proof of an RH contradiction. Equations (QT.17)–(QT.26) compute its exact contribution on the retained arithmetic programme.

169.6 The literal finite relation complex and its computed homotopy

The repair also acts on the original finite cochain complex, not just on its quotient. Put the two terms in degrees $-1, 0$:

$$\mathcal{C}^{-1} = \mathbb{C}[S]_{\leq q}, \quad \mathcal{C}^0 = H, \quad \partial = B = \times\chi, \quad H_F = B^*MB.$$

These are exactly the $N = 2q$ terms of (AT3), before taking cohomology. Multiplication by the literal monic χ is injective, so H_F is positive definite. Define the three actual coefficient maps

$$\begin{aligned} X_{\text{deg}}^{-1} &:= H_F^{-1}B^*MTB : \mathcal{C}^{-1} \longrightarrow \mathcal{C}^{-1}, & X_{\text{deg}}^0 &:= X : \mathcal{C}^0 \longrightarrow \mathcal{C}^0, \\ K_X &:= H_F^{-1}B^*M(T - I) : \mathcal{C}^0 \longrightarrow \mathcal{C}^{-1}. \end{aligned} \quad (\text{QT.27})$$

The superscript -1 in X_{deg}^{-1} labels cochain degree; it does not denote the inverse operator. The latter exists, as the calculation below also proves. Substituting the original projection $Q = BH_F^{-1}B^*M$ gives every chain and homotopy identity:

$$X_{\text{deg}}^0 B = BX_{\text{deg}}^{-1}, \quad X_{\text{deg}}^0 - I_H = BK_X, \quad X_{\text{deg}}^{-1} - I_{\mathcal{C}^{-1}} = K_X B. \quad (\text{QT.28})$$

For the first equality, $\Pi B = 0$, hence $XB = QT B = BH_F^{-1}B^*MTB$. For the second, $X - I = QT + \Pi - I = Q(T - I) = BK_X$. For the third use $H_F = B^*MB$ directly in (QT.27). These three substitutions prove that the displayed two-term map is a cochain map and that K_X is a cochain homotopy from its identity to that map, with the displayed signs and degrees. Moreover $X(F) = F$ by (QT.7), and $X|_F = d$ is invertible. Since $B : \mathcal{C}^{-1} \rightarrow F$ is an isomorphism, the first equality identifies $X_{\text{deg}}^{-1} = B^{-1}(X|_F)B$, proving its invertibility without using an inverse on the infinite source.

In particular, for every polynomial vector $z \in H$, the change of its original source representative is the literal relation $\chi K_X z$, with its full coefficients given by (QT.27). Composing the original source comparison $\mathcal{V}$ of (AT2) gives $\mathcal{V}Xz - \mathcal{V}z = \mathcal{V}(\chi K_X z)$. The comparison identifies the latter's arithmetic class with $\mathcal{I}J(\chi K_X z) = 0$, using the same full unit $v_h^{\otimes k}$ of (QT.2). Thus the computed finite homotopy and the equality in the original arithmetic target agree under the already constructed source map; no new choice of cohomology section is made here. Every map in (QT.27)–(QT.28) lifts at a nonempty original support label by retaining that label and its displayed coefficient map, with $\tau \mapsto \tau$. Both sides of the homotopy equations therefore agree at each such supported fibre, including its supported zero. This is the exact morphism connecting the repaired source calculation to the relation complex used by the programme.

170 The closest unitary preserving the actual arithmetic observation

The source isometry in AW9–AW10 has a unique closest unitary preserving the original arithmetic observation. This calculation constructs that unitary and proves its exact source-metric cost. It also

computes the coefficient defect of the triangular relation-preserving repair and the positive triangular quotient block forced by the prescribed Gram–Schmidt phases. Every formula retains the original polynomial, arithmetic measure, Taylor unit, relation quotient, and absolute τ base.

170.1 Original objects and forms

Fix $g = 2\xi$, its actual full packet h , the full coefficient algebra $E_h = \mathbb{C}[s]/(h)$, a positive integer k , the exact monic cyclic polynomial $\chi = \chi_{h,k}$ of degree $q \geq 1$, and $t \in [0, 1]$. Retain

$$H = \mathbb{C}[S]_{\leq 2q}, \quad E = \mathbb{C}[S]/(\chi), \quad J = J_{2q} : H \longrightarrow E.$$

Here J is literal remainder in the original increasing-power frame. The original arithmetic observation is

$$\mathcal{O} = \iota J, \quad \iota = \sigma_h^{\otimes k} \eta, \quad \eta[P] = v_h^{\otimes k} P(A_h^{(k)})1, \quad v_h = j_h(g/h) \in E_h^\times.$$

Both η and ι are the original injections; thus $\ker \mathcal{O} = \ker J$. Every Taylor coefficient of the unit remains present.

Write $v_{2q}(u) = (1, S(u), \dots, S(u)^{2q})$. Give H its actual form

$$\langle x, y \rangle_t = x^* M(t) y, \quad M(t) = \int_{\mathbb{R}} v_{2q}(u)^* v_{2q}(u) m_t(u) du, \quad S = k/2 + iu,$$

$$m_t = (1 - t)m_0 + tm_1, \quad m_1 = w_h^{*k}, \quad w_h(u) = \frac{|(g/h)(1/2 + iu)|^2}{2\pi},$$

$$m_0(u) = \frac{(\sqrt{2\pi})^k |\Gamma(k/4 + iu/2)|^2}{c_{k/4} 2\pi}, \quad c_a = 2^{1-2a} \Gamma(2a).$$

With $\mu_h = \int_{\mathbb{R}} w_h(u) du$, the original masses are μ_h^k and $(2\pi)^{k/2}$. Adjoints denoted star below use this form and the induced subspace forms. In the fixed coefficient frame, $Z^* = M^{-1} Z^* M$. Define $\|Z\|_{\text{HS},t}^2 = \text{Tr}(Z^* Z)$.

Set

$$F = \chi \mathbb{C}[S]_{\leq q} = \ker J, \quad K = F^\perp, \quad L = \mathbb{C}[S]_{\leq q-1}, \quad Q = Q_F, \quad \Pi = I - Q. \quad (\text{VR1})$$

Here Q_F is the orthogonal projection onto F in the actual form. Their dimensions are $q + 1, q, q$ respectively. Polynomial division proves $H = L \oplus F$ algebraically: their intersection is zero by degree and their dimensions add to $2q + 1$. No orthogonality is assigned to that direct sum.

Let $s : E \rightarrow L$ be the remainder section, $R = R_{2q} : E \rightarrow K$ the original minimum section, and $G = G_{2q} = R^* M R$. AT6 gives

$$JR = I_E, \quad RJ = \Pi, \quad R^* M p = G J p \quad (p \in H). \quad (\text{VR2})$$

Indeed RJ and Π have image K , kernel F , and equal the identity on K . For the last identity decompose $p = R J p + Q p$ and use $R(E) \perp F$. Thus R is an isometry from the original G -space E to K . Write $G_0 = s^* M s = G_{q-1}$; this subscript denotes the low section, not parameter value zero.

The prescribed AW isometry satisfies

$$T^* T = T T^* = I, \quad T L = K, \quad T L^\perp = F, \quad U = T W T^*, \quad (\text{VR3})$$

with exactly the original window operators U, W . Relative to $H = K \oplus F$ set

$$T = \begin{pmatrix} A & B \\ C & D \end{pmatrix}, \quad A = \Pi T|_K, \quad B = \Pi T|_F, \quad C = Q T|_K, \quad D = Q T|_F. \quad (\text{VR4})$$

Here C is the block $K \rightarrow F$, not the derivative operator of AT/AW.

170.2 Invertible blocks and strict leakage

Multiplication of the two unitarity identities gives

$$\begin{aligned} A^*A + C^*C &= I_K, & AA^* + BB^* &= I_K, \\ D^*D + B^*B &= I_F, & DD^* + CC^* &= I_F, \\ A^*B + C^*D &= 0, & AC^* + BD^* &= 0. \end{aligned} \quad (\text{VR5})$$

Both A, D are invertible. If $Ax = 0$ with $x \in K$, then $Tx \in F$, so $x \in K \cap T^{-1}F = F^\perp \cap L^\perp = (F + L)^\perp = 0$. If $Dy = 0$ with $y \in F$, then $Ty \in K$, so $y \in F \cap T^{-1}K = F \cap L = 0$. Both maps are square maps on their displayed spaces, proving invertibility.

Their singular values lie in $(0, 1]$. Define $|A| = (A^*A)^{1/2}$ and $\text{polar}(A) = A|A|^{-1}$; both are defined because A is invertible. Taking traces in VR5 gives

$$\ell := \|B\|_{\text{HS},t}^2 = \|C\|_{\text{HS},t}^2 = q - \text{Tr}(A^*A). \quad (\text{VR6})$$

In fact $\ell > 0$ on the actual source. For $\chi(S) = \sum_{j=0}^q a_j S^j$, define $\chi^\dagger(S) = \sum_{j=0}^q \overline{a_j}(k - S)^j$. Then $v = \chi\chi^\dagger \in F$ and

$$\langle 1, v \rangle_t = \int_{\mathbb{R}} |\chi(k/2 + iu)|^2 m_t(u) du > 0. \quad (\text{VR7})$$

On the unchanged line $k - S = \overline{S}$, proving the equality. The moment bounds give finiteness; the nonzero polynomial χ has only finitely many zeros on that line, and m_t is positive almost everywhere, giving strict positivity. Thus $1 \in L$ is not in K , so $K \neq L$. If $\ell = 0$ then $B = 0$, so $T(F) = F$ by equal finite dimensions. But $T^{-1}F = L^\perp$ by VR3; hence $F = L^\perp$ and $K = L$, a contradiction.

If $s_1, \dots, s_q$ are all singular values of A , those of D are exactly

$$1, s_1, \dots, s_q. \quad (\text{VR8})$$

For any $\lambda > 0$ the maps B^* and $\lambda^{-1}B$ identify the λ -eigenspaces of BB^* and B^*B . Their nonzero spectra therefore coincide, including multiplicities; the respective dimensions add one zero eigenvalue to the latter. Subtracting from one in $AA^* = I - BB^*$ and $D^*D = I - B^*B$, then taking positive square roots, proves VR8, including rank-deficient B .

170.3 Closest repairs

The unique closest linear map to T under the exact constraint $JX = J$ is

$$X = QT + \Pi = \begin{pmatrix} I_K & 0 \\ C & D \end{pmatrix}. \quad (\text{VR9})$$

Indeed $JY = J$ is equivalent, by multiplication by R , to $\Pi Y = \Pi$. It fixes the upper blocks of Y to $I_K, 0$ and leaves its lower blocks free. The four block spaces are orthogonal in Hilbert–Schmidt inner product, so the unique minimizers of the remaining block errors are C, D . Thus

$$\begin{aligned} d_{\text{lin}}^2 &:= \min_{JY=J} \|Y - T\|_{\text{HS},t}^2 \\ &= \|I_K - A\|_{\text{HS},t}^2 + \|B\|_{\text{HS},t}^2 = 2q - 2 \text{Re Tr } A. \end{aligned} \quad (\text{VR10})$$

The last equality expands the square and uses $AA^* + BB^* = I_K$.

The complete class of exact-observation-preserving unitaries is

$$\{V : V^*V = VV^* = I, JV = J\} = \{I_K \oplus V_F : V_F \text{ unitary on } F\}. \quad (\text{VR11})$$

For $JV = J$ implies $V(F) \subset F$, hence $V(F) = F$. Unitarity then preserves K . For $x \in K, Vx - x \in K$ and $J(Vx - x) = 0$, hence $Vx = x$. Conversely every displayed block map has $JV = J$.

Since D is invertible, $|D| = (D^*D)^{1/2}$ is positive definite and $V_D = D|D|^{-1}$ is unitary on F . The unique closest member of VR11 is

$$V_{\text{obs}} = \Pi + V_D Q = I_K \oplus V_D. \quad (\text{VR12})$$

Only the lower diagonal block varies in the distance, so one maximizes $\text{Re Tr}(V_F^* D)$. Write $Z = V_F^* V_D$, a unitary, and diagonalize $|D|$ in an orthonormal basis with positive eigenvalues d_j . The expression is $\sum_j d_j \text{Re } Z_{jj} \leq \sum_j d_j$. Equality forces $Z_{jj} = 1$ for every j . The unit length of each column then makes its other entries zero, so $Z = I$. This proves attainment and uniqueness.

The exact minimum is

$$\begin{aligned} d_{\text{unit}}^2 &:= \min_{\substack{V^* V = I \\ J V = J}} \|V - T\|_{\text{HS},t}^2 \\ &= d_{\text{lin}}^2 + \|C\|_{\text{HS},t}^2 + \|V_D - D\|_{\text{HS},t}^2 \\ &= d_{\text{lin}}^2 + 2 \text{Tr}_F(I_F - |D|) \\ &= 2q - 2 \text{Re Tr } A + 2q - 2 \text{Tr}_K |A|. \end{aligned} \quad (\text{VR13})$$

The second line adds orthogonal block errors beyond X . For the third, $\|C\|^2 = \text{Tr}(I_F - |D|^2)$ and $\|V_D - D\|^2 = \text{Tr}((I_F - |D|)^2)$. Adding these polynomials gives the stated expression; VR8 gives the last line. Consequently

$$\ell \leq d_{\text{unit}}^2 - d_{\text{lin}}^2 = 2 \sum_{j=1}^q (1 - s_j) \leq 2\ell, \quad d_{\text{unit}}^2 \geq 2\ell > 0. \quad (\text{VR14})$$

Each inequality follows termwise from $1 - s_j^2 \leq 2(1 - s_j) \leq 2(1 - s_j^2)$, with $\ell = \sum_j (1 - s_j^2)$, and from $d_{\text{lin}}^2 \geq \ell$.

If only preservation of F is imposed on the unitary, its two diagonal blocks may vary independently. The same positive-weight trace argument proves that the unique closest one is

$$V_{\text{rel}} = \text{polar}(A) \oplus \text{polar}(D), \quad \|V_{\text{rel}} - T\|_{\text{HS},t}^2 = 4(q - \text{Tr } |A|). \quad (\text{VR15})$$

Its quotient action is the unitary corresponding to $\text{polar}(A)$, not necessarily the identity. The exact extra cost of the entire original observation is

$$d_{\text{unit}}^2 - \|V_{\text{rel}} - T\|_{\text{HS},t}^2 = 2(\text{Tr } |A| - \text{Re Tr } A) \geq 0. \quad (\text{VR16})$$

The last inequality follows from the preceding trace maximization with the identity as a candidate unitary against A .

170.4 AW's specified phases and a determinant bound for the repair cost

This calculation uses the prescribed Gram–Schmidt recursion. Write the positive definite original Grams as

$$G_0 = L_0^* L_0, \quad G = L_G^* L_G, \quad (\text{VR17})$$

with upper triangular Cholesky factors having positive real diagonals. These factors follow directly by the Gram–Schmidt recursion on the ordered remainder monomials: the change matrix is upper triangular with positive diagonal and its orthonormality equation gives VR17. The successive positive norms uniquely determine every entry, proving uniqueness as well.

The prescribed orthonormal frames of L and K are

$$p = sL_0^{-1} : \mathbb{C}^q \longrightarrow L, \quad c = RL_G^{-1} : \mathbb{C}^q \longrightarrow K. \quad (\text{VR18})$$

The preceding triangular uniqueness verifies every Gram–Schmidt phase, and AW10 gives $Tp = c$.

Let $a = JTR : E \rightarrow E$. The matrix of the block A in the K -orthonormal frame c is

$$A_c = c^* T c = p^* c = L_0^{-*} G L_G^{-1} = L_0^{-*} L_G^*. \quad (\text{VR19})$$

Here $c^* T = p^*$ follows from $T^* c = p$, and $s^* M R = G$ follows from VR2. Thus A_c is lower triangular with positive real diagonal entries

$$\lambda_j = (L_G)_{jj} / (L_0)_{jj} \in (0, 1] \quad (1 \leq j \leq q). \quad (\text{VR20})$$

Their upper bound follows because they are eigenvalues of the contraction A . Hence $\text{Tr } A$ is positive real, and

$$\det a = \det A_c = \frac{\det L_G}{\det L_0} = \sqrt{\frac{\det G}{\det G_0}} > 0. \quad (\text{VR21})$$

The square root is positive, forced by the actual AW phases. Since L_G identifies the original remainder frame with the c -frame, its full original-frame matrix is

$$a = L_G^{-1} A_c L_G = L_G^{-1} L_0^{-*} G. \quad (\text{VR22})$$

Define the actual two-endpoint quantity

$$\beta = \log \frac{\det G_0}{\det G} = \log \frac{V_{q-1}(t)}{V_{2q}(t)}. \quad (\text{VR23})$$

It is strictly positive. Indeed least-norm minimization gives $G \leq G_0$ and $G_0 - G = s^* M Q s$. Equality would imply $Q s = 0$, hence $L = K$, contradicting VR7. Thus $G_0^{-1/2} G G_0^{-1/2}$ has all eigenvalues in $(0, 1]$ with at least one smaller than one; its determinant is strictly smaller than one.

The positive λ_j have product $e^{-\beta/2}$, as do the positive singular values s_j . The arithmetic-geometric mean inequality gives $\text{Tr } A \geq q e^{-\beta/(2q)}$ and $\text{Tr } |A| \geq q e^{-\beta/(2q)}$. To recall a proof without an extra hypothesis, among nonnegative q -tuples $(z_1, \dots, z_q)$ with a fixed sum the product has a maximum by compactness. Since the target product is positive, zero entries are excluded at the maximum. Replacing two unequal entries x, y by their common mean increases their product by $(x-y)^2/4$ while preserving the other factors and the sum. Thus every maximizing entry is equal, proving $\prod_{j=1}^q z_j \leq (q^{-1} \sum_{j=1}^q z_j)^q$. Applying this to the two actual positive lists proves

$$\begin{aligned} 0 < d_{\text{lin}}^2 &= 2(q - \text{Tr } A) \leq 2q(1 - e^{-\beta/(2q)}), \\ 2\ell &\leq d_{\text{unit}}^2 = 4q - 2 \text{Tr } A - 2 \text{Tr } |A| \leq 4q(1 - e^{-\beta/(2q)}). \end{aligned} \quad (\text{VR24})$$

These estimates retain the prescribed AW phase. An abstract unitary intertwiner with arbitrary phase on its zero eigenspace could change $\text{Tr } A$ while retaining its singular values; VR19 removes that ambiguity for the actual T .

For $q = 1$, A is the positive scalar $\sqrt{G/G_0}$, and the formulas reduce exactly to $d_{\text{lin}}^2 = 2(1 - \sqrt{G/G_0})$ and $d_{\text{unit}}^2 = 4(1 - \sqrt{G/G_0})$, retaining the original norms in AW19.

170.5 Full coefficient action and the exact defect

For $f \in E$ let $m_f : E \rightarrow E$ be multiplication by the full residue class f , including all nilpotents. The original full-jet action obeys

$$\eta m_f = f(A_h^{(k)}) \eta. \quad (\text{VR25})$$

Both sides on $[P]$ equal the full coefficient $v_h^{\otimes k} f(A_h^{(k)}) P(A_h^{(k)}) 1$; the Taylor unit commutes with these polynomial actions in the same commutative tensor coefficient algebra. The annihilating relation χ makes the expression independent of representatives.

The relation-preserving triangular repair

$$Y_{\text{rel}} = T - \Pi T Q = \begin{pmatrix} A & 0 \\ C & D \end{pmatrix} \quad (\text{VR26})$$

is invertible because A, D are. It has the exact quotient and arithmetic actions

$$JY_{\text{rel}} = aJ, \quad \mathcal{O}Y_{\text{rel}} = \iota aJ. \quad (\text{VR27})$$

Its value on $R(E)$ is TR , so its induced quotient map is $a = JTR$; its value on F stays in F . This proves the first identity on the direct sum $R(E) \oplus F$, and the second follows by ι .

The coefficient-equivariance defect is exactly

$$\eta(am_f - m_fa) = \eta am_f - f(A_h^{(k)})\eta a. \quad (\text{VR28})$$

It vanishes for every f if and only if a is multiplication by $a(1)$: commutation gives $a(f) = a(m_f 1) = m_fa(1) = fa(1)$, and multiplication by a fixed element conversely commutes with every m_f . Since E is generated by $[S]$, it is equivalent to the single matrix identity

$$am_{[S]} - m_{[S]}a = 0. \quad (\text{VR29})$$

Commutation with the generator implies commutation with its powers by induction and with every polynomial by linearity. Thus VR22 and the literal full companion multiplication matrix compute the entire defect, without replacing E by its reduced root algebra. No unsupported assertion that this actual commutator vanishes or is nonzero is made.

For a fully typed source formula define $\rho_f = Rm_f J : H \rightarrow H$. Then

$$J[T, \rho_f]R = am_f - m_fa. \quad (\text{VR30})$$

This follows by substitution of $JR = I$. Its identity element acts by $\rho_1 = \Pi$, so this extension by zero is not asserted to be a unital action on all H . On the canonical image K it is precisely the unital original coefficient action.

The closest observation-preserving unitary satisfies

$$JV_{\text{obs}} = J, \quad \mathcal{O}V_{\text{obs}} = \mathcal{O}, \quad V_{\text{obs}}R = R, \quad V_{\text{obs}}\rho_f = \rho_f V_{\text{obs}} = \rho_f \quad (f \in E). \quad (\text{VR31})$$

Its identity block on K proves the first three equalities; their substitution in $Rm_f J$ proves the last. It therefore preserves the full arithmetic coefficient action on the original canonical quotient, with every nilpotent and the full Taylor unit. There is no claim of commutation for an undefined degree-truncated source multiplication.

The contraction of a has the exact original G -energy

$$\|x\|_G^2 - \|ax\|_G^2 = \|CRx\|_t^2 = \|QTRx\|_t^2 \quad (x \in E). \quad (\text{VR32})$$

Indeed $\Pi TRx = Rax$ and $QTRx = CRx$ are orthogonal, T is an isometry, and R is the original G -isometry. Thus, in the original remainder frame,

$$G - a^*Ga = R^*T^*MQTR \succeq 0, \quad \ell = \text{Tr}(G^{-1}(G - a^*Ga)). \quad (\text{VR33})$$

The first identity is the just-proved norm identity with $Q^*Q = Q$; the trace equality transports C^*C by R .

170.6 No invertible relation-preserving exact intertwiner

There is no invertible $Z : H \rightarrow H$ with $Z(F) \subset F$ and $UZ = ZW$. For invertibility gives $Z(F) = F$ and $Z^{-1}(F) = F$. Since $\text{im } U = F$ from AW7–AW8, $ZW(H) = UZ(H) \subset F$, so $W(H) \subset Z^{-1}(F) = F$. But AW7 on the original polynomial flag gives $\text{im } W = L^\perp$, which has the same dimension $q + 1$ as F . Hence $F = L^\perp$ and $K = L$, contradicting VR7. This proof does not assume Z is unitary.

Consequently exact window intertwining on this actual source cannot coexist with an invertible map preserving the original relation quotient. The explicit VR9, VR12 and VR26 maps instead compute each available correction, its full quotient action, its original-metric energy, and the exact coefficient defect.

At each fixed nonempty support label A_0 all displayed linear maps lift by $(A_0, x) \mapsto (A_0, Zx)$, with external τ sent to τ . Their zero outputs remain supported zero coefficients at A_0 . In particular $\mathcal{O}V_{\text{obs}} = \mathcal{O}$ preserves the supported arithmetic observation and does not identify a supported zero with the external basepoint.

171 Actual boundary tilts and uniform convolution tails

This calculation retains the original arithmetic density and the complete hypothetical actual quartet. It does not replace that density with a reference measure. The estimates do not assume RH or a pointwise lower bound for zeta.

171.1 1. Objects and the exact retained expression

Fix $0 < \delta < 1/2$, $\gamma > 0$, and an integer $m \geq 1$, and suppose the selected full-order quartet is a quartet of zeros of the original $g = 2\xi$. Its monic polynomial is

$$h(s) = \prod_{\epsilon, \eta \in \{-1, 1\}} (s - \tfrac{1}{2} - \epsilon\delta - i\eta\gamma)^m, \quad \deg h = 4m. \quad (\text{BT1})$$

The entire function g/h , its original Taylor unit, source maps, and measure remain unchanged:

$$w_h(t) = \frac{|(g/h)(1/2 + it)|^2}{2\pi}, \quad \alpha = \frac{\pi}{2}, \quad R_0 = \sqrt{\delta^2 + \gamma^2}. \quad (\text{BT2})$$

The original completion formula gives, exactly,

$$\begin{aligned} w_h(t) &= \frac{(t^2 + 1/4)^2}{\sqrt{\pi}} \frac{|\zeta(1/2 + it)|^2}{|h(1/2 + it)|^2} \sigma(t), \\ \sigma(t) &= \frac{|\Gamma(1/4 + it/2)|^2}{2\pi}, \\ |h(1/2 + it)|^2 &= [((t - \gamma)^2 + \delta^2)((t + \gamma)^2 + \delta^2)]^{2m}. \end{aligned} \quad (\text{BT3})$$

The two factors with each fixed imaginary sign contribute a minus sign before multiplication, so their product is the positive expression in the last line. Every denominator in (BT3) is positive. Conjugation of the original g and the real coefficients of h give $w_h(-t) = w_h(t)$.

171.2 2. A centered partial-sum bound from the original floor formula

For every integer $N \geq 1$, initially for $\Re s > 1$,

$$\zeta(s) = \sum_{n=1}^N n^{-s} + \frac{N^{1-s}}{s-1} - s \int_N^\infty \{x\} x^{-s-1} dx. \quad (\text{BT4})$$

To verify (BT4), integrate the constant value $\lfloor x \rfloor$ on each interval $[n, n+1)$, or telescope integration by parts of the absolutely convergent tail. The last integral is absolutely and locally uniformly convergent for $\Re s > 0$, so the identity continues to that half-plane with $s \neq 1$.

Let $B_1(x) = \{x\} - 1/2$, so $|B_1(x)| \leq 1/2$. The identity $\int_N^\infty x^{-s-1} dx = N^{-s}/s$ gives exactly

$$\zeta(s) = \sum_{n=1}^{N-1} n^{-s} + \frac{1}{2}N^{-s} + \frac{N^{1-s}}{s-1} - s \int_N^\infty B_1(x)x^{-s-1} dx. \quad (\text{BT5})$$

No asymptotic remainder is substituted here.

On $s = 1/2 + it$, put $\varrho = \sqrt{t^2 + 1/4}$, which is both $|s|$ and $|s-1|$. For $N \geq 2$,

$$\sum_{n=1}^{N-1} n^{-1/2} + \frac{1}{2}N^{-1/2} \leq 2\sqrt{N-1} - 1 + \frac{1}{2\sqrt{N}} \leq 2\sqrt{N} - 1.$$

The first inequality follows from the integral bound for the decreasing function $x^{-1/2}$. For the second, $2(\sqrt{N} - \sqrt{N-1}) = 2/(\sqrt{N} + \sqrt{N-1}) \geq 1/\sqrt{N}$. At $N = 1$, the same asserted inequality holds directly, with left side $1/2$. The absolute integral in (BT5), before its multiplier s , is at most $\frac{1}{2} \int_N^\infty x^{-3/2} dx = N^{-1/2}$. Therefore

$$|\zeta(1/2 + it)| \leq 2\sqrt{N} - 1 + \frac{\sqrt{N}}{\varrho} + \frac{\varrho}{\sqrt{N}} \quad (t \in \mathbb{R}, N \geq 1). \quad (\text{BT6})$$

The infimum over these explicitly specified integer choices is also a bound.

For $x = |t| \geq 1$, choose $N = \lfloor x \rfloor$. Then

$$x/2 \leq N \leq x, \quad \varrho \leq \frac{\sqrt{5}}{2}x, \quad \frac{\sqrt{N}}{\varrho} \leq x^{-1/2}.$$

Since $-1 + x^{-1/2} \leq 0$, (BT6) yields

$$|\zeta(1/2 + it)| \leq Z_* \sqrt{|t|} \quad (|t| \geq 1), \quad Z_* = 2 + \sqrt{5/2}. \quad (\text{BT7})$$

This improves the polynomial exponent in the uncentered estimate used in TG.15. It is not a claim that (BT7) is the strongest known zeta bound. On the whole real line the original $N = 1$ uncentered formula gives independently

$$|\zeta(1/2 + it)| \leq 1 + 2\sqrt{t^2 + 1/4}. \quad (\text{BT8})$$

171.3 3. Explicit two-sided Gamma bounds

The complete Binet calculation included below proves

$$c_\Gamma e^{-\alpha|t|}(1+|t|)^{-1/2} \leq \sigma(t) \leq C_\Gamma e^{-\alpha|t|}(1+|t|)^{-1/2} \quad (t \in \mathbb{R}), \quad (\text{BT9})$$

where

$$c_\Gamma = \sqrt{2}e^{-7/6}, \quad C_\Gamma = \sqrt{2\sqrt{5}}e^{2/3}. \quad (\text{BT10})$$

For completeness, its exact starting identity for $\Re z > 0$ is

$$\log \Gamma z = (z - \tfrac{1}{2}) \log z - z + \tfrac{1}{2} \log(2\pi) + R(z), \quad R(z) = \int_0^\infty e^{-zu} \left(\frac{1}{e^u - 1} - \frac{1}{u} + \frac{1}{2} \right) \frac{du}{u}.$$

The logarithmic branch is the one real on the positive real axis. The kernel is $(\coth x - 1/x)/(4x)$, with $x = u/2 > 0$. Define

$$F(x) = x \cosh x - \sinh x, \quad G(x) = (x^2 + 3) \sinh x - 3x \cosh x.$$

Both vanish at zero, and $F'(x) = x \sinh x \geq 0$, $G'(x) = xF(x) \geq 0$. Dividing their nonnegative values by the appropriate positive factors gives $0 \leq \coth x - 1/x \leq x/3$. Thus the kernel lies between zero and $1/12$. At $z = 1/4 + it/2$, integration of $e^{-u/4}/12$ proves $|R(z)| \leq 1/3$.

Twice the real part of Binet's identity, with $x = |t|$, gives exactly

$$\sigma(t) = |z|^{-1/2} \exp[-x \arctan(2x) - 1/2 + 2\Re R(z)].$$

For $x > 0$,

$$-x \arctan(2x) - \frac{1}{2} = -\alpha x + x \arctan(1/(2x)) - \frac{1}{2} \leq -\alpha x,$$

because $\arctan v \leq v$ for $v \geq 0$. At $x = 0$, the same inequality is $-1/2 \leq 0$. The lower bound uses $\arctan(2x) \leq \pi/2$. Hence the full exponent is between $-\alpha x - 7/6$ and $-\alpha x + 2/3$, including zero.

Finally $|z|^2 = 1/16 + x^2/4$, and the exact squared differences

$$\frac{(1+x)^2}{4} - |z|^2 = \frac{3+8x}{16}, \quad |z|^2 - \frac{(1+x)^2}{20} = \frac{(4x-1)^2}{80}$$

give

$$\sqrt{2}(1+x)^{-1/2} \leq |z|^{-1/2} \leq \sqrt{2\sqrt{5}}(1+x)^{-1/2}.$$

These prove (BT9)–(BT10) with no unproved Stirling remainder and no unquantified compact Gamma minimum.

171.4 4. A global explicit actual boundary-tilt bound

Set

$$p = 8m - \frac{9}{2}, \quad \beta = p - \frac{1}{2} = 8m - 5, \quad T_h = \max(1, 2R_0). \quad (\text{BT11})$$

Then $p \geq 7/2 > 1$ and $\beta > 0$. Define

$$\begin{aligned} C_{\text{comp}} &= \frac{C_\Gamma}{\sqrt{\pi}} (T_h^2 + 1/4)^2 [1 + 2\sqrt{T_h^2 + 1/4}]^2 \delta^{-8m} (1 + T_h)^\beta, \\ C_{\text{tail}} &= \frac{25C_\Gamma Z_*^2}{16\sqrt{\pi}} \left(\frac{4}{3}\right)^{4m} \left(1 + \frac{1}{T_h}\right)^\beta, \\ C_h^{\text{tilt}} &= \max(C_{\text{comp}}, C_{\text{tail}}). \end{aligned} \quad (\text{BT12})$$

These constants are explicit in the fixed quartet and elementary constants. None is an unevaluated zeta supremum, and none changes the source mass.

For $|t| \leq T_h$, (BT3) has $|h(1/2 + it)|^2 \geq \delta^{8m}$. Apply (BT8) and the upper inequality of (BT9). Multiplying by $e^{\alpha|t|}(1+|t|)^p$ leaves the factor $(1+|t|)^\beta$; bounding $|t|$ by T_h proves the constant C_{comp} .

For $x = |t| \geq T_h$, retain the exact identity

$$((t - \gamma)^2 + \delta^2)((t + \gamma)^2 + \delta^2) = (t^2 - R_0^2)^2 + 4\delta^2 t^2 \geq \frac{9}{16} t^4. \quad (\text{BT13})$$

The last inequality uses $t^2 \geq 4R_0^2$. Thus

$$|h(1/2 + it)|^2 \geq (3/4)^{4m} x^{8m}, \quad (t^2 + 1/4)^2 \leq (25/16)x^4.$$

Applying (BT7) and (BT9) to (BT3) gives

$$e^{\alpha x} w_h(t) \leq \frac{25C_\Gamma Z_*^2}{16\sqrt{\pi}} \left(\frac{4}{3}\right)^{4m} x^{5-8m} (1+x)^{-1/2}.$$

Multiplication by $(1+x)^p$ leaves $((1+x)/x)^\beta \leq (1+1/T_h)^\beta$. This proves the global bound

$$0 \leq e^{\alpha|t|} w_h(t) \leq C_h^{\text{tilt}} (1+|t|)^{-p} \quad (t \in \mathbb{R}). \quad (\text{BT14})$$

The exact expression (BT3), including its actual zeta numerator and complete quartet denominator, is the object bounded throughout.

171.5 5. Boundary moments and finite derivative orders

Define the original two boundary tilts and their actual masses:

$$f_{\pm}(t) = e^{\pm\alpha t} w_h(t), \quad M_{\pm} = \int_{\mathbb{R}} f_{\pm}(t) dt. \quad (\text{BT15})$$

The nonzero entire function g/h has only isolated zeros on the integration line, so both masses are positive. Evenness gives $M_+ = M_- =: M_{\alpha}$. Integration of (BT14) proves

$$0 < M_{\alpha} = M_h(\alpha) = M_h(-\alpha) \leq \frac{2C_h^{\text{tilt}}}{p-1} < \infty. \quad (\text{BT16})$$

For every real $j \geq 0$ with $j < p-1$, the inequality $|t|^j \leq (1+|t|)^j$ gives

$$\int_{\mathbb{R}} |t|^j e^{\pm\alpha t} w_h(t) dt \leq \frac{2C_h^{\text{tilt}}}{p-j-1}. \quad (\text{BT17})$$

More precisely, for $R \geq 0$, the part $|t| \geq R$ is at most

$$\frac{2C_h^{\text{tilt}}}{p-j-1} (1+R)^{j-p+1}. \quad (\text{BT18})$$

Thus every integer order $0 \leq j \leq 8m-6$ is absolutely integrable at both boundary tilts. For a simple quartet, this includes orders zero, one and two.

For the actual Laplace function $M_h(z) = \int e^{zt} w_h(t) dt$, differentiation in $|\Re z| < \alpha$ gives $\int t^j e^{zt} w_h(t) dt$. For each stated order, (BT14) dominates the absolute integrand uniformly on $|\Re z| \leq \alpha$ by the integrable function $C_h^{\text{tilt}} |t|^j (1+|t|)^{-p}$. Dominated convergence therefore extends those derivatives continuously to the closed strip with exactly the boundary moments above. This does not assert holomorphic continuation through the boundary or finiteness of every endpoint derivative.

171.6 6. A uniform convolution envelope with the literal tilted mass

If a nonnegative integrable function f has actual mass $M > 0$ and $f(x) \leq C(1+|x|)^{-p}$, then for every integer $k \geq 1$,

$$f^{*k}(u) \leq kCM^{k-1}(1+|u|/k)^{-p}. \quad (\text{BT19})$$

For $k=1$ this is the hypothesis. In the convolution integral with $x_1 + \cdots + x_k = u$, at least one index has $|x_i| \geq |u|/k$. Bound its integrand by the sum of the k restrictions to these events. On the event for index i , the factor $f(x_i)$ is at most $C(1+|u|/k)^{-p}$. Parametrize the convolution hyperplane by the other $k-1$ coordinates; the change from any such convolution parametrization to another has absolute determinant one. Dropping the event now leaves the full product integral M^{k-1} . Summing proves (BT19), without a probability normalization.

Multiplication inside the original convolution gives exactly

$$f_{\pm}^{*k}(u) = e^{\pm\alpha u} m_{h,k}(u), \quad m_{h,k} = w_h^{*k}. \quad (\text{BT20})$$

Use the plus tilt for $u \geq 0$, the minus tilt for $u < 0$, and their same actual mass M_{α} . The result is

$$m_{h,k}(u) \leq kC_h^{\text{tilt}} M_{\alpha}^{k-1} e^{-\alpha|u|} (1+|u|/k)^{-p} \quad (k \geq 1, u \in \mathbb{R}). \quad (\text{BT21})$$

All dependence on k is displayed. The constants $C_h^{\text{tilt}}, p, M_{\alpha}$ belong to fixed h .

For every integer $n \geq 0$ with $2n > p - 1$, use $(1 + u/k)^{-p} \leq k^p u^{-p}$ for $u > 0$. The Gamma integral gives

$$\int_{\mathbb{R}} u^{2n} m_{h,k}(u) du \leq 2C_h^{\text{tilt}} k^{p+1} M_\alpha^{k-1} \frac{\Gamma(2n - p + 1)}{\alpha^{2n-p+1}}. \quad (\text{BT22})$$

The condition $2n > p - 1$ is precisely what makes this comparison integrable at zero. The actual raw moments exist also when the condition fails, but (BT22) is not used there.

For the retained source comparison, one direct corollary is

$$m_{h,k}(u) \leq b_k \sigma(u), \quad b_k = \frac{C_h^{\text{tilt}}}{c_\Gamma} k^{p+1} M_\alpha^{k-1} > 0. \quad (\text{BT23})$$

Indeed $1 + |u|/k \geq (1 + |u|)/k$; (BT21) and the lower Gamma bound leave the additional factor $(1 + |u|)^{-p+1/2} \leq 1$. This is a proved identity-map norm comparison; it does not assert equality of the measures.

172 Internal derivation of the exact Binet identity

This note proves the exact identity used in the actual boundary-tilt calculation from the defining Gamma integral, elementary integration, locally uniform products, and the Beta substitution. No Stirling formula, Gamma asymptotic, or cited Binet identity is assumed.

All complex powers of positive real integration variables use their real logarithms. The notation $\text{Log } z$ on $\Re z > 0$ denotes the principal holomorphic logarithm. The holomorphic logarithm of Gamma will be constructed below and will be real on the positive real axis.

172.1 1. Defining integrals and the finite Euler formula

For $\Re z > 0$, define

$$\Gamma(z) = \int_0^\infty x^{z-1} e^{-x} dx. \quad (\text{BI1})$$

This is absolutely convergent. On a compact set with $0 < a \leq \Re z \leq b$, its integrand and each of its first finitely many derivatives in z are bounded in absolute value by

$$(x^{a-1} + x^{b-1})(1 + |\log x|^j) e^{-x},$$

with the appropriate fixed integer j . This function is integrable at zero and infinity. Differentiation under the integral is therefore valid, and Γ is holomorphic on the right half-plane. Integration by parts gives

$$\Gamma(z + 1) = z\Gamma(z), \quad \Gamma(1) = 1, \quad (\text{BI2})$$

because $x^z e^{-x}$ tends to zero at both endpoints for $\Re z > 0$.

For $\Re z, \Re w > 0$, let

$$B(z, w) = \int_0^1 t^{z-1} (1-t)^{w-1} dt. \quad (\text{BI3})$$

For an integer $N \geq 1$, integration by parts gives

$$B(z, N + 1) = \frac{N}{z} B(z + 1, N).$$

Iterating, and using $B(z + N, 1) = 1/(z + N)$, proves the exact finite formula

$$B(z, N + 1) = \frac{N!}{z(z + 1) \cdots (z + N)}. \quad (\text{BI4})$$

In particular none of these denominators vanishes in the right half-plane.

Set

$$E_N(z) = N^z B(z, N+1) = \frac{N^z N!}{z(z+1) \cdots (z+N)}, \quad N \geq 1. \quad (\text{BI5})$$

The substitution $t = x/N$ gives

$$E_N(z) = \int_0^N x^{z-1} (1 - x/N)^N dx. \quad (\text{BI6})$$

For $0 \leq x < N$, $\log(1 - x/N) \leq -x/N$, so

$$0 \leq (1 - x/N)^N \leq e^{-x}.$$

For each fixed $x > 0$, the expression on the left tends to e^{-x} , with the indicator of $x < N$ understood.

On a compact set as above, therefore

$$\sup_z |E_N(z) - \Gamma(z)| \leq \int_0^\infty (x^{a-1} + x^{b-1}) \cdot |(1 - x/N)^N \mathbf{1}_{\{x < N\}} - e^{-x}| dx \rightarrow 0$$

by dominated convergence. The same argument with an additional factor $|\log x|^j$, for $j = 1, 2$, proves locally uniform convergence of those two derivatives as well. Thus the Euler limit and the derivative limits are established directly from their integrals.

172.2 2. Nonvanishing and the holomorphic Gamma logarithm

Write $H_N = \sum_{j=1}^N 1/j$. The real numbers

$$\gamma_N = H_N - \log N$$

decrease and are bounded below by zero. Indeed

$$\gamma_{N+1} - \gamma_N = \frac{1}{N+1} - \log(1 + 1/N) < 0$$

by integrating $1/x > 1/(N+1)$ on $[N, N+1)$, while $H_N \geq \int_1^{N+1} dx/x = \log(N+1)$. Let $\gamma_E = \lim_N \gamma_N$.

For $\Re z > 0$, every $1 + z/j$ has positive real part. Its principal logarithm is holomorphic. Define

$$Q_N(z) = \text{Log } z + z(H_N - \log N) + \sum_{j=1}^N (\text{Log}(1 + z/j) - z/j). \quad (\text{BI7})$$

Exponentiating this literal sum and using (BI5) gives exactly

$$e^{Q_N(z)} = z N^{-z} \prod_{j=1}^N (1 + z/j) = \frac{1}{E_N(z)}. \quad (\text{BI8})$$

The logarithmic series in (BI7) converges locally uniformly. To prove this explicitly, for $|w| \leq 1/2$,

$$\text{Log}(1 + w) - w = - \int_0^1 \frac{tw^2}{1 + tw} dt,$$

whence $|\operatorname{Log}(1+w) - w| \leq |w|^2$. On a compact set with $|z| \leq R$, this bounds the j -th summand by R^2/j^2 whenever $j \geq 2R$. The finite initial part is holomorphic and the summable bound proves uniform convergence of the tail. Hence

$$Q(z) = \operatorname{Log} z + \gamma_E z + \sum_{j=1}^{\infty} (\operatorname{Log}(1+z/j) - z/j) \quad (\text{BI9})$$

is holomorphic and $Q_N \rightarrow Q$ locally uniformly.

Taking limits in $E_N e^{Q_N} = 1$, using Section 1, proves

$$\Gamma(z) e^{Q(z)} = 1. \quad (\text{BI10})$$

This proves that Gamma is nowhere zero on the entire right half-plane. It also constructs the required holomorphic logarithm:

$$\mathcal{G}(z) := -Q(z), \quad e^{\mathcal{G}(z)} = \Gamma(z). \quad (\text{BI11})$$

For $x > 0$, every term in $Q(x)$ is real and the defining Gamma integral is positive. Thus $\mathcal{G}(x)$ is precisely the real logarithm of $\Gamma(x)$; there is no unspecified additive $2\pi i$ constant.

The second derivatives of the series in (BI9) converge locally uniformly, since $\sum_j |z+j|^{-2}$ does. Termwise differentiation gives

$$\mathcal{G}''(z) = \sum_{j=0}^{\infty} \frac{1}{(z+j)^2} \quad (\Re z > 0). \quad (\text{BI12})$$

For justification without assuming a derivative-series theorem, on any slightly larger compact subset of the same half-plane the series converges uniformly; Cauchy's integral formula on small circles then gives uniform convergence of its derivatives. Direct estimates of the derivatives of its summands give the same conclusion.

172.3 3. Beta product, duplication, and the factor $\sqrt{\pi}$

The absolutely convergent product of the two defining Gamma integrals admits the change of variables

$$x = rt, \quad y = r(1-t), \quad r > 0, \quad 0 < t < 1.$$

Its Jacobian matrix has determinant $-r$, so the positive integration Jacobian is r . Consequently

$$\Gamma(z)\Gamma(w) = \Gamma(z+w)B(z, w) \quad (\Re z, \Re w > 0). \quad (\text{BI13})$$

All powers here are powers of positive real bases. Fubini and the change of variables are justified by the same integrals with real parts of the exponents.

In $B(z, z)$, first substitute $t = (1+u)/2$, and then use symmetry and $v = u^2$. Every factor is retained:

$$\begin{aligned} B(z, z) &= 2^{1-2z} \int_{-1}^1 (1-u^2)^{z-1} du \\ &= 2^{2-2z} \int_0^1 (1-u^2)^{z-1} du \\ &= 2^{1-2z} B(1/2, z). \end{aligned} \quad (\text{BI14})$$

Finally $x = t^2$ in (BI1) gives $\Gamma(1/2) = 2 \int_0^\infty e^{-t^2} dt$. The latter is the positive integral over the whole real line. Its square is $\int_{\mathbb{R}^2} e^{-(x^2+y^2)} dx dy$. Polar coordinates, whose positive Jacobian is r , evaluate this square as

$$2\pi \int_0^\infty r e^{-r^2} dr = \pi.$$

Thus $\Gamma(1/2) = \sqrt{\pi}$. Inserting (BI13) into (BI14), and using the nonvanishing established in (BI10), proves

$$\boxed{\Gamma(z)\Gamma(z+1/2) = 2^{1-2z}\sqrt{\pi}\Gamma(2z) \quad (\Re z > 0).} \quad (\text{BI15})$$

On the positive real axis all these factors are positive, so their real logarithms obey the corresponding additive identity without any branch ambiguity.

172.4 4. The bounded integral remainder

For $u > 0$, define

$$K(u) = \left(\frac{1}{e^u - 1} - \frac{1}{u} + \frac{1}{2} \right) \frac{1}{u}. \quad (\text{BI16})$$

We prove its exact bounds rather than assuming a Bernoulli expansion. With $x = u/2 > 0$,

$$K(u) = \frac{\coth x - 1/x}{4x}.$$

The two functions

$$F_0(x) = x \cosh x - \sinh x, \quad F_1(x) = (x^2 + 3) \sinh x - 3x \cosh x$$

vanish at zero and satisfy $F'_0(x) = x \sinh x \geq 0$ and $F'_1(x) = xF_0(x) \geq 0$. Dividing their nonnegative values by positive factors gives

$$0 \leq \coth x - \frac{1}{x} \leq \frac{x}{3}.$$

Therefore

$$\boxed{0 \leq K(u) \leq \frac{1}{12} \quad (u > 0).} \quad (\text{BI17})$$

Define the actual remainder candidate

$$R(z) = \int_0^\infty e^{-zu} K(u) du, \quad \Re z > 0. \quad (\text{BI18})$$

It is absolutely convergent and holomorphic. Differentiating j times is justified on every compact set with $\Re z \geq a > 0$ by $u^j e^{-au}/12$. In particular

$$|R(z)| \leq \frac{1}{12\Re z}, \quad 0 \leq R(x) \leq \frac{1}{12x} \quad (x > 0). \quad (\text{BI19})$$

172.5 5. Equality of second derivatives

Put $c = \frac{1}{2} \log(2\pi)$, and define

$$\mathcal{F}(z) = (z - \tfrac{1}{2}) \text{Log } z - z + c + R(z). \quad (\text{BI20})$$

Differentiation and the exact algebraic identity

$$u^2 K(u) = \frac{u}{e^u - 1} - 1 + \frac{u}{2}$$

give

$$\begin{aligned} \mathcal{F}''(z) &= \frac{1}{z} + \frac{1}{2z^2} + \int_0^\infty e^{-zu} \left(\frac{u}{e^u - 1} - 1 + \frac{u}{2} \right) du \\ &= \frac{1}{z^2} + \int_0^\infty \frac{ue^{-zu}}{e^u - 1} du. \end{aligned} \quad (\text{BI21})$$

Here $\int_0^\infty e^{-zu} du = 1/z$ and $\int_0^\infty ue^{-zu} du = 1/z^2$ follow by elementary integration on $\Re z > 0$; all cancellation factors are displayed.

The geometric series $1/(e^u - 1) = \sum_{j=1}^\infty e^{-ju}$ is valid for $u > 0$. Its absolute integral after multiplication by ue^{-zu} is bounded by the same expression with $\Re z$, which is integrable at zero and infinity. Hence termwise integration is valid, and

$$\mathcal{F}''(z) = \frac{1}{z^2} + \sum_{j=1}^\infty \int_0^\infty ue^{-(z+j)u} du = \sum_{j=0}^\infty \frac{1}{(z+j)^2} = \mathcal{G}''(z). \quad (\text{BI22})$$

The right half-plane is connected, so the holomorphic function $\mathcal{F} - \mathcal{G}$ has zero second derivative and consequently equals $az + b$ there, for constants $a, b \in \mathbb{C}$.

172.6 6. The recurrence fixes the linear constant

For positive real x , (BI2) and the real-axis branch in (BI11) give

$$\mathcal{G}(x+1) - \mathcal{G}(x) = \log x.$$

The corresponding exact difference of the explicit function (BI20) is

$$\mathcal{F}(x+1) - \mathcal{F}(x) - \log x = (x + \tfrac{1}{2}) \log(1 + 1/x) - 1 + R(x+1) - R(x). \quad (\text{BI23})$$

The left side equals a . The elementary integral bounds

$$\frac{y}{1+y} \leq \log(1+y) \leq y \quad (y > 0)$$

show that $x \log(1 + 1/x) \rightarrow 1$ and $\frac{1}{2} \log(1 + 1/x) \rightarrow 0$. The remainder bound (BI19) makes the remaining difference tend to zero. Thus $a = 0$, and $\mathcal{F} - \mathcal{G} = b$ throughout the right half-plane.

172.7 7. Duplication fixes the additive constant

For $x > 0$, the positive-real logarithm of (BI15) is

$$\mathcal{G}(x) + \mathcal{G}(x + 1/2) - \mathcal{G}(2x) = (1 - 2x) \log 2 + \tfrac{1}{2} \log \pi. \quad (\text{BI24})$$

Since $\mathcal{F} = \mathcal{G} + b$, the difference between the same expression using $\mathcal{F}$ and the right side of (BI24) equals exactly $b + b - b = b$.

Insert (BI20) without dropping any constant. The terms containing $\log x$ cancel, and the resulting difference is

$$b = x \log(1 + 1/(2x)) - \tfrac{1}{2} + (c - \tfrac{1}{2} \log(2\pi)) + R(x) + R(x + 1/2) - R(2x). \quad (\text{BI25})$$

Our displayed $c = \frac{1}{2} \log(2\pi)$ cancels exactly. The same elementary logarithm bounds show $x \log(1 + 1/(2x)) \rightarrow 1/2$, and each remainder tends to zero by (BI19). Thus $b = 0$.

Combining Sections 5–7 proves the complete exact identity

$$\boxed{\log \Gamma(z) = (z - \tfrac{1}{2}) \text{Log } z - z + \tfrac{1}{2} \log(2\pi) + \int_0^\infty e^{-zu} \left(\frac{1}{e^u - 1} - \frac{1}{u} + \frac{1}{2} \right) \frac{du}{u}, \quad \Re z > 0.} \quad (\text{BI26})$$

The logarithm on the left is the uniquely specified holomorphic branch from (BI11). The integral is absolutely convergent, and its bound and all differentiations have been justified. This is the identity used by the actual boundary-tilt proof.

173 Uniform original source comparison and the two growing norm windows

Retain an actual complete off-line quartet $1/2 \pm \delta \pm i\gamma$ of common order m , with $0 < \delta < 1/2$ and $\gamma > 0$. The polynomial h , the entire quotient $v_h = (2\xi)/h$, its full Taylor unit, and the original source are unchanged. Set

$$w_h(u) = \frac{|v_h(1/2 + iu)|^2}{2\pi}, \quad m_{h,k} = w_h^{*k}, \quad \mu_h = \int_{\mathbb{R}} w_h(u) du, \quad \alpha = \pi/2. \quad (\text{TW1})$$

The proved actual boundary-tilt calculation supplies

$$p = 8m - \frac{9}{2} > 1, \quad e^{\alpha|u|} w_h(u) \leq C_h(1 + |u|)^{-p}, \quad M_\alpha = \int_{\mathbb{R}} e^{\alpha u} w_h(u) du \in (0, \infty). \quad (\text{TW2})$$

Here C_h denotes exactly the explicit constant C_h^{tilt} of (BT12), with its original compact and tail expressions. Its proof retains the exact factor $-\pi^{-1/4}(u^2 + 1/4)e^{-iu \log \pi/2} \zeta(1/2 + iu)$ and the full quartet denominator. In particular (TW2) does not use a positive lower bound for ζ or an assumption about its zero locations.

The comparison measure used below is the fixed original one-factor Gamma measure

$$d\sigma(u) = \frac{|\Gamma(1/4 + iu/2)|^2}{2\pi} du, \quad \int d\sigma = \sqrt{2\pi}. \quad (\text{TW3})$$

Its proved two-sided boundary bounds are

$$c_\Gamma e^{-\alpha|u|}(1 + |u|)^{-1/2} \leq \frac{d\sigma}{du} \leq C_\Gamma e^{-\alpha|u|}(1 + |u|)^{-1/2}, \quad c_\Gamma = \sqrt{2}e^{-7/6}, \quad C_\Gamma = \sqrt{2\sqrt{5}}e^{2/3}. \quad (\text{TW4})$$

This fixed measure has mass $\sqrt{2\pi}$ for every k . It is distinct from the k -fold Gamma convolution of mass $(2\pi)^{k/2}$ in (AT4). Both comparisons, with their exact connecting constants, will be retained.

173.1 A uniform convolution bound at the actual exponential boundary

For every integer $k \geq 1$ and every $u \in \mathbb{R}$,

$$m_{h,k}(u) \leq kC_h M_\alpha^{k-1} (1 + |u|/k)^{-p} e^{-\alpha|u|}. \quad (\text{TW5})$$

To prove this, put $f_+(x) = e^{\alpha x} w_h(x)$. Its mass is exactly M_α , and $f_+(x) \leq C_h(1 + |x|)^{-p}$. The original product integral gives $f_+^{*k}(u) = e^{\alpha u} m_{h,k}(u)$. On the hyperplane $x_1 + \cdots + x_k = u$, at least one coordinate satisfies $|x_i| \geq |u|/k$. Split this integral into the union of those k sets. On its i th set the i th factor is at most $C_h(1 + |u|/k)^{-p}$. Eliminate $x_i = u - \sum_{j \neq i} x_j$; the change from the original convolution coordinates has absolute Jacobian one. Integrate the other $k - 1$ nonnegative factors over all their original domains; the resulting bound is $C_h(1 + |u|/k)^{-p} M_\alpha^{k-1}$. Summing proves the bound with $e^{-\alpha u}$. Conjugation of the original real-entire 2ξ and of the complete quartet polynomial proves $w_h(-x) = w_h(x)$. Thus $f_-(x) = e^{-\alpha x} w_h(x)$ has the same mass, and the same argument with f_- proves the bound with $e^{\alpha u}$. Taking the smaller of these two proved expressions gives exactly (TW5). This argument also covers $k = 1$ directly. Tonelli's theorem applies because all integrands are nonnegative and the displayed masses are finite.

For integers n with $2n > p - 1$, this yields the literal raw moment bound

$$\int_{\mathbb{R}} u^{2n} m_{h,k}(u) du \leq 2C_h k^{p+1} M_\alpha^{k-1} \frac{\Gamma(2n - p + 1)}{\alpha^{2n-p+1}}. \quad (\text{TW6})$$

Indeed $(1 + u/k)^{-p} \leq k^p u^{-p}$ for $u > 0$, and substitution $y = \alpha u$ evaluates the remaining positive half-line integral. No arithmetic density has been assigned the value of a Gamma density.

173.2 Pointwise comparison of the original convolution

For $k \geq 3$, retain the proved original convolution lower envelope

$$m_{h,k}(u) \geq c_h \vartheta_h^{k-3} e^{-\alpha(|u|+k-3)} (k-2+|u|)^{-B}, \quad B = 42 + 8m, \quad \vartheta_h = \int_{-1}^1 w_h(u) du > 0. \quad (\text{TW7})$$

Its complete proof is the original arithmetic envelope (AU.10), also retained as (CJ.15); it concerns this same g/h convolution. Define the following explicit constants, without altering either measure:

$$M = B/2 = 21 + 4m, \\ a_k = \frac{c_h \vartheta_h^{k-3} e^{-\alpha(k-3)} (k-2)^{-B}}{C_\Gamma 2^{B/2}}, \quad A_k = \frac{C_h}{c_\Gamma} k^{p+1} M_\alpha^{k-1}. \quad (\text{TW8})$$

Then

$$\boxed{a_k (1+u^2)^{-M} \frac{d\sigma}{du} \leq m_{h,k}(u) \leq A_k \frac{d\sigma}{du}}. \quad (\text{TW9})$$

For the upper bound, $1 + |u|/k \geq (1 + |u|)/k$ in (TW5), and the lower inequality of (TW4) leaves the factor $(1 + |u|)^{-(p-1/2)} \leq 1$. This gives precisely A_k . For the lower bound, $k-2 \geq 1$ gives $k-2+|u| \leq (k-2)(1+|u|)$. The upper inequality of (TW4) implies $e^{-\alpha|u|} \geq C_\Gamma^{-1} d\sigma/du$. Finally $(1+|u|)^B \leq 2^{B/2} (1+u^2)^{B/2}$. Substitution of these three inequalities in (TW7) proves its lower counterpart in (TW9), with its displayed constant and direction.

173.3 Full finite polynomial forms, with the original coordinate maps

Let b_j be the fixed Gamma monic polynomials in u . The original generating-integral calculation (TG.7)–(TG.14) proves

$$\gamma_j = \|b_j\|_\sigma^2 = \sqrt{2} j! \Gamma(j+1/2) = \sqrt{2\pi} \frac{(2j)!}{4^j}, \quad ub_j = b_{j+1} + j(j-1/2)b_{j-1}. \quad (\text{TW10})$$

The last term is absent at $j = 0$. The second equality follows by induction from $\Gamma(1/2) = \sqrt{\pi}$ and the Gamma recurrence; no asymptotic formula is used there.

For $N \geq 0$ put

$$D_N = [1 + 4(N+M)^2]^M.$$

Every polynomial P of degree at most N satisfies

$$\int |P(u)|^2 (1+u^2)^M d\sigma(u) \leq D_N \int |P(u)|^2 d\sigma(u). \quad (\text{TW11})$$

Here is the full multiplication estimate. The orthonormal vectors $e_j = b_j/\sqrt{\gamma_j}$ obey

$$ue_j = \sqrt{(j+1)(j+1/2)} e_{j+1} + \sqrt{j(j-1/2)} e_{j-1}.$$

On degrees at most N , the first weighted shift has norm at most $N+1$ and the second has norm at most N ; this follows by taking squared norms of their orthogonal images term by term. The triangle inequality therefore gives $\|uP\|_\sigma \leq 2(N+1)\|P\|_\sigma$. After each multiplication the degree increases by one. Iteration gives $\|u^j P\|_\sigma \leq [2(N+M)]^j \|P\|_\sigma$ for $0 \leq j \leq M$. Expand $(1+u^2)^M$, integrate its nonnegative summands, and use the binomial theorem; the result is exactly (TW11).

Apply Cauchy–Schwarz with the two functions $|P|(1+u^2)^{-M/2}$ and $|P|(1+u^2)^{M/2}$ in $L^2(\sigma)$:

$$\left(\int |P|^2 d\sigma \right)^2 \leq \left(\int |P|^2 (1+u^2)^{-M} d\sigma \right) \left(\int |P|^2 (1+u^2)^M d\sigma \right).$$

For $P \neq 0$, divide by its positive σ norm and apply (TW11). For $P = 0$ the resulting inequality is immediate. Combining with (TW9) proves the full finite-form comparison

$$\boxed{\frac{a_k}{D_N} \int |P|^2 d\sigma \leq \int |P|^2 m_{h,k}(u) du \leq A_k \int |P|^2 d\sigma \quad (\deg P \leq N).} \quad (\text{TW12})$$

It holds for every complex coefficient vector, not just monic polynomials. In particular $A_k D_N / a_k \geq 1$ by applying (TW12) to any nonzero P .

The original sum coordinate is $S = c + iu$, $c = k/2$. Its exact algebra map is $\Psi_k : \mathbb{C}[S] \rightarrow \mathbb{C}[u]$, $\Psi_k P(u) = P(c + iu)$, with inverse $f \mapsto f((S - c)/i)$. In degree at most N its coefficient matrix has diagonal $1, i, \dots, i^N$. Thus (TW12) is a congruence statement in the original S coordinates as well. On the monic degree- n affine space, $P \mapsto i^{-n} \Psi_k P$ is a bijection to the monic u polynomials and preserves the norm because $|i^{-n}| = 1$. No degree-dependent phase is asserted to be a single algebra map. Consequently, writing $H_{k,N}$ for the actual original polynomial Gram and $H_N^{\sigma,k}$ for the fixed σ Gram evaluated at $S = c + iu$, the fully typed matrix form is

$$\boxed{(a_k/D_N) H_N^{\sigma,k} \preceq H_{k,N} \preceq A_k H_N^{\sigma,k}.} \quad (\text{TW13})$$

The identity on the original polynomial source commutes with remainder modulo the same $\chi_{h,k}$ and hence with its full unitful jet observation. Neither this comparison nor the coordinate congruence changes $\chi_{h,k}$, S , its full jets, or the original source norm.

173.4 Uniform arithmetic monic norms

Let $\omega_{h,k,n}$ be the minimum original squared norm of a monic degree- n polynomial. Minimizing (TW12) on that same affine space, using (TW10) for its fixed comparison minimum, gives

$$\boxed{\frac{a_k \gamma_n}{D_n} \leq \omega_{h,k,n} \leq A_k \gamma_n, \quad k \geq 3, n \geq 0.} \quad (\text{TW14})$$

The upper bound may equivalently be verified on the explicit trial polynomial b_n ; the lower bound applies to every monic polynomial. Thus no minimizer was transferred between different metrics without the stated inequality.

Here and below constants in O_h may depend on the fixed complete quartet and the fixed proven envelope constants, but not on k, n . Taking logarithms of the exact constants in (TW8) gives

$$\log a_k = (k-3)(\log \vartheta_h - \alpha) - B \log(k-2) + \log c_h - \log C_\Gamma - (B/2) \log 2,$$

$$\log A_k = (k-1) \log M_\alpha + (p+1) \log k + \log(C_h/c_\Gamma).$$

Also $\log D_n = M \log(1 + 4(n+M)^2) = O_h(1 + \log(n+1))$. These displayed equalities prove, uniformly for $k \geq 3, n \geq 0$,

$$\boxed{\log \omega_{h,k,n} = \log \left(\sqrt{2\pi} \frac{(2n)!}{4^n} \right) + O_h(k + \log(n+1)).} \quad (\text{TW15})$$

This is a high-degree norm estimate for the actual arithmetic convolution. It is not an assertion that consecutive norm ratios have an asymptotic; the error in (TW15) does not justify that differentiation in n .

The same all-polynomial comparison also controls the original raw even moments $I_{k,2n} = \int_{\mathbb{R}} u^{2n} m_{h,k}(u) du$. For $k \geq 3$ and $n \geq 1$ it gives the explicit two-sided bounds

$$\boxed{\frac{a_k \sqrt{2} c_\Gamma e^{-\alpha} (2n-1)!}{D_n \alpha^{2n}} \leq I_{k,2n} \leq 2 A_k C_\Gamma \frac{(2n)!}{\alpha^{2n+1}}.} \quad (\text{TW15a})$$

For the lower comparison moment, restrict (TW4) to $u \geq 1$ and use $(1+u)^{-1/2} \geq 1/(\sqrt{2}u)$. Both half-lines give $\int u^{2n} d\sigma \geq \sqrt{2}c_\Gamma \alpha^{-2n} \Gamma(2n, \alpha)$. Repeated integration by parts gives $\Gamma(2n, \alpha) = (2n-1)!e^{-\alpha} \sum_{j=0}^{2n-1} \alpha^j/j! \geq (2n-1)!e^{-\alpha}$. For the upper comparison moment, drop the factor $(1+|u|)^{-1/2} \leq 1$ in (TW4) and evaluate the Gamma integral. Applying (TW12) to the original degree- n polynomial u^n proves (TW15a). Its logarithms give, uniformly on these stated degrees,

$$\log I_{k,2n} = \log((2n)!\alpha^{-2n}) + O_h(k + \log(n+1)). \quad (\text{TW15b})$$

The full one-factor zeta numerator and actual tilted mass in (TW2) remain in a_k, A_k ; (TW15a) is a bound on the original moments.

173.5 The two original windows with full finite errors

Put $q = [1 + k(m-1)](k+1)^2$. For $n = q-1$ or $n = q$, division of (TW14) at the two exact degrees gives

$$\log \frac{\gamma_{n+q}}{\gamma_n} - \log \frac{A_k D_{n+q}}{a_k} \leq \log \frac{\omega_{h,k,n+q}}{\omega_{h,k,n}} \leq \log \frac{\gamma_{n+q}}{\gamma_n} + \log \frac{A_k D_n}{a_k}. \quad (\text{TW16})$$

All logarithmic error bounds here are nonnegative by (TW12). The exact factorial formula (TW10) and monotonicity of $\log x$ give

$$\log \frac{\gamma_{2q}}{\gamma_q} = 2q \log(4q/e) + \eta_q, \quad 0 \leq \eta_q \leq \log 2. \quad (\text{TW17})$$

Indeed the logarithm of $(4q)!/(2q)!$ is $\sum_{j=2q+1}^{4q} \log j$. Its excess over $\int_{2q}^{4q} \log x dx$ is nonnegative and at most $\sum_{j=2q+1}^{4q} (\log j - \log(j-1)) = \log 2$. Subtracting $q \log 4$ gives precisely (TW17). The other original window satisfies the exact identity

$$\frac{\gamma_{2q-1}}{\gamma_{q-1}} = \frac{\gamma_{2q}}{\gamma_q} \frac{q-1/2}{4q-1}, \quad \frac{1}{6} \leq \frac{q-1/2}{4q-1} < \frac{1}{4}.$$

It follows in particular that

$$4q \log(4q/e) - \log 6 \leq \log \frac{\gamma_{2q-1} \gamma_{2q}}{\gamma_{q-1} \gamma_q} \leq 4q \log(4q/e). \quad (\text{TW18})$$

For fixed h , one has $k/q \rightarrow 0$ and $\log q/q \rightarrow 0$. Thus each finite error in (TW16), divided by $2q$, tends to zero. Equations (TW16)–(TW18) prove both limits on their stated windows:

$$\lim_{k \rightarrow \infty} \frac{1}{q} \left(\frac{\omega_{h,k,2q}}{\omega_{h,k,q}} \right)^{1/(2q)} = \lim_{k \rightarrow \infty} \frac{1}{q} \left(\frac{\omega_{h,k,2q-1}}{\omega_{h,k,q-1}} \right)^{1/(2q)} = \frac{4}{e}. \quad (\text{TW19})$$

No limit with an unspecified ratio n/q is asserted.

173.6 The resulting actual four-window lower estimate

Retain the original relative controls ε_N , phases ϕ_N , and contraction penalties P_- , P_+ of (HC1)–(HC2). Their exact first boundary and regular products, inherited from (CJ.9)–(CJ.13), give

$$\mathcal{B}_k = \sum_{N=q-1}^{2q-1} w_N \log(\varepsilon_N^2 + \phi_N^2) - \log \frac{\omega_{h,k,2q-1} \omega_{h,k,2q}}{\omega_{h,k,q-1} \omega_{h,k,q}} + P_- + P_+,$$

where the endpoint weights are $1, 2, \dots, 2, 1$. Set

$$E_k = 2 \log(A_k/a_k) + \log D_{q-1} + \log D_q \geq 0, \quad E_k = O_h(k + \log q).$$

Adding the upper sides of (TW16) and applying (TW18) gives the actual sum-norm upper bound $4q \log(4q/e) + E_k$. Consequently, with the full original trace $\mathcal{L} = 2\delta\ell_k(k+1)\lfloor(k+1)^2/4\rfloor$,

$$\begin{aligned} \mathcal{B}_k &\geq 4q \log(\delta ek/8) - E_k + P_- + P_+ \\ &\quad + \sum_N w_N \log(1 + \phi_N^2/\mathcal{L}^2) + \sum_N w_N \log \frac{\varepsilon_N^2 + \phi_N^2}{\mathcal{L}^2 + \phi_N^2} + 4q \log \frac{2\mathcal{L}}{\delta kq}. \end{aligned} \quad (\text{TW20})$$

All terms after $-E_k$ are the displayed original nonnegative costs. The sums retain both endpoint degrees and all their multiplicities. To verify the constant, $4q \log \mathcal{L} - 4q \log(4q/e)$ equals $4q \log(\delta ek/8) + 4q \log(2\mathcal{L}/(\delta kq))$. This proves the identity used in the bound with no rescaling of S . Since $E_k/q \rightarrow 0$, the quantified refinement includes

$$\liminf_{k \rightarrow \infty} \frac{\mathcal{B}_k - 4q \log k}{q} \geq 4 \log(\delta e/8). \quad (\text{TW21})$$

The leading threshold four is inherited. The new content is the actual boundary-tilt comparison, its uniform finite-degree errors, and the sharper literal window constant. These lower estimates alone do not assign a sign to the signed arithmetic correction in (AT14)–(AT17).

174 Fixed-packet asymptotics of the complete original Gamma jet determinant

Fix the original positive integer k , put $c = k/2$, and retain the actual monic cyclic annihilator $\chi = \chi_{h,k}$, with all its distinct roots $\lambda_1, \dots, \lambda_d$ and their complete multiplicities $m_1, \dots, m_d$. Write $q = \sum_i m_i$. The finite-packet hypothesis only specifies these original objects; no new arithmetic zero or replacement annihilator enters this section. The same computation applies to every specified finite jet observation on the given source line. This last fact will be used to transport the original observation through a literal comparison-measure dilation.

The source line and comparison density are exactly

$$S = c + iu, \quad \sigma(u) = \frac{|\Gamma(1/4 + iu/2)|^2}{2\pi}. \quad (\text{FPK.1})$$

Use the original monic polynomials and squared norms

$$p_n(S) = i^n b_n((S - c)/i), \quad \gamma_n = \sqrt{2\pi} n! (1/2)_n = \sqrt{2} n! \Gamma(n + 1/2). \quad (\text{FPK.2})$$

The generating-integral calculation in the retained Gamma chapter proves their orthogonality for (FPK.1), including these constants and phases. We calculate the full confluent kernel, not just the diagonal scalar evaluation kernel.

For $f^{[j]} = f^{(j)}/j!$, let E_χ be the original Taylor-coordinate map from the increasing-power remainder frame:

$$(E_\chi)_{(i,j),r} = \begin{cases} \binom{r}{j} \lambda_i^{r-j}, & r \geq j, \\ 0, & r < j, \end{cases} \quad 0 \leq j < m_i, \quad 0 \leq r < q. \quad (\text{FPK.3})$$

Define

$$(\mathbf{K}_N)_{(i,j),(a,l)} = \sum_{n=0}^N \frac{p_n^{[j]}(\lambda_i) \overline{p_n^{[l]}(\lambda_a)}}{\gamma_n} \quad (N \geq q - 1). \quad (\text{FPK.4})$$

The minimum-norm quotient Gram and its original determinant are

$$G_N^\sigma = E_\chi^* \mathbf{K}_N^{-1} E_\chi, \quad V_N^\sigma = \det G_N^\sigma = \frac{|\det E_\chi|^2}{\det \mathbf{K}_N}. \quad (\text{FPK.5})$$

Indeed the normalized polynomial basis makes the source Gram identity, so the Gram of the onto jet observation is (FPK.4). Minimizing a Euclidean norm subject to that observation gives its inverse Gram. The first q monic polynomials span all remainders, proving that this Gram is positive definite. Transport by the actual map (FPK.3) gives (FPK.5). Thus V_N means the determinant of the Gram, as in (AT6), and does not mean its square root.

The exact determinant of the displayed coordinate map is

$$\det E_\chi = \prod_{i < a} (\lambda_a - \lambda_i)^{m_i m_a}. \quad (\text{FPK.6})$$

Here root blocks and derivatives are ordered as in (FPK.3). To prove the constant, replace the m_i evaluations in block i by evaluations at $\lambda_i + \epsilon x_{i,j}$ with fixed distinct $x_{i,j}$. Expand each row into its Taylor series and divide its block determinant by $\epsilon^{m_i(m_i-1)/2} \prod_{j < l} (x_{i,l} - x_{i,j})$. Multilinearity gives the determinant of the normalized derivative rows in the limit. The ordinary Vandermonde formula on all the evaluation points gives precisely the right side of (FPK.6); the within-block factors cancel the displayed divisors. This also proves that no factorial or orientation factor is missing.

174.1 The two singularities with the original coordinate and constants

Put $w = S - c$. Substituting iz in the retained generating function $(1 + z^2)^{-1/4} \exp(u \arctan z)$ gives the exact identity

$$\sum_{n=0}^{\infty} \frac{p_n(c+w)}{n!} z^n = (1-z)^{-a(w)} (1+z)^{-b(w)}, \quad a(w) = \frac{1}{4} + \frac{w}{2}, \quad b(w) = \frac{1}{4} - \frac{w}{2}. \quad (\text{FPK.7})$$

All powers use the branches equal to one at $z = 0$. Define the entire coefficient functions

$$C_+(w) = \frac{2^{-1/2+w/2}}{\Gamma(1/4 + w/2)}, \quad C_-(w) = \frac{2^{-1/2-w/2}}{\Gamma(1/4 - w/2)}. \quad (\text{FPK.8})$$

For every compact set of w and each fixed derivative order j , the normalized polynomials $e_n(w) = p_n(c+w)/\sqrt{\gamma_n}$ satisfy

$$e_n(w) = C_+(w)n^{w/2-1/2} + (-1)^n C_-(w)n^{-w/2-1/2} + R_n(w), \quad (\text{FPK.9})$$

$$|\partial_w^j R_n(w)| \leq C_j(1 + \log n)^j \left(n^{\Re w/2-3/2} + n^{-\Re w/2-3/2} + n^{-J} \right), \quad n \geq 2. \quad (\text{FPK.10})$$

The positive integer J can be chosen as large as needed, with the constant depending on the compact set, j , and J .

Here is a coefficient proof of these estimates. It is included so no unproved asymptotic theorem about the orthogonal polynomials is used. Near $z = 1$, expand the other factor in (FPK.7):

$$(1+z)^{-b} = 2^{-b} \sum_{r=0}^{L-1} \frac{(b)_r}{2^r r!} (1-z)^r + (1-z)^L A_L(z, w), \quad (\text{FPK.11})$$

where A_L is analytic near that point, uniformly with each specified parameter derivative on a compact parameter set. Near $z = -1$ use the same expansion with a, b exchanged and z replaced by $-z$. Subtract from (FPK.7) both finite lists of singular terms. Choose L larger than the maximum real part of a, b plus any specified integer $J_0 + 2$. The remainder and its first J_0 angular derivatives on the unit circle then extend continuously across both 1 and -1 . Indeed its nonanalytic local remainder is a power of real part greater than $J_0 + 1$, times an analytic bounded factor; parameter derivatives only add fixed powers of its logarithm. The singular terms subtracted at the other point are analytic there. Away from these two points everything is analytic across the circle.

The resulting boundary function is C^{J_0} and periodic. Integrating its Fourier coefficient by parts J_0 times bounds that coefficient by Cn^{-J_0} , uniformly for all the specified parameter derivatives. Its nonnegative Fourier coefficients are its Taylor coefficients: apply Cauchy's formula on circles of radius less than one and use uniform boundary convergence. Each subtracted term has its exact coefficient

$$[z^n](1-z)^{-a+r} = \frac{\Gamma(n+a-r)}{\Gamma(a-r)\Gamma(n+1)}, \quad (\text{FPK.12})$$

with analytic values at nonpositive integral $a-r$; the corresponding coefficient at -1 has the additional factor $(-1)^n$.

For completeness, uniformly on a compact complex set of α ,

$$\frac{\Gamma(n+\alpha)}{\Gamma(n+1)} = n^{\alpha-1}(1+O(n^{-1})), \quad (\text{FPK.13})$$

with differentiated estimates after retaining the derivatives of $n^{\alpha-1}$. One direct proof first arranges $\Re\alpha < 1$ by the gamma recurrence. The beta integral is

$$\frac{\Gamma(n+\alpha)}{\Gamma(n+1)} = \frac{n^{\alpha-1}}{\Gamma(1-\alpha)} \int_0^n (1-y/n)^{n+\alpha-1} y^{-\alpha} dy.$$

On $0 \leq y \leq n/2$, the Taylor estimate for $\log(1-y/n)$, with its integral remainder, bounds the difference from e^{-y} in the integral by $Cn^{-1}e^{-y/2}(1+y)^2y^{-\Re\alpha}$. One may first use $0 \leq y \leq n/4$ for this estimate and absorb $n/4 \leq y \leq n/2$ into its exponentially small bound. On $n/2 \leq y \leq n$, integrate the exponentially small factor $(1-y/n)^{n+\Re\alpha-1}$ directly. The same estimates hold after each fixed parameter derivative, with additional integrable powers of $|\log y|$ and $|\log(1-y/n)|$. The limiting integral is $\Gamma(1-\alpha)$; its reciprocal is bounded on the chosen compact set. This proves (FPK.13) and its parameter derivatives. Recurrence back to the original α multiplies by a fixed finite product of $n+\alpha-r$, yielding the asserted formula on every compact set.

In (FPK.12), the $r=0$ terms therefore have coefficients

$$2^{-b}n^{a-1}/\Gamma(a), \quad (-1)^n 2^{-a}n^{b-1}/\Gamma(b),$$

each with a relative error of order $1/n$ interpreted analytically when a reciprocal gamma factor vanishes. The terms $r \geq 1$ are of the next indicated order or smaller. The exact normalization (FPK.2) multiplies these coefficients by

$$\frac{n!}{\sqrt{\gamma_n}} = 2^{-1/4} \left(\frac{\Gamma(n+1)}{\Gamma(n+1/2)} \right)^{1/2} = 2^{-1/4} n^{1/4} (1+O(n^{-1})).$$

This proves (FPK.8)–(FPK.10), including the original factors of two and every derivative required for the full jet calculation.

174.2 The complete off-critical blocks

For $w_i = \lambda_i - c$, put $\delta_i = \Re w_i$. When $\delta_i \neq 0$, set $\epsilon_i = \text{sgn } \delta_i$. The dominant coefficient $C_{\epsilon_i}(w)$ is nonzero on a neighborhood of w_i , because the real part of its gamma argument at w_i is $1/4 + |\delta_i|/2 > 0$. On that full local jet block define $T_{N,i}$ to be multiplication by the analytic germ

$$\left(C_{\epsilon_i}(w) N^{\epsilon_i w/2} \right)^{-1}, \quad \det T_{N,i} = \left(C_{\epsilon_i}(w_i) N^{\epsilon_i w_i/2} \right)^{-m_i}. \quad (\text{FPK.14})$$

This retains all the derivatives of C_{ϵ_i} and the triangular logarithmic jet terms. It is a specified invertible coordinate map used to compute the determinant, and will be undone.

Apply it to the complete Taylor column of e_n at w_i . The dominant component in position j becomes

$$v_{N,n;i,j} = \vartheta_{i,n} n^{-1/2} (n/N)^{\epsilon_i w_i/2} \frac{(\epsilon_i \log(n/N)/2)^j}{j!}, \quad \vartheta_{i,n} = \begin{cases} 1, & \epsilon_i = 1, \\ (-1)^n, & \epsilon_i = -1. \end{cases} \quad (\text{FPK.15})$$

The difference between the normalized exact row and (FPK.15) has squared-sum norm tending to zero. To verify that claim without neglecting small indices, the nondominant term and each of its fixed derivatives have squared-sum bound

$$CN^{-|\delta_i|}(1 + \log N)^{2j} \sum_{n=1}^N n^{-1-|\delta_i|}(1 + \log n)^{2j} = o(1).$$

For the remainder (FPK.10), multiplication and differentiation in (FPK.14) give a bound by a constant times a fixed power of $\log N$ times

$$N^{-|\delta_i|} \sum_{n=2}^N n^{|\delta_i|-3} + N^{-|\delta_i|} \sum_{n=2}^N n^{-1-|\delta_i|}.$$

It tends to zero: the first term is $O(N^{-2})$ if $|\delta_i| > 2$, $O(N^{-2} \log N)$ if it equals two, and $O(N^{-|\delta_i|})$ otherwise. Choose J in (FPK.10) sufficiently large for the remaining rapidly decaying term. The finitely many initial columns obey the same vanishing conclusion directly, because their normalization is $O(N^{-|\delta_i|/2}(\log N)^j)$.

For two blocks in the same half-plane, the Gram of (FPK.15) converges by an integrable Riemann sum to

$$(\mathbf{H}_\epsilon)_{(i,j),(a,l)} = \int_0^1 x^{\epsilon(w_i + \bar{w}_a)/2 - 1} \frac{(\epsilon \log x/2)^{j+l}}{j!l!} dx = \frac{(-\epsilon/2)^{j+l}(j+l)!}{j!l! [\epsilon(w_i + \bar{w}_a)/2]^{j+l+1}}. \quad (\text{FPK.16})$$

Here $\epsilon_i = \epsilon_a = \epsilon$, and the denominator has positive real part. Convergence at zero follows, for every fixed power of $\log x$, from that positive real part. For a direct Riemann-sum justification, split at any $b > 0$; on $[b, 1]$ the integrand is smooth, and on $(0, b)$ its absolute sums and integrals are bounded by $Cb^\alpha(1 + |\log b|^{j+l})$, with some $\alpha > 0$, which tends to zero.

The matrix $\mathbf{H}_\epsilon$ is positive definite. It is the Gram of the complete list $x^{\epsilon w_i/2 - 1/2}(\epsilon \log x/2)^j/j!$ in $L^2(0, 1)$. An equality between these functions, after $x = e^{-y}$ and division by the common nonzero factor $e^{y/2}$, gives an exponential-polynomial equality on $y > 0$. Apply the product of $(\partial_y + \epsilon w_a/2)^{m_a}$ over $a \neq i$. It removes the other blocks and acts on the remaining polynomial by a product of nonzero constants plus nilpotent differentiation. That product is invertible on the specified finite polynomial space. Every remaining polynomial is therefore zero, proving independence.

For two opposite half-planes the Gram has instead an additional $(-1)^n$. Its absolute integrable Riemann envelope is the same with real exponent $(|\delta_i| + |\delta_a|)/2 > 0$ at zero. On $[b, 1]$, pairing successive indices proves that its alternating Riemann sum tends to zero by uniform continuity. The absolute bound on $(0, b)$ just proved then gives a zero limit for the whole sum. Thus the two half-plane blocks decouple in this exact limit; no entry of the original finite kernel has been set to zero.

174.3 Critical full jets and all mixed blocks

For $\delta_i = 0$, put $L_N = \log N$ and use the diagonal jet map

$$(\mathbf{T}_{N,i})_{j,j} = L_N^{-j-1/2}, \quad \det \mathbf{T}_{N,i} = L_N^{-m_i^2/2}. \quad (\text{FPK.17})$$

In a differentiated dominant term (FPK.9), the part in which all j derivatives hit the power of n is

$$\frac{(\log n)^j}{2^j j! \sqrt{n}} \left(C_+(w_i) n^{w_i/2} + (-1)^{n+j} C_-(w_i) n^{-w_i/2} \right). \quad (\text{FPK.18})$$

Every other differentiated term has a smaller power of $\log n$. After multiplication by (FPK.17), its squared-sum norm tends to zero, since $\sum_{n \leq N} n^{-1}(\log n)^r = O(1 + L_N^{r+1})$. The remainder in (FPK.10) and every fixed initial column vanish in the same normalized squared sum.

At the same critical point, the nonalternating products in (FPK.18) give the limit

$$(\mathbf{H}_i^0)_{j,l} = \frac{|C_+(w_i)|^2 + (-1)^{j+l}|C_-(w_i)|^2}{2^{j+l}j!!(j+l+1)} = \frac{|C_+(w_i)|^2}{2^{j+l}j!!} \int_{-1}^1 t^{j+l} dt. \quad (\text{FPK.19})$$

The last equality uses the exact relation $C_-(w_i) = \overline{C_+(w_i)}$ for purely imaginary w_i . The coefficient is nonzero, and (FPK.19) is a positive multiple of the Gram of independent real monomials of degrees below m_i . It is therefore positive definite, including every nilpotent direction.

For different critical points, a nonalternating product has $\sum_{n \leq N} n^{-1+i\theta}(\log n)^r$ with $\theta \neq 0$. Its difference from the corresponding integral is bounded uniformly in N : the derivative of $x^{-1+i\theta}(\log x)^r$ is absolutely integrable on $[1, \infty)$. Substitution $x = e^t$ and integration by parts bound that integral by $O(1 + L_N^r)$. Division by L_N^{r+1} gives zero. Alternating products are bounded uniformly before this division, by pairing successive terms and the same integrable derivative estimate. This includes the alternating products within a single critical block. Hence all different critical blocks have zero cross limit.

Every mixed off-critical/critical block also has zero limit. Here is a bound that does not require any oscillatory cancellation. The normalized off-critical row (FPK.15) has a limiting squared mass distribution on $x = n/N \in (0, 1)$ with integrable density $x^{|\delta_i|-1}$ times a fixed power of $\log x$. For any fixed $R > 0$, its mass in $n \leq Ne^{-R}$ has limiting upper bound equal to the integral of that density on $(0, e^{-R})$, which tends to zero as R grows. On the complementary indices, the squared mass of a normalized critical row is $O(R/L_N)$: use $(\log n)^{2j} \leq L_N^{2j}$ and $\sum_{Ne^{-R} < n \leq N} 1/n \leq R + o(1)$. Both rows have bounded total squared norm by their already-proved diagonal limits. Cauchy-Schwarz on the two index ranges, first letting N tend to infinity and then R tend to infinity, proves that their inner product tends to zero. The vanishing remainder rows do not change this conclusion.

174.4 The entire determinant and the original quotient volume

Let $\mathbf{T}_N$ be the block diagonal combination of (FPK.14) and (FPK.17), with any fixed root-block ordering. The preceding proofs establish the full finite-matrix limit

$$\mathbf{T}_N \mathbf{K}_N \mathbf{T}_N^* \longrightarrow \mathbf{H} := \mathbf{H}_+ \oplus \mathbf{H}_- \oplus \bigoplus_{\delta_i=0} \mathbf{H}_i^0 > 0. \quad (\text{FPK.20})$$

Absent blocks are omitted and their determinants are one. Put

$$\mathcal{A}_\chi = \sum_i m_i |\Re \lambda_i - c|, \quad \mathcal{B}_\chi = \sum_{\Re \lambda_i = c} m_i^2, \quad (\text{FPK.21})$$

$$\mathcal{C}_\chi = (\det \mathbf{H}) \prod_{\delta_i \neq 0} |C_{\epsilon_i}(\lambda_i - c)|^{2m_i} > 0. \quad (\text{FPK.22})$$

All entries defining this constant have been given in (FPK.8), (FPK.16), and (FPK.19), with their actual coordinates and factors.

Theorem 174.1 (Complete fixed-Gamma jet determinant). *For the original fixed source line, the entire original finite jet observation, and $N \rightarrow \infty$ through integers,*

$$\det \mathbf{K}_N = \mathcal{C}_\chi N^{\mathcal{A}_\chi} (\log N)^{\mathcal{B}_\chi} (1 + o(1)), \quad (\text{FPK.23})$$

$$V_N^\sigma = \frac{|\det \mathbf{E}_\chi|^2}{\mathcal{C}_\chi} N^{-\mathcal{A}_\chi} (\log N)^{-\mathcal{B}_\chi} (1 + o(1)), \quad (\text{FPK.24})$$

and therefore

$$\log V_N^\sigma = -\mathcal{A}_\chi \log N - \mathcal{B}_\chi \log \log N + \log \frac{|\det \mathbf{E}_\chi|^2}{\mathcal{C}_\chi} + o(1). \quad (\text{FPK.25})$$

Proof. Determinant is a polynomial in the matrix entries, so (FPK.20) gives $\det(\mathbf{T}_N \mathbf{K}_N \mathbf{T}_N^*) \rightarrow \det \mathbf{H} > 0$. The literal determinant factors of the coordinate maps are

$$|\det \mathbf{T}_N|^2 = N^{-\mathcal{A}_\chi} (\log N)^{-\mathcal{B}_\chi} \prod_{\delta_i \neq 0} |C_{\epsilon_i}(w_i)|^{-2m_i}.$$

Undoing this congruence proves (FPK.23). The exact original coordinate formula (FPK.5) proves (FPK.24). Its positive constant and positive determinants allow taking real logarithms, which gives (FPK.25). $\square$

The original arithmetic observation remains $\sigma_h^{\otimes k} \eta_{h,k} : E \hookrightarrow Q^{\otimes k}$, with $\eta_{h,k}$ containing its complete Taylor unit $v_h^{\otimes k}$. No factor in this injection was changed in forming the comparison norm on the original remainder coordinate E . If that coordinate is transported by a specified fixed invertible unit matrix U , the quotient Gram becomes $U^* G_N^\sigma U$ and its determinant is multiplied by the exact fixed factor $|\det U|^2$. Thus a unit-containing alternative frame retains the same two exponents and its own explicitly transported constant; the unit is never set to one.

This theorem is a fixed- k , fixed- χ statement. It provides no uniform error as the arithmetic packet or k changes, and does not assign a sign to the original signed four-window correction. Its assertions are exact asymptotic statements for the stated full kernel and quotient determinant, retaining every original jet.

174.5 The original tensor-Gamma reference with its full mass

The original reference in (AT4), on this same line $S = k/2 + iu$, is

$$m_0(u) = \frac{(2\pi)^{k/2}}{c_{k/4}} \frac{|\Gamma(k/4 + iu/2)|^2}{2\pi}, \quad c_a = 2^{1-2a} \Gamma(2a). \quad (\text{FPK.26})$$

Its mass is exactly $(2\pi)^{k/2}$; this scalar is retained. The original generating-integral calculation gives its monic polynomials $p_{k,n}(S) = i^n b_n^{(k/4)} ((S - c)/i)$ and squared norms

$$\gamma_{k,n} = (2\pi)^{k/2} \frac{n! \Gamma(n + k/2)}{\Gamma(k/2)}. \quad (\text{FPK.27})$$

Their generating function in (FPK.7) has $1/4$ replaced by $k/4$. The coefficient proof (FPK.11)–(FPK.13), with this fixed positive parameter, gives the normalized expansion (FPK.9)–(FPK.10) with the exact coefficients

$$C_{\pm,k}(w) = (2\pi)^{-k/4} \sqrt{\Gamma(k/2)} \frac{2^{-k/4 \pm w/2}}{\Gamma(k/4 \pm w/2)}. \quad (\text{FPK.28})$$

To verify the unchanged power of n , a singular coefficient is $n^{k/4 \pm w/2 - 1}$, while division of $n!$ by the square root of (FPK.27) contributes $n^{1/2 - k/4}$ and the displayed prefactor. Their product is $n^{\pm w/2 - 1/2}$. The next-order coefficient and every derivative have exactly the bounds already used above. The dominant coefficients remain nonzero, since their gamma arguments have positive real part. At critical points the two coefficients are conjugate. Thus every full-block estimate, positive Gram limit, and determinant argument (FPK.14)–(FPK.25) applies with (FPK.28), keeping the original root coordinates and the same E_χ . In particular

$$\log V_N^{m_0} = -\mathcal{A}_\chi \log N - \mathcal{B}_\chi \log \log N + \log \frac{|\det E_\chi|^2}{C_{\chi,k}} + o(1), \quad (\text{FPK.29})$$

where $C_{\chi,k} > 0$ is given by the literal constant formula (FPK.22) with every $C_\pm$ replaced by $C_{\pm,k}$, including their occurrences in the critical blocks (FPK.19). The off-critical Cauchy blocks (FPK.16) remain unchanged. This proves the corresponding fixed-packet result for the programme's original reference, with its entire original mass.

175 A fixed denominator in the Gamma weight

Throughout this section the original real number $c = k/2$, the original coordinate S , and the actual monic polynomial

$$\chi(S) = \prod_{\lambda \in \Lambda} (S - \lambda)^{m_\lambda}, \quad q = \sum_{\lambda \in \Lambda} m_\lambda \geq 1,$$

are fixed. Distinct elements of Λ denote distinct roots, and every m_λ is the full multiplicity in χ . No root is discarded. Set

$$\sigma(u) = \frac{|\Gamma(1/4 + iu/2)|^2}{2\pi}, \quad w_M(u) = \frac{\sigma(u)}{(1 + u^2)^M}, \quad M \in \mathbb{Z}_{\geq 0}. \quad (\text{LC.1})$$

For a positive weight w with finite moments, let

$$\|p\|_w^2 = \int_{\mathbb{R}} |p(c + iu)|^2 w(u) du, \quad p \in \mathcal{P}_N = \mathbb{C}[S]_{\leq N}. \quad (\text{LC.2})$$

For $N \geq q - 1$ and a remainder $a(S) = \sum_{j=0}^{q-1} a_j S^j$, put

$$\|[a]\|_{w,N,\chi}^2 = \min_{\substack{p \in \mathcal{P}_N \\ p-a \in (\chi)}} \|p\|_w^2 = \mathbf{a}^* G_N(w, \chi) \mathbf{a}, \quad V_N(w, \chi) = \det G_N(w, \chi). \quad (\text{LC.3})$$

The minimum exists uniquely because it is the minimum of a positive definite quadratic form on a nonempty affine subspace of a finite dimensional space. The form is positive definite since a polynomial vanishing almost everywhere on $c + i\mathbb{R}$ vanishes identically. In particular, V_N retains the original Gram determinant convention.

175.1 Explicit comparison of the weights

The exact Gamma envelope, including $u = 0$, is

$$c_\Gamma e^{-\alpha|u|} (1 + |u|)^{-1/2} \leq \sigma(u) \leq C_\Gamma e^{-\alpha|u|} (1 + |u|)^{-1/2}, \quad (\text{LC.4})$$

$$\alpha = \frac{\pi}{2}, \quad c_\Gamma = \sqrt{2}e^{-7/6}, \quad C_\Gamma = \sqrt{2\sqrt{5}}e^{2/3}.$$

For completeness, its proof is recalled. Binet's exact identity on $\Re z > 0$, with the logarithm real on positive reals, is

$$\log \Gamma(z) = (z - \tfrac{1}{2}) \log z - z + \tfrac{1}{2} \log(2\pi) + R(z), \quad R(z) = \int_0^\infty e^{-zt} \frac{1}{t} \left(\frac{1}{e^t - 1} - \frac{1}{t} + \frac{1}{2} \right) dt. \quad (\text{LC.5})$$

This identity is given in NIST DLMF, equation 5.9.10₂, https://dlmf.nist.gov/5.9.E10_2. Writing $x = t/2$ in the kernel, its value is $(\coth x - 1/x)/(4x)$. The functions $F(x) = x \cosh x - \sinh x$ and $H(x) = (x^2 + 3) \sinh x - 3x \cosh x$ vanish at zero and satisfy $F'(x) = x \sinh x \geq 0$ and $H'(x) = xF(x) \geq 0$ for $x \geq 0$. Dividing by the positive denominators $x \sinh x$ and $3x \sinh x$ gives $0 \leq \coth x - 1/x \leq x/3$ for $x > 0$. Thus the kernel in (LC.5) lies between 0 and $1/12$, and $|R(z)| \leq 1/(12\Re z)$.

At the retained argument $z = 1/4 + iu/2$, put $x = |u|$ and $\rho = |z| = (1/16 + x^2/4)^{1/2}$. Twice the real part of (LC.5) gives exactly

$$\sigma(u) = \rho^{-1/2} \exp(-x \arctan(2x) - \tfrac{1}{2} + 2\Re R(z)). \quad (\text{LC.6})$$

The remainder bound is $|R(z)| \leq 1/3$. For $x \geq 0$ the exponent lies between $-\alpha x - 7/6$ and $-\alpha x + 2/3$: the lower inequality uses $\arctan(2x) \leq \pi/2$, while for $x > 0$ the upper inequality follows from

$\arctan(2x) = \pi/2 - \arctan(1/(2x))$ and $\arctan y \leq y$ for $y \geq 0$. At $x = 0$ the upper inequality follows directly from $-1/2 \leq 0$. The exact squared differences

$$\frac{(1+x)^2}{4} - \rho^2 = \frac{3+8x}{16}, \quad \rho^2 - \frac{(1+x)^2}{20} = \frac{(4x-1)^2}{80}$$

give $(1+x)/(2\sqrt{5}) \leq \rho \leq (1+x)/2$. Combining these inequalities with (LC.6) proves (LC.4), including the origin.

Fix $r > 1$ and put $\beta = \alpha(r-1) > 0$. Define the finite explicit constant

$$B_{r,M} = \frac{C_\Gamma}{c_\Gamma} \sum_{j=0}^{2M} \binom{2M}{j} \frac{j!}{\beta^j}. \quad (\text{LC.7})$$

For $x = |u| \geq 0$, the Gamma envelope gives

$$\frac{\sigma(ru)}{\sigma(u)} \leq \frac{C_\Gamma}{c_\Gamma} e^{-\beta x} \left(\frac{1+x}{1+rx} \right)^{1/2} \leq \frac{C_\Gamma}{c_\Gamma} e^{-\beta x}.$$

For each integer $j \geq 0$, the exponential series implies $e^{\beta x} \geq (\beta x)^j / j!$, so that $x^j e^{-\beta x} \leq j! \beta^{-j}$, with the case $j = 0$ read directly. Since $(1+x^2)^M \leq (1+x)^{2M}$, expansion of the latter polynomial now proves

$$B_{r,M}^{-1} \sigma(ru) \leq w_M(u) \leq \sigma(u) \quad (u \in \mathbb{R}). \quad (\text{LC.8})$$

Every comparison is global, and r is fixed independently of N .

175.2 The exact morphism on the original jet constraints

Order the roots once and use that ordering throughout. For a polynomial p , write its divided jets as

$$J_\chi p = \left(\frac{p^{(j)}(\lambda)}{j!} \right)_{\lambda \in \Lambda, 0 \leq j < m_\lambda}.$$

Let E_χ be the matrix of J_χ on the original remainder frame $1, S, \dots, S^{q-1}$. This matrix is invertible: a remainder in its kernel has a zero of order at least m_λ at every λ , is consequently divisible by χ , and has degree less than q , hence is zero. For all polynomials p, a , the same multiplicity criterion proves

$$p - a \in (\chi) \iff J_\chi p = J_\chi a. \quad (\text{LC.9})$$

For the comparison parameter $r > 0$, define the polynomial bijection

$$(T_r p)(S) = p \left(c + \frac{S-c}{r} \right), \quad \zeta_\lambda(r) = c + r(\lambda - c), \quad D_r = \text{diag}_{\lambda,j}(r^j). \quad (\text{LC.10})$$

Its inverse is $T_{1/r}$. The locations $\zeta_\lambda(r)$ are pairwise distinct, because $r > 0$. Write J_r for the divided-jet map of the same multiplicities at these locations. The chain rule, with all constants retained, gives

$$\frac{(T_r p)^{(j)}(\zeta_\lambda(r))}{j!} = r^{-j} \frac{p^{(j)}(\lambda)}{j!}, \quad J_r T_r = D_r^{-1} J_\chi. \quad (\text{LC.11})$$

The literal substitution $v = ru$ in the integral on the original line gives

$$\|p\|_{\sigma(r \cdot)}^2 = r^{-1} \int_{\mathbb{R}} \left| p \left(c + \frac{iv}{r} \right) \right|^2 \sigma(v) dv = r^{-1} \|T_r p\|_{\sigma}^2. \quad (\text{LC.12})$$

Equations (LC.11)–(LC.12) are the exact relation between the comparison measure and the original observation. In particular, the original condition $p \equiv a \pmod{\chi}$ becomes the condition $J_r(T_r p) =$

$D_r^{-1}E_\chi \mathbf{a}$; it has not been discarded or replaced by an independent arithmetic condition. The symbols $\zeta_\lambda(r)$ describe these transported evaluation functionals only.

Let $K_N^\sigma(r)$ be the Gram matrix of all these divided-jet functionals on $(\mathcal{P}_N, \|\cdot\|_\sigma)$. More explicitly, for any orthonormal basis $e_0, \dots, e_N$ of this space,

$$[K_N^\sigma(r)]_{(\lambda,j),(\mu,l)} = \sum_{n=0}^N \frac{e_n^{(j)}(\zeta_\lambda(r))}{j!} \overline{\frac{e_n^{(l)}(\zeta_\mu(r))}{l!}}. \quad (\text{LC.13})$$

The map J_r is onto, since its restriction to $\mathcal{P}_{q-1}$ is injective by the same multiplicity proof as for E_χ and the two spaces have dimension q . Hence $K_N^\sigma(r)$ is positive definite. For clarity, if L is the q by $N+1$ matrix of J_r in an orthonormal basis, then $K_N^\sigma(r) = LL^*$. For any required jet vector y , the vector $b_0 = L^*(LL^*)^{-1}y$ satisfies $Lb_0 = y$. Every other solution is $b_0 + h$ with $Lh = 0$, and $h^*b_0 = h^*L^*(LL^*)^{-1}y = (Lh)^*(LL^*)^{-1}y = 0$. Thus the minimum squared norm is $y^*(K_N^\sigma(r))^{-1}y$. Applying this identity to the exact original constraints yields

$$G_N(\sigma(r\cdot), \chi) = r^{-1}E_\chi^* D_r^{-1} (K_N^\sigma(r))^{-1} D_r^{-1} E_\chi. \quad (\text{LC.14})$$

Since $\det D_r = r^{\sum_\lambda m_\lambda(m_\lambda-1)/2}$,

$$V_N(\sigma(r\cdot), \chi) = r^{-\sum_\lambda m_\lambda^2} \frac{|\det E_\chi|^2}{\det K_N^\sigma(r)}. \quad (\text{LC.15})$$

This is an identity in the original remainder frame, with the original χ on its left and the full transported jet matrix on its right.

There is an equivalent check on the remainder determinant. On $\mathcal{P}_{q-1}$ the coefficient matrix C_r of T_r is upper triangular with entries

$$(C_r)_{l,j} = \binom{j}{l} c^{j-l} (1 - r^{-1})^{j-l} r^{-l} \quad (0 \leq l \leq j < q), \quad \det C_r = r^{-q(q-1)/2}. \quad (\text{LC.16})$$

Let E_r be the divided-jet matrix at $\zeta_\lambda(r)$ on this displayed polynomial frame. Equation (LC.11) reads $E_r C_r = D_r^{-1} E_\chi$. Consequently

$$G_N(\sigma(r\cdot), \chi) = r^{-1} C_r^* [E_r^* (K_N^\sigma(r))^{-1} E_r] C_r,$$

and taking determinants gives the total frame factor r^{-q^2} . This explicitly agrees with (LC.15); no modulus, Jacobian, or derivative factor has been absorbed into a normalization.

175.3 Passage to the asymptotic coefficient

Write

$$A_\chi = \sum_{\lambda \in \Lambda} m_\lambda |\Re \lambda - c|, \quad B_\chi = \sum_{\substack{\lambda \in \Lambda \\ \Re \lambda = c}} m_\lambda^2. \quad (\text{LC.17})$$

The full confluent Gamma-kernel theorem (Theorem 174.1) proved in the preceding module, applied to the particular fixed functionals in (LC.13), gives

$$\log \det K_N^\sigma(r) = r A_\chi \log N + B_\chi \log \log N + O_{r,\chi}(1). \quad (\text{LC.18})$$

Indeed, $\Re \zeta_\lambda(r) - c = r(\Re \lambda - c)$, and the roots on the line are exactly those original roots with $\Re \lambda = c$, with all their multiplicities unchanged. This use of the Gamma theorem is for each fixed $r > 0$; no uniformity in a moving parameter is asserted or needed. Equation (LC.15) therefore proves

$$\log V_N(\sigma(r\cdot), \chi) = -r A_\chi \log N - B_\chi \log \log N + O_{r,\chi}(1). \quad (\text{LC.19})$$

We next pass the pointwise inequalities to the fixed quotient without altering the admissible polynomial space. If $b w_1 \leq w_2 \leq d w_3$ pointwise with $b, d > 0$, then for every polynomial p the same inequalities hold for the squared norms. Taking the infimum over the identical set $\{p \in \mathcal{P}_N : p - a \in (\chi)\}$ gives

$$b \mathbf{a}^* G_N(w_1, \chi) \mathbf{a} \leq \mathbf{a}^* G_N(w_2, \chi) \mathbf{a} \leq d \mathbf{a}^* G_N(w_3, \chi) \mathbf{a}.$$

Thus these are inequalities of positive definite Hermitian matrices. If $0 < H \leq G$, then $H^{-1/2} G H^{-1/2} \geq I$; all its eigenvalues are at least one, and $\det G \geq \det H$. This proves, in particular,

$$B_{r,M}^{-q} V_N(\sigma(r \cdot), \chi) \leq V_N(w_M, \chi) \leq V_N(\sigma, \chi). \quad (\text{LC.20})$$

Using (LC.19) at r and at 1, we obtain, for each fixed $r > 1$,

$$-r A_\chi \log N - B_\chi \log \log N + O_{r,M,\chi}(1) \leq \log V_N(w_M, \chi) \leq -A_\chi \log N - B_\chi \log \log N + O_\chi(1). \quad (\text{LC.21})$$

Dividing by $\log N$ for $N > 1$ and taking lower and upper limits gives

$$-r A_\chi \leq \liminf_{N \rightarrow \infty} \frac{\log V_N(w_M, \chi)}{\log N} \leq \limsup_{N \rightarrow \infty} \frac{\log V_N(w_M, \chi)}{\log N} \leq -A_\chi.$$

Here $A_\chi \geq 0$. The lower inequality holds separately for every fixed $r > 1$. Taking its supremum as r decreases to 1 proves the exact limit

$$\lim_{N \rightarrow \infty} \frac{\log V_N(w_M, \chi)}{\log N} = - \sum_{\lambda \in \Lambda} m_\lambda |\Re \lambda - c|. \quad (\text{LC.22})$$

This order of limits makes the possible growth of $B_{r,M}$ near $r = 1$ irrelevant: the constant is fixed before N tends to infinity.

If every original root lies on $\Re S = c$, then $A_\chi = 0$. Already a single fixed choice, for example $r = 2$, makes the two sides of (LC.21) equal up to bounded errors. Hence in this case

$$\log V_N(w_M, \chi) = - \left(\sum_{\lambda \in \Lambda} m_\lambda^2 \right) \log \log N + O_{M,\chi}(1). \quad (\text{LC.23})$$

For $A_\chi > 0$, equation (LC.22) is the conclusion proved by this comparison; it does not assert a bounded remainder at the $\log \log N$ scale.

175.4 Application to the actual arithmetic weight

Retain the actual weight $m_{h,k}$ and the original polynomial χ from the arithmetic construction. The proved arithmetic-tail envelope for fixed $k \geq 3$ is

$$a_k \frac{\sigma(u)}{(1+u^2)^M} \leq m_{h,k}(u) \leq A_k \sigma(u), \quad u \in \mathbb{R}, \quad (\text{LC.24})$$

where a_k, A_k are the positive constants calculated there and M is its fixed integer exponent. Applying the same quotient order argument gives

$$a_k^q V_N(w_M, \chi) \leq V_N(m_{h,k}, \chi) \leq A_k^q V_N(\sigma, \chi). \quad (\text{LC.25})$$

The constants k, q, a_k, A_k, M , every root, and every root multiplicity are fixed in this limit. Equations (LC.22) and (LC.19) at $r = 1$ now prove

$$\lim_{N \rightarrow \infty} \frac{\log V_N(m_{h,k}, \chi)}{\log N} = - \sum_{\lambda \in \Lambda} m_\lambda |\Re \lambda - k/2|. \quad (\text{LC.26})$$

If all original roots lie on $\Re S = k/2$, the stronger conclusion is

$$\log V_N(m_{h,k}, \chi) = - \left(\sum_{\lambda \in \Lambda} m_\lambda^2 \right) \log \log N + O_{h,k,\chi}(1). \quad (\text{LC.27})$$

These statements concern the actual fixed quotient. They provide no uniform estimate when the arithmetic polynomial or k changes with N , and they do not determine a signed difference of growing-window quotient determinants. All such parameters remain in their original domains.

Finally retain the original tensor-Gamma density m_0 of (AT4), with its original mass $(2\pi)^{k/2}$. Its proved complete asymptotic (FPK.29) has the same leading coefficient $-A_\chi$. Hence the actual end-point quotient ratio satisfies

$$\lim_{N \rightarrow \infty} \frac{1}{\log N} \log \frac{V_N(m_{h,k}, \chi)}{V_N(m_0, \chi)} = 0. \quad (\text{LC.28})$$

If all original roots lie on $\Re S = k/2$, (LC.27) and (FPK.29) give the stronger bounded logarithmic ratio, equivalently positive upper and lower bounds for this ratio for all sufficiently large N . Both conclusions are for the original fixed h, k, χ . No uniformity needed for a varying-packet four-window expression is asserted by (LC.28).

176 The original arithmetic classes under Hilbert completion

Fix the original complete counterfactual quartet h of (HT1), the integer $k \geq 3$, and its complete cyclic annihilator $\chi = \chi_{h,k}$ of degree $q \geq 1$. Every parameter remains fixed as $N \rightarrow \infty$. Retain

$$\begin{aligned} c &= k/2, \quad \mathcal{P} = \mathbb{C}[S], \quad E = \mathcal{P}/\chi\mathcal{P}, \quad J : \mathcal{P} \longrightarrow E, \\ \mathcal{H}_{h,k} &= L^2(\mathbb{R}, m_{h,k}(u) du), \quad \iota : \mathcal{P} \longrightarrow \mathcal{H}_{h,k}, \quad (\iota P)(u) = P(c + iu). \end{aligned} \quad (\text{FKG.1})$$

The map ι is injective, since the original density is positive almost everywhere and a nonzero polynomial has finitely many zeros on the source line. We write $\mathcal{P}$ and $\chi\mathcal{P}$ for these actual embedded subspaces when taking Hilbert-space quotients. All quotient arrows below are complex linear. Multiplication by S on the full Hilbert space has its unbounded-operator domain; no everywhere-defined polynomial-module structure on that space is assumed.

176.1 Vanishing of the entire quotient Gram

Put $w_i = \lambda_i - c$ and $\delta_i = \Re w_i$ as in (FPK.14). For a noncritical block, write $a_i(w) = C_{\epsilon_i}(w)^{-1}$, where $\epsilon_i = \text{sgn } \delta_i$. In normalized Taylor coordinates the complete triangular matrix in (FPK.14) has entries

$$(\mathsf{T}_{N,i})_{j,l} = \begin{cases} N^{-\epsilon_i w_i/2} \sum_{r=0}^{j-l} a_i^{[r]}(w_i) \frac{(-\epsilon_i \log N/2)^{j-l-r}}{(j-l-r)!}, & l \leq j, \\ 0, & l > j. \end{cases} \quad (\text{FKG.2})$$

This follows by the product rule for Taylor coefficients of $a_i(w) \exp(-\epsilon_i w \log N/2)$; thus no derivative of the original gamma unit has been dropped. For fixed roots and multiplicities,

$$\|\mathsf{T}_{N,i}\| \leq C_i N^{-|\delta_i|/2} (1 + \log N)^{m_i-1} \longrightarrow 0 \quad (\delta_i \neq 0). \quad (\text{FKG.3})$$

For a critical block, (FPK.17) gives $\|\mathsf{T}_{N,i}\| = (\log N)^{-1/2} \rightarrow 0$ for $N \geq 3$. There are finitely many blocks, so $\|\mathsf{T}_N\| \rightarrow 0$.

Let $A_N = \mathsf{T}_N \mathsf{K}_N \mathsf{T}_N^*$. The complete matrix limit (FPK.20) gives $A_N \rightarrow \mathsf{H} > 0$. If h_0 is the smallest eigenvalue of H , then $A_N \geq (h_0/2)I$ for all sufficiently large N : for each unit vector the difference of

the quadratic forms is at most $\|A_N - H\|$. In particular $\|A_N^{-1}\| \leq 2/h_0$. Undoing the exact congruence gives

$$\begin{aligned} K_N^{-1} &= T_N^* A_N^{-1} T_N, \\ G_N^\sigma &= E_\chi^* T_N^* A_N^{-1} T_N E_\chi, \\ \|G_N^\sigma\| &\leq \frac{2\|E_\chi\|^2}{h_0} \|T_N\|^2 \longrightarrow 0. \end{aligned} \tag{FKG.4}$$

All norms on E here use the original increasing-power remainder frame. In particular this is vanishing of the entire positive operator, not merely of its determinant. The explicit bounds (FKG.3) also give

$$\|G_N^\sigma\| \leq C_\chi \left(\frac{\mathbf{1}_{\{\exists i: \delta_i=0\}}}{\log N} + \sum_{\delta_i \neq 0} N^{-|\delta_i|} (1 + \log N)^{2m_i-2} \right) \tag{FKG.5}$$

for all sufficiently large N , with one finite constant for the fixed original observation.

Write $R_N^{\text{ar}} : E \rightarrow \mathcal{P}_N$ for the canonical least-norm polynomial lift in the original arithmetic form (AT6). It is the unique minimizer on each affine fibre $J_N P = x$: orthogonal projection onto $\chi \mathcal{P}_{N-q}$ in the finite positive-definite polynomial space proves existence and uniqueness. Its source Gram is G_N^{ar} , so

$$J_N R_N^{\text{ar}} = I_E, \quad \|\iota R_N^{\text{ar}} x\|_{\mathcal{H}_{h,k}}^2 = x^* G_N^{\text{ar}} x. \tag{FKG.6}$$

The proved actual envelope $m_{h,k} \leq A_k \sigma$ in (LC.24) applies to every polynomial in the same affine fibre. Taking the minimum first for the arithmetic norm and then comparing with the minimizing gamma lift proves

$$0 < G_N^{\text{ar}} \leq A_k G_N^\sigma, \quad \|G_N^{\text{ar}}\| \rightarrow 0, \quad \|\iota R_N^{\text{ar}}\|_{E \rightarrow \mathcal{H}_{h,k}} \rightarrow 0. \tag{FKG.7}$$

For the middle assertion a positive matrix has operator norm equal to the supremum of its unit-vector quadratic forms; the last assertion follows from (FKG.6). The constant A_k is the original arithmetic upper-comparison constant, including its full scalar mass.

176.2 Exact arithmetic observations and theta primitives

The original cohomology observation and its injection remain

$$\begin{aligned} \mathcal{O} &= q^{(k)} \mathcal{V} : \mathcal{P} \longrightarrow Q^{\otimes k}, \quad \mathcal{I} = \sigma_h^{\otimes k} \eta_{h,k} : E \hookrightarrow Q^{\otimes k}, \\ \mathcal{V} P &= P(D_1 + \cdots + D_k) F_h^{\otimes k}, \quad \eta_{h,k}[P] = v_h^{\otimes k} P(A_h^{(k)}) 1, \\ v_h &= j_h(g/h), \quad g = 2\xi, \quad D = -x\partial_x, \quad \mathcal{O} = \mathcal{I}J. \end{aligned} \tag{FKG.8}$$

These are precisely (AT2)–(AT2a), with the complete invertible Taylor unit v_h retained. Consequently for every $x \neq 0$ and every $N \geq q-1$,

$$\mathcal{O}(R_N^{\text{ar}} x) = \mathcal{I}x \neq 0, \quad \|\iota R_N^{\text{ar}} x\|_{\mathcal{H}_{h,k}} \longrightarrow 0. \tag{FKG.9}$$

This comparison also retains the exact original tensor-source norm: Mellin Plancherel on each variable gives

$$\|\mathcal{V} P\|_{L^2((0,\infty)^k, dx_1 \cdots dx_k)}^2 = \int_{\mathbb{R}^k} |P(k/2 + i \sum t_i)|^2 \prod_i w_h(t_i) dt = \|\iota P\|_{\mathcal{H}_{h,k}}^2. \tag{FKG.10}$$

Indeed the Mellin transform of the source is $P(\sum s_i) \prod_i v_h(s_i)$, the k Plancherel factors $(2\pi)^{-k}$ are exactly those in $\prod_i w_h(t_i)$, and the change $(t_1, \dots, t_k) \mapsto (t_1, \dots, t_{k-1}, u)$ has determinant one. The final equality is the defining convolution. Thus (FKG.9) quantifies the original source representatives themselves.

For $q - 1 \leq a < b$, monic division gives a unique polynomial $\kappa_x \in \mathcal{P}_{b-q}$ satisfying

$$R_a^{\text{ar}}x - R_b^{\text{ar}}x = \chi\kappa_x. \quad (\text{FKG.11})$$

The inclusions into $\mathcal{P}_b$ are the literal coefficient inclusions. Both remainders are x , so their difference is divisible by χ ; the degree bound and uniqueness follow from monicity. Division also proves linearity in x . To retain the entire original boundary, successive monic division in $s_1, \dots, s_k$ gives specific polynomials Q_i with

$$\chi(\sum s_i) = \sum_{i=1}^k h(s_i)Q_i(\mathbf{s}). \quad (\text{FKG.12})$$

The final multivariable remainder is zero because the monomials of degree less than $\deg h$ in each variable form a basis of $(\mathbb{C}[s]/h)^{\otimes k}$ and the original χ annihilates the sum operator on this algebra. Using the original $h(D)F_h = \Theta\phi_0$, where $\phi_0 = (4\pi^2x^4 - 6\pi x^2)e^{-\pi x^2}$, form the cochain

$$\mathcal{P}_\chi(\kappa_x) = \sum_{i=1}^k (-1)^{i-1} Q_i(\mathbf{D})\kappa_x(\sum_j D_j)(F_h^{\otimes(i-1)} \otimes \phi_0 \otimes F_h^{\otimes(k-i)}). \quad (\text{FKG.13})$$

It has degree $k - 1$ and

$$d_{\text{tot}}\mathcal{P}_\chi(\kappa_x) = \mathcal{V}(R_a^{\text{ar}}x - R_b^{\text{ar}}x). \quad (\text{FKG.14})$$

At position i , the $i - 1$ preceding degree-one factors contribute $(-1)^{i-1}$ to the tensor differential, cancelling the displayed sign. The relation $\Theta\phi_0 = h(D_i)F_h$ then makes the sum equal to (FKG.12) applied to the original tensor source. Polynomial Euler operators commute with this differential by the original identity $D\Theta = \Theta D$. This proves (FKG.14) term by term. It is the full primitive (EW.47)–(EW.48), with the actual canonical arithmetic lifts substituted.

176.3 The exact algebraic quotient and its Hausdorff reduction

Polynomials are dense in $\mathcal{H}_{h,k}$. Here the exponential moment needed for the complete density theorem (ND.11)–(ND.12) follows in the original sum coordinate: for $0 < \eta < \pi/2$, Tonelli's theorem and $|\sum t_i| \leq \sum |t_i|$ give

$$\int_{\mathbb{R}} e^{\eta|u|} m_{h,k}(u) du \leq \left(\int_{\mathbb{R}} e^{\eta|t|} w_h(t) dt \right)^k < \infty. \quad (\text{FKG.15})$$

Finiteness follows directly from (ND.3), choosing $\eta < 2b < \pi/2$. To specify the density argument in this one-dimensional application, if f is orthogonal to all polynomials, the finite complex measure $d\nu = \bar{f} m_{h,k} du$ has an exponential moment of any order less than $\eta/2$, by Cauchy–Schwarz and (FKG.15). Its Fourier transform is holomorphic on the corresponding strip and all its derivatives at zero vanish, because polynomials in u are exactly polynomials in $S = c + iu$ under this invertible affine coordinate map. Its Taylor series and then the identity theorem make the transform zero on the strip. The Gaussian convolution and approximate-identity proof (ND.12) then gives $\nu = 0$ and $f = 0$ almost everywhere. Taking orthogonal complements proves the asserted density, including the original measure and mass.

For any $P \in \mathcal{P}$ and $N \geq \max(q - 1, \deg P)$, put

$$B_N(P) = P - R_N^{\text{ar}}JP \in \chi\mathcal{P}. \quad \|\iota(P - B_N(P))\|_{\mathcal{H}_{h,k}} \longrightarrow 0. \quad (\text{FKG.16})$$

The first assertion follows by taking its remainder; the second is (FKG.7) at the fixed vector JP . Thus the closure of $\chi\mathcal{P}$ contains $\mathcal{P}$, whose density was just proved. Consequently

$$\overline{\chi\mathcal{P}}^{\mathcal{H}_{h,k}} = \mathcal{H}_{h,k}. \quad (\text{FKG.17})$$

Every approximating relation in (FKG.16) has a literal polynomial quotient by χ , and hence the primitive (FKG.13) as well. The isometry (FKG.10) also extends to the exact original tensor-source completion:

$$\begin{aligned} \overline{\mathcal{V}} : \mathcal{H}_{h,k} &\xrightarrow{\cong} \overline{\mathcal{V}(\mathcal{P})}^{L^2((0,\infty)^k)}, \\ \overline{\mathcal{V}(\chi\mathcal{P})}^{L^2((0,\infty)^k)} &= \overline{\mathcal{V}(\mathcal{P})}^{L^2((0,\infty)^k)}. \end{aligned} \quad (\text{FKG.17a})$$

Indeed polynomial approximants form Cauchy sequences in the original tensor norm by (FKG.10); completeness defines the extension, and that norm equality proves its independence of the approximants and its isometry. Its range is closed by completeness and contains the dense polynomial source, hence is the displayed closure. Applying this isometry to (FKG.17) proves the second equality. Every vector before closure on its left is the boundary (FKG.14) for its literal polynomial quotient. No full test-space cohomology is quotiented in forming these two specified Hilbert closures.

There is nevertheless an injective map of the unchanged algebraic quotient into the algebraic Hilbert-space quotient, in the exact sequence

$$\begin{aligned} 0 \longrightarrow E &\xrightarrow{j} \mathcal{H}_{h,k}/\chi\mathcal{P} \xrightarrow{\pi} \mathcal{H}_{h,k}/\mathcal{P} \longrightarrow 0, \\ j([P]) &= \iota P + \chi\mathcal{P}, \quad \pi(f + \chi\mathcal{P}) = f + \mathcal{P}. \end{aligned} \quad (\text{FKG.18})$$

The first map is independent of the polynomial representative. Its kernel is zero because ι is injective and membership in the embedded $\chi\mathcal{P}$ means literal polynomial divisibility. The second map is well-defined and surjective since $\chi\mathcal{P} \subset \mathcal{P}$; its kernel consists exactly of the cosets represented by polynomials, which is the image of j . This proves exactness at every term without a topological closure.

With the quotient seminorm inherited from the original Hilbert norm, the Hausdorff reduction is instead the specific map

$$\begin{aligned} \mathcal{H}_{h,k}/\chi\mathcal{P} &\longrightarrow \mathcal{H}_{h,k}/\overline{\chi\mathcal{P}} = 0, \\ f + \chi\mathcal{P} &\longmapsto f + \overline{\chi\mathcal{P}}. \end{aligned} \quad (\text{FKG.19})$$

Indeed the seminorm of any coset is its distance to the dense subspace $\chi\mathcal{P}$, hence zero. In particular (FKG.19) kills the injected algebraic copy $j(E)$, although every nonzero $x \in E$ retains the nonzero arithmetic class $\mathcal{I}x$ in (FKG.8). This is an exact comparison between these two quotients.

One can also compute the entire closure of the original remainder graph. Give E its finite-dimensional topology in its original frame. For any $f \in \mathcal{H}_{h,k}$ and $x \in E$, choose polynomials $P_j \rightarrow f$ by density. For each fixed j , (FKG.7) permits an $N_j \geq \max(q-1, \deg P_j)$ such that $\|\iota R_{N_j}^{\text{ar}}(x - JP_j)\| < 1/j$. Then

$$\tilde{P}_j = P_j + R_{N_j}^{\text{ar}}(x - JP_j), \quad J\tilde{P}_j = x, \quad \iota\tilde{P}_j \longrightarrow f. \quad (\text{FKG.20})$$

It follows that the graph of $J : \mathcal{P} \subset \mathcal{H}_{h,k} \rightarrow E$ has closure $\mathcal{H}_{h,k} \times E$. In particular this densely defined observation is not closable when $q \geq 1$: (FKG.9) gives sequences tending to zero with any prescribed nonzero remainder. This precisely states why a continuous extension of the same nonzero finite observation to this Hilbert completion is impossible.

At an original nonempty support label α , each linear comparison just written lifts as $(\alpha, v) \mapsto (\alpha, Lv)$ and sends the external point τ to τ . Thus the killed amplitude in (FKG.19) maps to $(\alpha, 0)$, and the exact boundary (FKG.14) has that same supported zero observation. The label remains specified. These maps quantify this particular Hilbert completion; they do not identify its zero Hausdorff quotient with the entire original arithmetic cohomology or alter any original support restriction.

176.4 The coefficient for the complete counterfactual quartet

In the actual off-line counterfactual (HT1)–(HT2), retain $\rho = 1/2 + \delta + i\gamma$ with $0 < \delta < 1/2, \gamma > 0$, and its full order m . Put $\ell_k = 1 + k(m-1)$. The distinct cyclic roots and their complete multiplicities

are exactly

$$\lambda_{a,b} = k/2 + (2a - k)\delta + i(2b - k)\gamma, \quad 0 \leq a, b \leq k, \quad m_{a,b} = \ell_k. \quad (\text{FKG.21})$$

For completeness, in each ordered tensor-local factor the nilpotent sum $n_1 + \cdots + n_k$, with $n_i^m = 0$, has nonzero top coefficient $(k(m-1))!/((m-1)!)^k$ at total degree $k(m-1)$ and its next power vanishes. Its index is therefore ℓ_k . The real and imaginary signs may be chosen independently in each tensor factor, so every pair (a, b) occurs. Since $\delta\gamma \neq 0$, different pairs give different sums. The full annihilator is consequently the product over (FKG.21), each to power ℓ_k , with $q = \ell_k(k+1)^2$ as originally specified.

The exponents of the full gamma determinant therefore evaluate to

$$\begin{aligned} \mathcal{A}_\chi &= \delta\ell_k(k+1) \sum_{a=0}^k |2a - k| = 2\delta\ell_k(k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor = \mathcal{L}_{h,k}, \\ \mathcal{B}_\chi &= \begin{cases} (k+1)\ell_k^2, & k \text{ even,} \\ 0, & k \text{ odd.} \end{cases} \end{aligned} \quad (\text{FKG.22})$$

To verify the finite sum, pair a with $k-a$. For $k = 2r$ the sum of its positive terms is $2(1 + \cdots + r) = r(r+1)$; for $k = 2r-1$ it is $1 + 3 + \cdots + (2r-1) = r^2$. Doubling gives $2\lfloor (k+1)^2/4 \rfloor$ in both cases. A root is critical exactly when $2a = k$, which occurs only for even k , with its $k+1$ distinct imaginary coordinates and multiplicity ℓ_k . This proves the second exponent with all nilpotent jets included. The equality with $\mathcal{L}_{h,k}$ uses its exact definition in (HT8), not a change of normalization.

In particular (LC.26) gives, on the actual unchanged arithmetic source for every fixed $k \geq 3$,

$$\lim_{N \rightarrow \infty} \frac{\log V_N^{\text{ar}}}{\log N} = -2\delta\ell_k(k+1) \left\lfloor \frac{(k+1)^2}{4} \right\rfloor. \quad (\text{FKG.23})$$

The value of $\mathcal{B}_\chi$ in (FKG.22) is the proved gamma $\log \log N$ coefficient. For a mixed critical and non-critical arithmetic packet, the envelope proof establishes (FKG.23), and does not establish its next $\log \log N$ coefficient. None of (FKG.3)–(FKG.23) supplies an error uniform in growing k , q , or the packet. Their precise conclusions concern fixed original objects and the displayed exact maps.

177 The actual arithmetic form passes to every original quotient

Retain $g = 2\xi$, the full actual hypothetical quartet polynomial h , its complete common order m , and $v_h = g/h$. For $k \geq 3$ put $c = k/2$, $\ell = 1 + k(m-1)$, and $q = \ell(k+1)^2$. The original cyclic polynomial is

$$\chi(S) = \prod_{a,b=0}^k (S - c - (2a - k)\delta - i(2b - k)\gamma)^\ell. \quad (\text{CA1})$$

Thus $E = \mathbb{C}[S]/(\chi)$ has the increasing-power frame of length q . No distinct factors or nilpotent orders are merged. The original observation is $\mathcal{O}_N = \sigma_h^{\otimes k} \eta J_N : \mathcal{P}_N \rightarrow Q_{\text{ar}}^{\otimes k}$, with $Q_{\text{ar}} = \mathcal{B}/\Theta V$, where J_N is monic remainder and $\eta : E \hookrightarrow E_h^{\otimes k}$, $\eta[P] = v_h^{\otimes k} P(A_h^{(k)})1$ retains the full Taylor unit $v_h = j_h(g/h)$. For $N \geq q-1$ its original source and relation sequence is

$$0 \longrightarrow \mathcal{P}_{N-q} \xrightarrow{B_N = \times \chi} \mathcal{P}_N \xrightarrow{J_N} E \longrightarrow 0. \quad (\text{CA2})$$

The empty relation space at $N = q-1$ is zero. All comparison maps below are the identity on $\mathcal{P}_N$ and E in this sequence; they therefore commute with $\mathcal{O}_N$ and retain its supported label.

Let $m_{h,k} = w_h^{*k}$, with $w_h(u) = |v_h(1/2 + iu)|^2/(2\pi)$, and let

$$\sigma(u) = \frac{|\Gamma(1/4 + iu/2)|^2}{2\pi}, \quad H_N^\sigma = \int v_N(u)^* v_N(u) \sigma(u) du, \quad v_N(u) = (1, c + iu, \dots, (c + iu)^N). \quad (\text{CA3})$$

The masses are respectively μ_h^k and $\sqrt{2\pi}$. In particular this fixed one-factor comparison is different from the inherited k -fold Gamma convolution, whose mass is $(2\pi)^{k/2}$. Write H_N^{ar} for the same moment matrix with density $m_{h,k}$. The preceding boundary-tilt calculation proves positive explicit a_k, A_k and a fixed integer M depending on h , with

$$\frac{a_k \sigma(u)}{(1+u^2)^M} \leq m_{h,k}(u) \leq A_k \sigma(u), \quad D_N = [1 + 4(N+M)^2]^M, \quad c_{k,N} = a_k/D_N, \quad (\text{CA4})$$

and proves, by its finite Gamma recurrence and weighted Cauchy argument,

$$c_{k,N} H_N^\sigma \preceq H_N^{\text{ar}} \preceq A_k H_N^\sigma. \quad (\text{CA5})$$

The complete definitions and proofs of these constants and estimates are in the preceding chapter. Equations (CA4)–(CA5) invoke those proved arithmetic estimates; they add no assumption about a zeta lower bound or about the sign of a determinant correction.

For $\star \in \{\text{ar}, \sigma\}$ retain the exact matrices

$$K_N^\star = J_N (H_N^\star)^{-1} J_N^\star, \quad G_N^\star = (K_N^\star)^{-1}, \quad R_N^\star = (H_N^\star)^{-1} J_N^\star G_N^\star, \quad V_N^\star = \det G_N^\star. \quad (\text{CA6})$$

Positivity and surjectivity give positive invertible matrices $H_N^\star, K_N^\star, G_N^\star$ of their displayed square dimensions. The map $R_N^\star : E \rightarrow \mathcal{P}_N$ is the displayed right inverse, which is rectangular when $N > q - 1$. Direct multiplication gives $J_N R_N^\star = I$ and $B_N^\star H_N^\star R_N^\star = 0$. Every lift of $x \in E$ is uniquely $R_N^\star x + B_N y$, with squared norm $x^\star G_N^\star x + y^\star B_N^\star H_N^\star B_N y$. Thus $G_N^\star$ is the minimum on the same original affine remainder fibre. Applying (CA5) to each point of that fibre and taking its infimum proves

$$c_{k,N} G_N^\sigma \preceq G_N^{\text{ar}} \preceq A_k G_N^\sigma, \quad c_{k,N}^q V_N^\sigma \leq V_N^{\text{ar}} \leq A_k^q V_N^\sigma. \quad (\text{CA7})$$

For the determinant claim, conjugate a positive comparison by the inverse square root of its smaller form; all relative eigenvalues are at least one, so their product is at least one. This also proves the claim when the forms do not commute.

There is an exact original cochain connecting the two representatives. Use the original two-term complex $[V \xrightarrow{\Theta} \mathcal{B}]$ in degrees zero and one and the polynomial source map $\mathcal{V}_{h,k} : \mathbb{C}[S] \rightarrow \mathcal{B}^{\otimes k}$, $P \mapsto P(\sum_j D_j) F_h^{\otimes k}$. Since $J_N(R_N^{\text{ar}} - R_N^\sigma)x = 0$, monic division gives the unique $\kappa_x \in \mathcal{P}_{N-q}$ with

$$(R_N^{\text{ar}} - R_N^\sigma)x = \chi \kappa_x. \quad (\text{CA8})$$

Its coefficients depend linearly on x . Use the original polynomials Q_i from successive tensor division, with $\chi(\sum s_j) = \sum_i h(s_i) Q_i(\mathbf{s})$, and the original F_h satisfying $\mathcal{M}F_h = v_h$ and $h(D)F_h = \Theta\phi_*$. Then

$$\mathfrak{p}_x = \sum_{i=1}^k (-1)^{i-1} Q_i(\mathbf{D}) \kappa_x(\sum_j D_j) (F_h^{\otimes(i-1)} \otimes \phi_* \otimes F_h^{\otimes(k-i)}) \quad (\text{CA9})$$

has degree $k - 1$ in the original tensor theta complex and satisfies

$$d_{\text{tot}} \mathfrak{p}_x = \mathcal{V}_{h,k} (R_N^{\text{ar}} - R_N^\sigma)x. \quad (\text{CA10})$$

Indeed the $i - 1$ preceding factors have degree one, so the differential contributes $(-1)^{i-1}$, cancelling the written sign. Its remaining factor is $\Theta\phi_* = h(D_i)F_h$; the displayed polynomial identity then proves (CA10) term by term. This is the same explicit primitive as inherited EW.46–48 applied to the new representative difference. It maps to the supported zero in the original labelled fibre; external τ is unchanged.

178 A finite computable comparison for the four arithmetic volumes

Define on the four original endpoints

$$B_{\text{ar}} = \log \frac{V_{q-1}^{\text{ar}} V_q^{\text{ar}}}{V_{2q-1}^{\text{ar}} V_{2q}^{\text{ar}}}, \quad B_{\sigma} = \log \frac{V_{q-1}^{\sigma} V_q^{\sigma}}{V_{2q-1}^{\sigma} V_{2q}^{\sigma}}, \quad \Delta_{\sigma} = B_{\text{ar}} - B_{\sigma}. \quad (\text{CA11})$$

All are in the original quotient frame. Quotient minima decrease with source degree, hence both B 's are nonnegative. Applying (CA7) at the four endpoints gives the asymmetric exact scalar enclosures

$$-q \log \frac{A_k^2}{c_{k,q-1} c_{k,q}} \leq \Delta_{\sigma} \leq q \log \frac{A_k^2}{c_{k,2q-1} c_{k,2q}}. \quad (\text{CA12})$$

For example the upper numerator is at most $A_k^{2q} V_{q-1}^{\sigma} V_q^{\sigma}$, and the lower denominator is at least $(c_{k,2q-1} c_{k,2q})^q V_{2q-1}^{\sigma} V_{2q}^{\sigma}$. The opposite choices prove the lower bound without imposing a sign on Δ_{σ} .

For the stronger common-source comparison let

$$D_* = (H_{2q}^{\sigma})^{-1} H_{2q}^{\text{ar}}, \quad b_1 \leq \dots \leq b_{2q+1}, \quad \Lambda_k = \log(A_k D_{2q}/a_k). \quad (\text{CA13})$$

The b_j are all positive eigenvalues of this specified relative operator, including every multiplicity. The Rayleigh quotient in (CA5) gives $c_{k,2q} \leq b_j \leq A_k$ for each j ; in particular $\log(b_{2q+1}/b_1) \leq \Lambda_k$ and $\Lambda_k \geq 0$. The unchanged source flags and their minimum relation maps have the AW.7 spectrum $0^q, 1^2, 2^{q-1}$ along $H(t) = (1-t)H_{2q}^{\sigma} + tH_{2q}^{\text{ar}}$. Applying its fully proved spectral trace calculation gives

$$|\Delta_{\sigma}| \leq L_q(D_*) := \log \frac{b_{q+2}}{b_q} + 2 \sum_{j=1}^{q-1} \log \frac{b_{2q+2-j}}{b_j} \leq (2q-1)\Lambda_k. \quad (\text{CA14})$$

This application changes the endpoint form to (CA3) on the same polynomial and relation spaces; all hypotheses of the finite AW proof hold by (CA3)–(CA6). Its explicit conjugation is a spectral calculation of those forms, not an assertion that an arbitrary isometry preserves their arithmetic observation.

The stronger nonlinear angle estimate is already proved in the original source EW.25–35c for every packet dimension and every window length. For these endpoints its $s = \min(q, q) = q$. To retain its attribution and its exact effect, define

$$\Phi_q(B) = 2 \operatorname{arcosh}(e^{B/(4q)}), \quad \Psi_q(t) = 4q \log \cosh(t/2) \quad (t \geq 0), \quad A_{\sigma} = \Phi_q(B_{\sigma}). \quad (\text{CA15})$$

They are mutually inverse increasing continuous functions on $[0, \infty)$. That inherited theorem gives

$$|\Phi_q(B_{\text{ar}}) - \Phi_q(B_{\sigma})| \leq \log(b_{2q+1}/b_1) \leq \Lambda_k. \quad (\text{CA16})$$

Equivalently it supplies

$$\Psi_q(\max(0, A_{\sigma} - \Lambda_k)) \leq B_{\text{ar}} \leq \Psi_q(A_{\sigma} + \Lambda_k). \quad (\text{CA17})$$

For clarity its exact derivative mechanism is as follows. The two pairs of original canonical-lift projections have at most $2q$ nonzero angle losses $x_i = -\log \sigma_i^2$, with $\sum_i x_i = B(t)$. Their trace norms and concavity of $\sqrt{1-e^{-x}}$ give $|B'(t)| \leq 2q o(t) \sqrt{1-e^{-B(t)/(2q)}}$, where $o(t) = \lambda_{\max}(H(t)^{-1} H') - \lambda_{\min}(H(t)^{-1} H')$. At $B > 0$, division is differentiation of Φ_q , and replacing B by $B + \varepsilon$ justifies integration through $B = 0$. The exact eigenvalues $(b_j - 1)/(1 - t + tb_j)$ integrate to $\log b_j$, proving (CA16). This recalls the proved inherited argument; it does not claim it as a new generalization of the one-dimensional AW angle result.

The accompanying calculation AGT, from the coordinating programme, sharpens this inherited method by pairing the same endpoints as $(q-1, 2q)$ and $(q, 2q-1)$. The second pair lies in the actual $(2q-1)$ -dimensional space $\mathcal{P}_{2q-1} \cap (\chi\mathcal{P}_0)^\perp$; its two q -dimensional section images therefore have a common direction. One of its angles is exactly zero. There are consequently at most $2q-1$ nonzero angle contributions in the same four-volume, rather than the $2q$ allowed in the equal-gap pairing. Its full proof is included in this reader. Put

$$\widehat{\Phi}_q(B) = 2 \operatorname{arcosh}(e^{B/(4q-2)}), \quad \widehat{\Psi}_q(t) = (4q-2) \log \cosh(t/2), \quad \widehat{A}_\sigma = \widehat{\Phi}_q(B_\sigma). \quad (\text{CA17a})$$

Apply the same finite angle sum to (CA3)–(CA6), whose positive moment form and relation flags meet all the proved hypotheses of AGT. The concavity argument just displayed now has $2q-1$ terms. Its derivative bound is $(2q-1)o(t)\sqrt{1-e^{-B(t)/(2q-1)}}$; its factor multiplying $o(t)$ is exactly $1/\widehat{\Phi}'_q(B(t))$. Integration therefore proves

$$\widehat{\Psi}_q(\max(0, \widehat{A}_\sigma - \Lambda_k)) \leq B_{\text{ar}} \leq \widehat{\Psi}_q(\widehat{A}_\sigma + \Lambda_k). \quad (\text{CA17b})$$

The strict positive moment $\int |\chi|^2 m_t > 0$ used in AGT holds for this interpolation as well, so its differentiation is valid throughout the compact interval. This states the precise improvement over EW; the general angle mechanism and its original theta primitive remain attributed to their earlier source.

The reference number B_σ itself is a fully specified finite calculation with the identical original χ . Define real monic $b_n^{(1/4)}(u)$ by

$$b_0 = 1, \quad b_1 = u, \quad b_{n+1} = ub_n - n(n-1/2)b_{n-1}, \quad \gamma_n = \sqrt{2\pi}(2n)!/4^n, \quad p_n(S) = i^n b_n^{(1/4)}((S-c)/i). \quad (\text{CA18})$$

The fixed Gamma integral proves that p_n is monic in the original S coordinate and has squared norm γ_n . Put $z_n = [p_n] \bmod \chi$ in the length- q remainder frame for every $n \geq 0$. Orthogonal expansion of (CA6) gives, exactly,

$$K_N^\sigma = \sum_{n=0}^N \frac{z_n z_n^*}{\gamma_n}, \quad B_\sigma = \log \frac{\det K_{2q-1}^\sigma \det K_{2q}^\sigma}{\det K_{q-1}^\sigma \det K_q^\sigma}. \quad (\text{CA19})$$

To prove the kernel formula, the monic polynomial columns form an invertible triangular matrix Z with diagonal one and $Z^* H_N^\sigma Z = \operatorname{diag}(\gamma_0, \dots, \gamma_N)$. Thus $(H_N^\sigma)^{-1} = Z \operatorname{diag}(\gamma_n^{-1}) Z^*$. Multiplying by J_N and J_N^* gives the displayed sum, and the determinant identity follows from $V_N = 1/\det K_N$. This retains the original phases, centre, degree, unit, and mass.

179 The strengthened restriction and its exact reach

The preceding actual-tail chapter proves the original arithmetic lower bound

$$B_{\text{ar}} \geq 4q \log(\delta ek/8) - E_k, \quad E_k = 2 \log(A_k/a_k) + \log D_{q-1} + \log D_q \geq 0. \quad (\text{CA20})$$

It is obtained from the inherited CJ identity, the full-multiplicity trace floor, and the newly proved norm bounds. Its exact nonnegative contraction, phase, control and trace residuals are retained in that chapter. Equations (CA14), (CA17b), and (CA20) give simultaneously

$$\begin{aligned} & \max\{0, 4q \log(\delta ek/8) - E_k, B_\sigma - L_q(D_*), \\ & \quad \widehat{\Psi}_q(\max(0, \widehat{A}_\sigma - \Lambda_k))\} \\ & \leq B_{\text{ar}} \leq \min\{B_\sigma + L_q(D_*), \widehat{\Psi}_q(\widehat{A}_\sigma + \Lambda_k)\}. \end{aligned} \quad (\text{CA21})$$

Each entry bounds the same original scalar (CA11); taking the indicated maximum and minimum therefore proves (CA21). The earlier original upper bounds and full-spectrum old-Gamma bounds remain simultaneous bounds and may also be inserted in this minimum. They are not discarded.

For the fixed hypothetical actual packet the proved constants give $\log A_k - \log a_k = O_h(k + \log k)$ and hence

$$E_k = O_h(k + \log q) = o(q), \quad \Lambda_k = O_h(k + \log q), \quad |B_{\text{ar}} - B_{\sigma}| = O_h(qk + q \log q) = o(q^2). \quad (\text{CA22})$$

Indeed $q = \ell(k + 1)^2 \geq (k + 1)^2$, while $\ell \leq mk$ for $k \geq 1$, so $\log q = O_h(\log k)$, $k/q \rightarrow 0$, and $\log q/q \rightarrow 0$. Also $\log D_{2q} = M \log[1 + 4(2q + M)^2] = O_h(\log q)$. Substitution in (CA14) and (CA20) proves every assertion in (CA22). In particular the actual arithmetic four-volume loss and the explicitly specified fixed-Gamma four-volume loss have the same leading quadratic scale:

$$\frac{B_{\text{ar}} - B_{\sigma}}{q^2} \rightarrow 0. \quad (\text{CA23})$$

This statement specifies their difference; it asserts neither separate limit exists without its calculation.

The improved exact lower restriction is

$$\liminf_{k \rightarrow \infty} \left(\frac{B_{\text{ar}}}{q} - 4 \log k \right) \geq 4 \log(\delta e/8). \quad (\text{CA24})$$

It follows by dividing (CA20) by q and using $E_k/q \rightarrow 0$. The coefficient four was already present in CJ; the literal constant and vanishing per-dimension error here follow from the new arithmetic tail estimate. Since the error bound in (CA14) has order qk , it is larger than the $q \log k$ lower scale in (CA20). Thus (CA23) alone does not establish an opposing estimate on that smaller scale. No actual off-critical zero is constructed by any comparison here, and no contradiction to its counterfactual is asserted. What is proved is the sharper arithmetic restriction (CA21), the exact cochain map (CA8)–(CA10), and the subquadratic comparison (CA23) on the unchanged original source.

180 The original convolution reference has a compulsory spectral spread

The old k -fold Gamma comparison remains part of the programme and has the explicit density and monic squared norms

$$m_k^{\Gamma}(u) = \frac{(\sqrt{2\pi})^k |\Gamma(k/4 + iu/2)|^2}{c_{k/4} 2\pi}, \quad c_a = 2^{1-2a} \Gamma(2a), \quad \gamma_{k,n}^{\Gamma} = (2\pi)^{k/2} n! \frac{\Gamma(n + k/2)}{\Gamma(k/2)}. \quad (\text{CA25})$$

These are the inherited generating-integral identities with their literal mass. On its original degree- $2q$ space put $D_{\text{old}} = (H_{2q}^{\Gamma})^{-1} H_{2q}^{\text{ar}}$ and let κ_{old} be the ratio of its largest to smallest eigenvalues. The preceding actual estimate forces

$$\kappa_{\text{old}} \geq \max \left\{ 1, \frac{\mu_h^k}{\sqrt{2} A_k \Gamma(k/2)} \frac{\Gamma(2q + k/2)}{\Gamma(2q + 1/2)} \right\}. \quad (\text{CA26})$$

To prove it without changing a source frame, let b_- , b_+ be these two extreme eigenvalues. The constant polynomial gives $b_+ \geq \mu_h^k / (2\pi)^{k/2}$. The full form comparison defining b_- gives $\omega_{h,k,n} \geq b_- \gamma_{k,n}^{\Gamma}$ on every monic affine fibre with $n \leq 2q$; take its infimum to see this directly. Thus $b_- \leq \omega_{h,k,2q} / \gamma_{k,2q}^{\Gamma}$. The proved TW.14 inequality further gives $\omega_{h,k,2q} \leq A_k \gamma_{2q}^{\Gamma}$. Combining these inequalities and substituting (CA18), (CA25) proves (CA26), including the factor $\Gamma(1/2)/\sqrt{2\pi} = 1/\sqrt{2}$. The independent lower bound one is the ordered positive-spectrum inequality.

Here the size of the compulsory spread can also be proved explicitly. For integers $n \geq 1$, $k \geq 1$ one has

$$n^{(k-1)/2} \leq \frac{\Gamma(n + k/2)}{\Gamma(n + 1/2)} \leq (n + k/2)^{(k-1)/2}. \quad (\text{CA27})$$

For odd $k = 2r + 1$, the ratio is the exact product $\prod_{j=0}^{r-1} (n + 1/2 + j)$, and bounding each factor proves it. For even $k = 2r$, separate the product $\prod_{j=1}^{r-1} (n + j)$ and the factor $\Gamma(n + 1)/\Gamma(n + 1/2)$. The Gamma integral and Cauchy–Schwarz give $\Gamma((x + y)/2)^2 \leq \Gamma(x)\Gamma(y)$ for $x, y > 0$: apply that inequality to the functions $t^{(x-1)/2}e^{-t/2}$ and $t^{(y-1)/2}e^{-t/2}$. Using $(x, y) = (n, n + 1)$ and $(n + 1/2, n + 3/2)$, and using the Gamma recurrence in both cases, yields

$$\sqrt{n} \leq \frac{\Gamma(n + 1)}{\Gamma(n + 1/2)} \leq \sqrt{n + 1/2}.$$

Every factor is positive, so multiplication proves (CA27) also for even k . Empty products in the cases $k = 1, 2$ are one. In particular the error in replacing the logarithm of its ratio by $((k - 1)/2) \log n$ lies between zero and $((k - 1)/2) \log(1 + k/(2n)) \leq k^2/(4n)$.

The actual A_k in TW.8 satisfies $\log A_k = O_h(k + \log k)$. Also $\log \Gamma(k/2) = (k/2) \log k + O(k)$ for integer $k \rightarrow \infty$. For the latter claim no complex asymptotic is needed: bounding the sum $\log(r!)$ between its two adjacent integrals of $\log x$ gives $\log(r!) = r \log r - r + O(\log(r + 1))$. For even k apply this to $\Gamma(k/2) = (k/2 - 1)!$; for odd $k = 2r + 1$ use the exact identity $\Gamma(r + 1/2) = \sqrt{\pi}(2r)!/(4^r r!)$ and the same two bounds. Both substitutions give the stated $O(k)$ form. Taking logarithms in (CA26), using the lower side of (CA27) at $n = 2q$, and retaining the fixed original mass, proves

$$\log \kappa_{\text{old}} \geq \frac{k - 1}{2} \log(2q) - \frac{k}{2} \log k + O_h(k + \log k). \quad (\text{CA28})$$

Here the meaning of the signed O_h term is a function bounded in absolute value by a fixed multiple of $k + \log k$, as follows from the preceding explicit formula. This inequality yields

$$\liminf_{k \rightarrow \infty} \frac{\log \kappa_{\text{old}}}{k \log k} \geq \begin{cases} \frac{1}{2}, & m = 1, \\ 1, & m \geq 2. \end{cases} \quad (\text{CA29})$$

Indeed when $m = 1$, $q = (k + 1)^2$ gives $\log(2q) = 2 \log k + O(1)$. When $m \geq 2$ is fixed, $q = [1 + k(m - 1)](k + 1)^2$ gives $\log(2q) = 3 \log k + O_h(1)$. Substitution in (CA28), division by $k \log k$, and passage to the lower limit prove both cases.

This is a constraint on the actual relative moment operator, not on freely chosen positive matrices. It shows that the old convolution reference cannot have a uniformly bounded condition number along these original amplified sources. In contrast, (CA13) proves the upper bound $\log \kappa(D_*) = O_h(k + \log k)$ for the fixed reference, with the exact identity comparison through (CA2). Both source masses and both reference maps remain explicit. A condition-number lower bound does not fix the orientation of the original window projections in its eigenvectors; consequently (CA29) assigns no sign to the original signed four-volume correction.

181 The certified theta moments as observations of the total original object

The two certified matrices attach to the same original theta seed and the same finite arithmetic packets in $\mathbf{C}_U$. The global moment sum includes critical and offcritical packets in the ambient $Q = \mathcal{B}/\Theta V$ of (T0.5). Its offcritical part is exactly the already constructed $T_U Q$ of (T0.7), not a replacement for that carrier. We construct the attachment and calculate what the finite certificate excludes.

181.1 From the original theta boundary to the finite moment matrices

Retain the original operators and seed, with every scalar unchanged:

$$\begin{aligned} D &= -x\partial_x, \quad \phi_* = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2} \in V, \quad f_0 = \Theta\phi_* = 2 \sum_{n \geq 1} \phi_*(nx), \\ \mathcal{M}F(s) &= \int_0^\infty F(x)x^s \frac{dx}{x}, \quad \mathcal{M}f_0 = g = 2\xi, \quad \psi(y) = e^{y/2}f_0(e^y). \end{aligned} \quad (\text{HCA.1})$$

The complete theta calculation (WBR1)–(WBR8) gives $\psi(-y) = \psi(y) > 0$ and, for $y \geq 0$, $\psi(y) \leq C_\theta e^{9y/2 - \pi e^{2y}}$ with $C_\theta = 8\pi^2 \sum_{n \geq 1} n^4 e^{-\pi(n^2-1)} < \infty$. It follows by differentiation under this integrable majorant that

$$M_{2j} = \int_{\mathbb{R}} y^{2j} \psi(y) dy = g^{(2j)}(1/2), \quad a_j = \frac{(-1)^j M_{2j}}{(2j)!}, \quad F(w) = \sum_{j \geq 0} a_j w^j, \quad F(z^2) = g(1/2 + iz). \quad (\text{HCA.2})$$

The map $z \mapsto z^2$ and the even entire Taylor series define F without choosing a square-root branch. Its mass is exactly $a_0 = M_0 = g(1/2) > 0$.

The original moment observation on a general $F_1 \in \mathcal{B}$ is the linear map

$$F_1 \mapsto \left(\int_{\mathbb{R}} y^{2j} e^{y/2} F_1(e^y) dy \right)_{j=0}^{32}. \quad (\text{HCA.3})$$

The two-ended defining bounds of $\mathcal{B}$ dominate each integrand by an integrable exponential times a polynomial, so every component is defined. At the actual boundary $f_0 = \Theta\phi_*$, this map has first component $M_0 > 0$. Thus it is an observation of the actual degree-one source functions, and does not factor through their theta quotient: factoring would send the class of f_0 to zero. This explicit map is permitted by the marked source vertices of (T0.1)–(T0.4), which retain ϕ_* , f_0 and their differential.

On the open set of coefficient vectors with $a_0 \neq 0$, define the finite rational recurrence

$$b_n = \frac{-(n+1)a_{n+1} - \sum_{j=1}^n a_j b_{n-j}}{a_0} \quad (0 \leq n \leq 31), \quad H_{15}^{(\nu)} = (b_{r+s+\nu})_{0 \leq r, s \leq 15}, \quad \nu = 0, 1. \quad (\text{HCA.4})$$

Multiplication of $-F'/F = \sum_{n \geq 0} b_n w^n$ by F proves each coefficient formula. Thus the source observation (HCA.3), the factorial/sign map (HCA.2), the recurrence and the two matrix assemblies form a single explicit composite. The recurrence is a rational observation of its coefficients; it is not asserted to be a linear or cochain map. This is exactly the typed convention for numerical observations in (T0.4)–(T0.6).

181.2 The reciprocal action on every full original packet

Let Z be any finite actual zero packet in the open strip, stable under reflection and conjugation, with all full orders m_ρ . Critical points are allowed in this ambient packet. Put

$$\begin{aligned} h(s) &= \prod_{\rho \in Z} (s - \rho)^{m_\rho}, \quad E_h = \mathbb{C}[s]/(h), \quad A_h = M_s, \quad v_h = g/h, \\ v_h &= j_h(v_h), \quad \varepsilon_h = v_h^{-1}, \quad R_h(u) = r_h(\varepsilon_h u), \\ s_h u &= S_h \Theta(R_h(u)(D)\phi_*), \quad \sigma_h u = [s_h u] \in Q, \quad J_h = j_h \mathcal{M}. \end{aligned} \quad (\text{HCA.5})$$

Here r_h is the unique degree-below-deg h remainder and S_h is the original iterated Euler inverse on zero full Mellin jets. These are precisely (AG6)–(AG8) and (WBR22)–(WBR25): the workbench's η_h is the same element as ε_h here. In particular

$$\mathcal{M}s_h u = v_h R_h(u), \quad J_h s_h = I, \quad J_h \Theta = 0, \quad D_Q \sigma_h = \sigma_h A_h. \quad (\text{HCA.6})$$

The first equality follows by dividing $gR_h(u)$ by h ; the second is $j_h(v_h)\varepsilon_h = 1$ with the entire Taylor unit retained. Thus σ_h is injective. Polynomial division gives $Ds_h - s_h A_h = \Theta\phi_*[s^{\deg h-1}]R_h$, proving the last equality before passing to the quotient, including its boundary. The range and inverse proofs used here apply to every root in the open strip and therefore include the ambient critical packets.

Since $g(1/2) > 0$, the polynomial $s - 1/2$ is a unit on every E_h . Define the actual finite-packet operator

$$T_h = -(A_h - \tfrac{1}{2}I)^{-2}, \quad \beta_\rho = -\frac{1}{(\rho - 1/2)^2}. \quad (\text{HCA.7})$$

No inverse on the whole quotient Q is required. On the full ρ -block, write $A_h = \rho I + N_\rho$ and $\lambda_\rho = \rho - 1/2$. The finite coordinate maps are

$$\begin{aligned} T_h &= \sum_{j=0}^{m_\rho-1} (-1)^{j+1} (j+1) \lambda_\rho^{-j-2} N_\rho^j, \quad Y_\rho = T_h - \beta_\rho I, \\ N_\rho &= \lambda_\rho \sum_{j=1}^{m_\rho-1} \binom{-1/2}{j} (Y_\rho/\beta_\rho)^j. \end{aligned} \quad (\text{HCA.8})$$

Multiplication of the first polynomial by $(\lambda_\rho + N_\rho)^2$ gives -1 modulo $N_\rho^{m_\rho}$. For the inverse, the element with constant term one solving $U^2(1 + Y_\rho/\beta_\rho) = 1$ is unique by successive coefficient comparison, whose leading scalar is two. The binomial polynomial and $1 + N_\rho/\lambda_\rho$ both solve it. This proves (HCA.8) with every nilpotent coefficient and with no analytic branch choice.

For $h \mid H$ with full orders, let ι_{hH} insert zero jets at added centres, let π_{Hh} restrict to old jets, and let $e_{hH} = \iota_{hH}(1)$ be the complete old-packet idempotent. The original arrows (AG10)–(AG12) give

$$\begin{aligned} \pi\iota &= I, \quad \iota\pi = M_{e_{hH}}, \quad s_H\iota = s_h, \quad \sigma_H\iota = \sigma_h, \\ \pi T_H &= T_h\pi, \quad T_H\iota = \iota T_h. \end{aligned} \quad (\text{HCA.9})$$

To prove the last two identities, the maps commute with $A - 1/2$; its invertibility on both domains makes them commute with its inverse, and then with its inverse square. Thus the reciprocal action is natural for the actual divisor arrows, including their full units and literal representatives. Through σ_h it acts on the actual finite image in Q .

The representative of each polynomial of this action is also fixed. Let $t_h(s) = r_h(-(s - 1/2)^{-2})$, let $p_h(s) = r_h(P(t_h(s)))$, and put

$$K_{P,h}(u; s) = \frac{p_h(s)R_h(u)(s) - R_h(P(T_h)u)(s)}{h(s)}. \quad (\text{HCA.10})$$

The numerator is zero modulo h because multiplication by the unit ε_h commutes with $P(T_h)$; thus the quotient is a literal polynomial. Mellin transformation gives

$$p_h(D)s_h u - s_h P(T_h)u = \Theta(K_{P,h}(u; D)\phi_*). \quad (\text{HCA.11})$$

Both sides have transform $g(s)K_{P,h}(u; s)$, so Mellin injectivity proves this equality. This is the full original theta boundary, not only equality of its classes. Tensoring (HCA.11) with the other source factors gives its boundaries in (TO.3) with the original tensor differential and its Koszul signs.

The Mellin isomorphism of (TO.7), (CAU.9) sends $\sigma_h u$ on its offcritical part to precisely its prescribed local jets u_ρ . Equations (HCA.7)–(HCA.8) therefore give the following endomorphism of the already constructed offcritical direct sum:

$$\bigoplus_{\rho \in U: g(\rho)=0} \mathcal{O}_{\mathbb{C},\rho}/(g) \longrightarrow \bigoplus_{\rho \in U: g(\rho)=0} \mathcal{O}_{\mathbb{C},\rho}/(g), \quad (u_\rho)_\rho \longmapsto (-(s - 1/2)^{-2}u_\rho)_\rho. \quad (\text{HCA.12})$$

Each denominator is a local analytic unit. Finite support is unchanged. Thus this is exactly the same reciprocal action as the one defined in the ambient finite images in Q .

181.3 The full half-trace and the exact global moment limit

For the packet Z , let $\mathcal{B}_Z$ be its distinct reciprocal nodes. Each fibre of $\rho \mapsto \beta_\rho$ is the pair $\rho, 1 - \rho$, since equality of nonzero reciprocal squares is equality up to sign. Reflection gives the same full order m_β at both points. Define

$$f_Z(X) = \prod_{\beta \in \mathcal{B}_Z} (X - \beta)^{m_\beta}, \quad \mathcal{A}_Z = \mathbb{C}[X]/(f_Z). \quad (\text{HCA.13})$$

The inverse local map (HCA.8) proves that the kernel of $P \mapsto P(T_h)$ is exactly (f_Z) . On choosing one point in each reflected pair it also gives the full module isomorphism $E_h \simeq \mathcal{A}_Z \oplus \mathcal{A}_Z$. A different choice interchanges the corresponding two factors; both remain present. Triangular multiplication in each local basis gives, for $\nu = 0, 1$,

$$\mathcal{L}_{Z,\nu}(PQ) := \frac{1}{2} \text{Tr}_{E_h} (T_h^{\nu+1} P(T_h) Q(T_h)) = \sum_{\beta \in \mathcal{B}_Z} m_\beta \beta^{\nu+1} P(\beta) Q(\beta). \quad (\text{HCA.14})$$

Indeed every diagonal entry on a length- m_β block equals $\beta^{\nu+1} P(\beta) Q(\beta)$, and there are two reflected blocks. This proves the factor $1/2$ and the retained multiplicity. The radical of this bilinear form on $\mathcal{A}_Z$ is exactly its nilradical $(\text{rad } f_Z)/(f_Z)$: vanishing at every node is sufficient by the sum, and Lagrange interpolation at a node where a value is nonzero proves necessity, since $m_\beta \beta^{\nu+1} \neq 0$. Thus (HCA.8) retains all local jets before the trace and (HCA.14) specifies its exact scalar kernel.

Packet growth has a specific trace law. From (HCA.9) and the idempotent splitting of the larger packet,

$$\begin{aligned} \frac{1}{2} \text{Tr}_{E_H} (M_{e_{hH}} T_H^{\nu+1} P(T_H) Q(T_H)) &= \mathcal{L}_{Z,\nu}(PQ), \\ \mathcal{L}_{Z',\nu}(PQ) &= \mathcal{L}_{Z,\nu}(PQ) + \mathcal{L}_{Z' \setminus Z,\nu}(PQ) \quad (Z \subseteq Z'). \end{aligned} \quad (\text{HCA.15})$$

The first is a trace on the old direct summand, conjugate by ι and π to the original endomorphism. The second is additivity of trace on the two complementary full summands. Thus uncompressed traces on growing packets are not asserted constant. Their precise change is the added original packet.

The growth calculation (WBR9) and the complete product proof (GF1)–(GF13) for this same F give distinct nonzero reciprocal nodes β_j , their full orders m_j , and

$$\sum_j m_j |\beta_j| < \infty, \quad F(w) = a_0 \prod_j (1 - \beta_j w)^{m_j}, \quad b_n = \sum_j m_j \beta_j^{n+1}. \quad (\text{HCA.16})$$

That proof applies the explicit bound $\log M_F(R) = O(\sqrt{R} \log R)$ with exponent $3/4 < 1$. Its circle-mean calculation bounds the zero count by $CR^{3/4}$; dyadic annuli then prove reciprocal summability. The uniformly convergent product has exactly the original zeros. Dividing F by it gives a nonvanishing entire function e^H . The selected circles in (GF7)–(GF9) bound $\Re H$ by $CR^{3/4} \log R$; the circle Fourier formula (GF10)–(GF11) forces every positive Taylor coefficient of H to vanish. Evaluation at zero fixes the remaining constant to a_0 . Thus no unproved factorization input, exponential factor, or change of mass enters (HCA.16). The complete product proof is included with the attachment. The nodes are bounded, since absolute summability excludes infinitely many nodes outside any disc about zero. Hence, for any fixed P, Q , the sum in (HCA.14) over all nodes is absolutely convergent, also for $\nu = 1$. Exhausting by finite full reflection- and conjugation-stable packets proves the exact limit

$$\begin{aligned} \mathcal{L}_\nu(PQ) &= \lim_Z \mathcal{L}_{Z,\nu}(PQ) = \sum_j m_j \beta_j^{\nu+1} P(\beta_j) Q(\beta_j), \\ \mathcal{L}_\nu(X^r X^s) &= b_{r+s+\nu}, \quad \mathcal{Q}_\nu(P) := \mathcal{L}_\nu(P^2) = c^\top H_{15}^{(\nu)} c \quad \left(P(X) = \sum_{r=0}^{15} c_r X^r \right). \end{aligned} \quad (\text{HCA.17})$$

Absolute convergence proves independence of the exhaustion and justifies the finite polynomial expansion. For real coefficients the value is real by conjugation of the full node set. The square in this identity is the algebraic square $P(\beta)^2$.

Equations (HCA.3)–(HCA.4) and (HCA.5)–(HCA.17) are therefore two equal evaluations of the same original data: the first through the theta integral and coefficient recurrence, the second through the full packet action and absolutely convergent half-trace. Their equality is proved by (HCA.16), not imposed as a new relation between independently adjustable matrices. Adjoining these specified observation vertices and the displayed maps to the path representation $\mathbf{C}_U$ of (TO.4) gives one represented extension: every path is evaluated by composition of the actual maps, and (HCA.9), (HCA.11), (HCA.15), (HCA.17) prove the new path relations. The old represented diagram is retained through its identity inclusion. No quotient identifies its offcritical component with a scalar or with a zero target.

In particular the global trace splits into the absolutely convergent critical and offcritical sums. The critical-only projection of (WBR37)–(WBR40) kills every full offcritical packet but need not kill its trace: its reciprocal primary idempotent e_β has $\text{Tr}_{\mathcal{A}_Z} M_{X^{\nu+1}e_\beta} = m_\beta \beta^{\nu+1} \neq 0$. Thus the full functional has this explicit omitted summand under critical projection. At the split support level all linear maps above send $(\mathfrak{a}, u)$ to $(\mathfrak{a}, Lu)$ and τ to τ ; a killed class lands at $(\mathfrak{a}, 0)$. The moment and quadratic evaluations remain the marked observations in their actual linear or polynomial types.

181.4 The certified finite restriction on this attached observation

The certified theta calculation (TC1)–(TC28) encloses exactly the moments (HCA.2). It retains theta terms $1 \leq n < 20$ on $0 \leq y \leq 4$, and, for $J = 0, 2, \dots, 64$, adds the proved nonnegative tails

$$\frac{16\pi^2 4^{J+1} e^{18} 20^4 e^{-400\pi}}{1 - e^{4/20-40\pi}}, \quad (HCA.18)$$

$$\frac{16\pi^2 4^J e^{18-\pi e^8}}{(1 - e^{4-2\pi})(2\pi e^8 - 9/2 - J/4)}.$$

These are exactly (TC5) at $N = 20, L = 4$, with N the first omitted integer. All denominators are strictly positive as proved there. The finite integrands, quadrature subdivisions and dyadic interval endpoints are preserved in the certificate. The interval recurrence (TC11)–(TC13) encloses the exact coefficients in (HCA.4) and their $LDL^\top$ decompositions in the unchanged coordinate order. Every one of its thirty-two pivot intervals has a positive lower endpoint, proving

$$H_{15}^{(0)} > 0, \quad H_{15}^{(1)} > 0. \quad (HCA.19)$$

The certificate is the actual file `certificate_dimension16_1024.json`, with SHA-256 869ebacd3f82e46c3fe5fac1f07bcbaae7f4c333e1a5ba2e0ffcb1f91884a0fc. Its exact endpoint checks and the full analytic tail and validated quadrature proof accompany this statement.

The exact rational endpoint check also gives a uniform quantitative margin in the original monomial coefficient frame. Write the exact decompositions as $H_{15}^{(\nu)} = L_\nu D_\nu L_\nu^\top$. The sum of the absolute upper endpoint bounds in every off-diagonal row and column of $L_\nu - I$ is strictly less than $1/64$. Every diagonal pivot of D_0 is greater than $6 \cdot 10^{-107}$, and every pivot of D_1 is greater than $7 \cdot 10^{-111}$. These comparisons use exact dyadic fractions in the certificate. For a matrix E , Cauchy–Schwarz with row weights proves $\|Ex\|_2^2 \leq \|E\|_\infty \|E\|_1 \|x\|_2^2$: bound the square of row i by $(\sum_j |E_{ij}|)(\sum_j |E_{ij}| |x_j|^2)$ and sum in i . Thus $\|L_\nu - I\|_2 < 1/64$ and $\|L_\nu^\top x\|_2 > (63/64)\|x\|_2$ for $x \neq 0$. Substitution in the exact decomposition proves

$$H_{15}^{(\nu)} \succ \gamma_\nu I_{16}, \quad \gamma_0 = (63/64)^2 6 \cdot 10^{-107}, \quad \gamma_1 = (63/64)^2 7 \cdot 10^{-111}. \quad (HCA.19a)$$

No polynomial basis or mass was changed in obtaining this bound.

Consequently, every nonzero real polynomial of degree at most fifteen satisfies $Q_\nu(P) > 0$ for both $\nu = 0, 1$. Padding its coefficient vector with zeros identifies its form with the corresponding leading principal submatrix; positivity of (HCA.19) proves the assertion. More generally, on the explicitly specified finite cone

$$\mathcal{C}_{15} = \left\{ \sum_j A_j(X)^2 + X \sum_j B_j(X)^2 : A_j, B_j \in \mathbb{R}[X]_{\leq 15}, \text{ finite sums} \right\}, \quad (\text{HCA.20})$$

one has $\mathcal{L}_0(C) > 0$ for every nonzero C in that cone. Indeed it is the sum of the positive forms in (HCA.19), and a nonzero polynomial represented in the cone has at least one nonzero summand. This uses the shifted matrix through $\mathcal{L}_0(XB^2) = Q_1(B)$; no characterization of larger polynomial cones or positivity at higher degrees is presumed.

181.5 The precise exclusion for an offcritical separator

Take any actual offcritical pair $\beta, \bar{\beta}$ of multiplicity m in (HCA.16). In original zero coordinates it is

$$\beta = -\frac{1}{(\rho - 1/2)^2} = \frac{\gamma^2 - \delta^2 + 2i\gamma\delta}{(\gamma^2 + \delta^2)^2}, \quad \rho = 1/2 + \delta + i\gamma. \quad (\text{HCA.21})$$

It is nonreal because $\delta\gamma \neq 0$. Put $r = |\beta|/2$, let $\mathcal{A}$ be the set of all other distinct nodes of modulus at least r , and define

$$B_\beta(X) = \prod_{\alpha \in \mathcal{A}} (X - \alpha), \quad B_0 = \prod_{\alpha \in \mathcal{A}} (r + |\alpha|), \quad a = \#\mathcal{A}. \quad (\text{HCA.22})$$

The set is finite by (HCA.16), conjugation stable, and excludes $\beta, \bar{\beta}$, so B_β is real and $B_\beta(\beta) \neq 0$. For $\nu = 0, 1$ choose either c_ν with $\beta^{\nu+1}c_\nu^2 = -1$, and retain the actual constants

$$C_\nu = \frac{|c_\nu|B_0}{|B_\beta(\beta)|} \left(1 + \frac{|\Re\beta| + r}{|\Im\beta|} \right), \quad T_\nu = \sum_{|\beta_j| < r} m_j |\beta_j|^{\nu+1}. \quad (\text{HCA.23})$$

Both tails converge and $T_1 \leq rT_0$. Define for every integer $N \geq 0$

$$\begin{aligned} w_{\nu,N} &= \frac{c_\nu}{\beta^N B_\beta(\beta)}, \quad v_{\nu,N} = \frac{\Im w_{\nu,N}}{\Im \beta}, \quad u_{\nu,N} = \Re w_{\nu,N} - (\Re \beta) v_{\nu,N}, \\ P_{\nu,N}(X) &= X^N B_\beta(X) (u_{\nu,N} + v_{\nu,N} X), \quad D_{\nu,N} = \deg P_{\nu,N} \leq N + a + 1. \end{aligned} \quad (\text{HCA.24})$$

This is precisely (TC24) for $\nu = 0$. The shifted version uses the original shifted form and its exponent $\nu + 1 = 2$. The polynomial is real and nonzero, because its value at β is $c_\nu \neq 0$. Its actual degree is $N + a + 1$ when $v_{\nu,N} \neq 0$, and $N + a$ otherwise. Evaluation proves $P_{\nu,N}(\beta) = c_\nu$ and conjugate equality at $\bar{\beta}$. Hence its selected two contributions to the actual scalar form are exactly $-2m$.

Every other node of modulus at least r is a zero of the polynomial. For $|X| \leq r$, the elementary estimates $|B_\beta(X)| \leq B_0$ and $|u_{\nu,N} + v_{\nu,N}X| \leq |w_{\nu,N}| + (|\Re\beta| + r)|w_{\nu,N}|/|\Im\beta|$ give $|P_{\nu,N}(X)| \leq C_\nu 2^{-N}$. Absolute summation proves the exact identity and tail bound

$$\begin{aligned} Q_\nu(P_{\nu,N}) &= -2m + \mathcal{T}_{\nu,N}, \quad \mathcal{T}_{\nu,N} = \sum_{|\beta_j| < r} m_j \beta_j^{\nu+1} P_{\nu,N}(\beta_j)^2 \in \mathbb{R}, \\ |\mathcal{T}_{\nu,N}| &\leq C_\nu^2 T_\nu 4^{-N}. \end{aligned} \quad (\text{HCA.25})$$

No tail is assigned a sign before applying the certificate. If $D_{\nu,N} \leq 15$, the nonzero polynomial in (HCA.24) is within (HCA.19), and therefore

$$\boxed{\mathcal{T}_{\nu,N} = 2m + Q_\nu(P_{\nu,N}) > 2m, \quad C_\nu^2 T_\nu 4^{-N} > 2m.} \quad (\text{HCA.26})$$

This is the finite exclusion on the actual packet together with its entire reciprocal tail. In particular, when $a \leq 14$, choosing $N = 14 - a$ makes its degree at most fifteen and gives

$$C_\nu^2 T_\nu > 2m 4^{14-a} \quad (\nu = 0, 1). \quad (\text{HCA.27})$$

If the affine factor has zero leading coefficient, the exact degree condition in (HCA.26) additionally retains that case. There is also an explicit strictly positive margin. For a polynomial $P(X) = \sum_{j=0}^D p_j X^j$ with $D \leq 15$, Cauchy-Schwarz gives $|P(\beta)|^2 \leq (\sum_j |p_j|^2)(\sum_{j=0}^D |\beta|^{2j})$. For $P = P_{\nu,N}$ its value is c_ν and $|c_\nu|^2 = |\beta|^{-\nu-1}$. Applying (HCA.19a) to its coefficient vector padded with zeros strengthens (HCA.26) to

$$C_\nu^2 T_\nu 4^{-N} \geq \mathcal{T}_{\nu,N} > 2m + \frac{\gamma_\nu |\beta|^{-\nu-1}}{\sum_{j=0}^{D_{\nu,N}} |\beta|^{2j}} \quad (D_{\nu,N} \leq 15). \quad (\text{HCA.27a})$$

The inequality on the left uses the actual tail's strict positivity already proved in (HCA.26), followed by its absolute upper bound.

The shifted certificate also tests the identical original polynomial $P_{0,N}$, without changing c_0 or any coefficient. Its two selected terms in $\mathcal{Q}_1$ are $m\beta^2 c_0^2 + m\bar{\beta}^2 \bar{c}_0^2 = -2m\Re\beta$. The absolute value of its remaining sum is at most $C_0^2 T_1 4^{-N} \leq r C_0^2 T_0 4^{-N}$. If $D_{0,N} \leq 15$ and p is its original coefficient vector padded with zeros through degree fifteen, (HCA.19a) consequently proves the simultaneous exact bounds

$$\begin{aligned} C_0^2 T_0 4^{-N} &> \max \left\{ 2m + \gamma_0 \|p\|_2^2, \frac{2m\Re\beta + \gamma_1 \|p\|_2^2}{r} \right\} \\ &> \max \left\{ 2m, \frac{4m\Re\beta}{|\beta|} \right\}. \end{aligned} \quad (\text{HCA.27b})$$

The second entry remains valid even when its numerator is negative: the absolute upper tail bound is still an upper bound for the signed tail. Both positive coefficient margins are strict. Substitution $\|p\|_2^2 \geq |\beta|^{-1} / \sum_{j=0}^{D_{0,N}} |\beta|^{2j}$ from the preceding evaluation argument retains an entirely explicit margin in both entries of the first maximum. The elementary shifted entry improves $2m$ exactly when $\Re\beta/|\beta| > 1/2$. In the original coordinates (HCA.21) that inequality is $\gamma^2 > 3\delta^2$, since $\Re\beta/|\beta| = (\gamma^2 - \delta^2)/(\gamma^2 + \delta^2)$. This additional comparison uses the same original unshifted separator, as well as the separately constructed shifted family.

There is a further comparison between the two separately phased families. Set $U_{\nu,N} = C_\nu^2 T_\nu 4^{-N}$. The exact modulus $|c_\nu|^2 = |\beta|^{-\nu-1}$ in (HCA.23) gives $C_1^2 = C_0^2/|\beta|$. Since $T_1 \leq rT_0$ and $r = |\beta|/2$, one obtains $U_{1,N} \leq U_{0,N}/2$. For $D_{1,N} \leq 15$, apply (HCA.19a) to the original coefficient vector p_1 of $P_{1,N}$, padded through degree fifteen, and use (HCA.25). The resulting exact inequalities are

$$\begin{aligned} U_{0,N} &\geq 2U_{1,N} > 4m + 2\gamma_1 \|p_1\|_2^2 \geq 4m + \frac{2\gamma_1 |\beta|^{-2}}{\sum_{j=0}^{D_{1,N}} |\beta|^{2j}}, \\ a \leq 14 &\implies C_0^2 T_0 > 4m 4^{14-a} = m 4^{15-a}. \end{aligned} \quad (\text{HCA.27c})$$

Here the last line chooses $N = 14 - a$, so that $D_{1,N} \leq 15$; the coefficient estimate is the same evaluation argument as in (HCA.27a). This estimate uses the shifted polynomial $P_{1,N}$ to bound the original unshifted tail constant. It is distinct from the same-polynomial comparison (HCA.27b), which retains $P_{0,N}$.

For the original unshifted quantitative separator of (TC23), put

$$N_* = \begin{cases} 0, & T_0 = 0, \\ \max \left\{ 0, 1 + \left\lfloor \frac{\log(C_0^2 T_0/m)}{\log 4} \right\rfloor \right\}, & T_0 > 0. \end{cases} \quad (\text{HCA.28})$$

Its definition gives $C_0^2 T_0 4^{-N_*} \leq m$ and thus $\mathcal{Q}_0(P_{0,N_*}) \leq -m < 0$ by (HCA.25). Comparison with (HCA.19) proves the concrete restriction

$$\deg P_{0,N_*} \geq 16, \quad N_* + a + 1 \geq 16. \quad (\text{HCA.29})$$

The shifted comparison strengthens the nominal bound for the same original threshold. If $a \leq 14$, (HCA.27c) implies $T_0 > 0$ and $\log(C_0^2 T_0 / m) / \log 4 > 15 - a$. Because $15 - a$ is an integer, its floor is at least $15 - a$, and (HCA.28) gives

$$a \leq 14 \implies N_* \geq 16 - a, \quad N_* + a + 1 \geq 17. \quad (\text{HCA.29a})$$

This is a bound on the nominal degree. Its actual degree remains $N_* + a + 1$ if $v_{0,N_*} \neq 0$ and $N_* + a$ otherwise; the latter case can still have degree sixteen. There is a further exact boundary case: if $a \leq 15$ and $v_{1,15-a} = 0$, the shifted polynomial with $N = 15 - a$ has degree exactly fifteen. The first line of (HCA.27c) then gives $C_0^2 T_0 > m 4^{16-a}$, and the identical integer-floor argument yields $N_* \geq 17 - a$. No assertion on a matrix of degree sixteen is needed for either conclusion.

The rational rounding of (TC25) keeps the actual quadratic form strictly negative and has degree at most $N_* + a + 1$. Its actual degree is therefore at least sixteen as well. Coefficient rounding cannot produce a smaller-degree negative witness against the certified matrices. The same conclusion holds for any rational negative polynomial in either shifted family, by (HCA.19).

The full finite packet alone may already contribute $-2m$ under the exact half-trace (HCA.14); its remaining original arithmetic nodes still enter (HCA.17). The certificate therefore excludes the low-degree global separators specified above, rather than deleting that offcritical packet from $T_U Q$. It imposes no positivity assertion on H_{16} or any larger matrix. Every source block, its full reciprocal coordinate, its scalar radical, its receiving supported zero and its exact ambient trace remain the explicitly constructed parts of this attachment.

182 Original theta Hankel witness: independent proof and full packet transport

This is an additive mathematical review of the complete supplied NOTE.md, equations (1)–(23), and its complete LaTeX counterpart. Both original files remain byte-for-byte unchanged. The proof of the Hankel criterion and the infinite-tail separator is accepted after the explicit symbol repair below. This proof supplies explicit growth constants, the inverse local coordinate, the complete finite algebra map, and the original theta-boundary representative of that map. The source note’s numerical results retain their exploratory status.

The source defines $u_N = \Re w_N - (\Re \beta) v_N$, but its boxed equation (16) uses the undefined symbol ν_N . The exact repair is the identity

$$\nu_N := u_N = \Re w_N - (\Re \beta) v_N.$$

This occurs at NOTE.md lines 212/216 and NOTE.tex lines 350/354. The user’s pasted narrative already uses u_N in both places. Equation (WBR16) below writes that complete definition and the polynomial using the same u_N . No value or coefficient is changed.

182.1 WBR1. Source and scalar factors

Let

$$D = -x \partial_x, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx,$$

$$V = \{ \phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \int_{\mathbb{R}} \phi = 0 \},$$

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^j F(x)| < \infty \ (b \in \mathbb{Z}, j \geq 0)\},$$

$$\Theta : V \rightarrow \mathcal{B}, \quad \Theta \phi(x) = 2 \sum_{n \geq 1} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}. \quad (\text{WBR1})$$

The quotient is the original $Q = \mathcal{B}/\Theta V$, with its quotient topology. Its split coefficient set is $G(R) = \{\tau\} \sqcup R^\bullet$, with represented zero $e_R = 0_R^\bullet$. A map on a coefficient fibre sends (ℓ, v) to (ℓ, fv) and fixes external absence τ . Thus $(\ell, 0)$ keeps the source label.

Put

$$q_0 = e^{-\pi x^2}, \quad \phi_* = (D^2 - D)q_0 = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad f_0 = \Theta \phi_*. \quad (\text{WBR2})$$

Direct differentiation gives $Dq_0 = 2\pi x^2 q_0$ and $D^2 q_0 = (4\pi^2 x^4 - 4\pi x^2)q_0$. The function ϕ_* is even and vanishes at zero. Integration by parts gives $\int Df = \int f$ on Schwartz functions, so $\int \phi_* = 0$. Hence $\phi_* \in V$. Fourier differentiation and integration by parts give $\mathcal{F}D = (1 - D)\mathcal{F}$. Since $\mathcal{F}q_0 = q_0$, this proves $\mathcal{F}\phi_* = \phi_*$. Poisson summation, with zero origin terms on both sides, gives

$$f_0(x) = x^{-1} f_0(1/x). \quad (\text{WBR3})$$

For $x \geq 1$, the series and its derivatives decay faster than every power. Reflection proves the same assertion at zero, so $f_0 \in \mathcal{B}$.

For $\Re s > 1$, absolute convergence allows termwise integration:

$$\begin{aligned} \mathcal{M}f_0(s) &= 2\zeta(s) \int_0^\infty (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2} x^{s-1} dx \\ &= 2\zeta(s) \pi^{-s/2} \{2\Gamma(s/2 + 2) - 3\Gamma(s/2 + 1)\} \\ &= s(s-1) \pi^{-s/2} \Gamma(s/2) \zeta(s) = 2\xi(s). \end{aligned} \quad (\text{WBR4})$$

The two-ended decay makes the Mellin transform entire. Thus this identity also supplies the entire continuation of the completed zeta expression. Write $g = 2\xi$, retaining its actual value at $1/2$. The conventional factor in ξ is given by [DLMF 25.4.4](#).

182.2 WBR2. Positive density and explicit growth

Define

$$\psi(y) = e^{y/2} f_0(e^y), \quad C_\theta = 8\pi^2 \sum_{n=1}^\infty n^4 e^{-\pi(n^2-1)}. \quad (\text{WBR5})$$

The constant is finite. Reflection gives $\psi(-y) = \psi(y)$. For $y \geq 0$, each theta summand is strictly positive because $2\pi n^2 e^{2y} > 3$. Dropping its negative term only for an upper bound, while retaining the complete summand in the definition, yields

$$0 < \psi(y) \leq 8\pi^2 e^{9y/2} \sum_{n \geq 1} n^4 e^{-\pi n^2 e^{2y}} \leq C_\theta e^{9y/2 - \pi e^{2y}}. \quad (\text{WBR6})$$

Reflection gives the same estimate with $|y|$ on the whole line. For any compact set of s , this dominates every $|y|^j \psi(y) e^{(\Re s - 1/2)y}$ by an integrable function. Therefore

$$g(s) = \int_{\mathbb{R}} \psi(y) e^{(s-1/2)y} dy, \quad M_{2j} = \int_{\mathbb{R}} y^{2j} \psi(y) dy = g^{(2j)}(1/2). \quad (\text{WBR7})$$

In particular $g(s) > 0$ for every real s , without numerical input.

The entire function $G(z) = g(1/2 + iz)$ is even. Its Taylor series gives

$$G(z) = \sum_{j \geq 0} \frac{(-1)^j M_{2j}}{(2j)!} z^{2j} = F(z^2), \quad F(w) = \sum_{j \geq 0} a_j w^j, \quad a_j = \frac{(-1)^j M_{2j}}{(2j)!}. \quad (\text{WBR8})$$

The map $z \mapsto z^2$ sends the circle of radius $\sqrt{R}$ onto the circle of radius R , so the convergent Taylor series proves that F is entire and $M_F(R) = M_G(\sqrt{R})$. No square-root branch is chosen. Its unchanged mass is $F(0) = a_0 = g(1/2) > 0$.

Set $a(R) = 9/4 + \sqrt{R}/2$. Substituting $t = e^{2y}$, with $dy = dt/(2t)$, into the majorant gives

$$\begin{aligned} M_F(R) &\leq 2C_\theta \int_0^\infty e^{(9/2 + \sqrt{R})y - \pi e^{2y}} dy \\ &= C_\theta \int_1^\infty t^{a(R)-1} e^{-\pi t} dt \\ &\leq C_\theta \pi^{-a(R)} \Gamma(a(R)) \\ &\leq 2C_\theta \pi^{-a(R)} \left(\frac{2(a(R) - 1)}{e} \right)^{a(R)-1}. \end{aligned} \tag{WBR9}$$

For the last inequality, maximize $t^{a-1}e^{-t/2}$ at $2(a-1)$ and integrate the remaining $e^{-t/2}$. Here $a(R) > 1$. Thus $\log M_F(R) = O(\sqrt{R} \log R)$, and the order is at most $1/2$.

182.3 WBR3. Reciprocal zeros and coefficient map

Use the standard genus-zero case of Hadamard factorization in this precise form: an entire function of finite order strictly below one, nonzero at zero, is its value at zero times the product $1 - w/\alpha$ over its zeros with multiplicity; the reciprocal absolute zero values are summable, and no nonconstant exponential factor occurs. WBR2 verifies its hypotheses for the actual F .

Let α_j be its distinct zeros, m_j their orders, and $\beta_j = 1/\alpha_j$. Then

$$F(w) = a_0 \prod_j (1 - \beta_j w)^{m_j}, \quad S_\beta = \sum_j m_j |\beta_j| < \infty. \tag{WBR10}$$

The reciprocal zeros are nonzero and have only zero as a possible accumulation point. On a disk where all $|\beta_j w| < 1/2$, the logarithmic derivative is dominated by $2 \sum m_j |\beta_j|$. Geometric expansion and absolute convergence give

$$-\frac{F'(w)}{F(w)} = \sum_j \frac{m_j \beta_j}{1 - \beta_j w} = \sum_{n \geq 0} b_n w^n, \quad b_n = \sum_j m_j \beta_j^{n+1}. \tag{WBR11}$$

Multiplying by F and equating coefficients, with a_0 retained, gives

$$b_n = \frac{-(n+1)a_{n+1} - \sum_{j=1}^n a_j b_{n-j}}{a_0}. \tag{WBR12}$$

These b_n are real because all a_j are real.

At a zero $\rho = 1/2 + \delta + i\gamma$, the exact coordinates are

$$z = -i(\rho - 1/2) = \gamma - i\delta, \quad \alpha = z^2, \quad \beta = -\frac{1}{(\rho - 1/2)^2} = \frac{\gamma^2 - \delta^2 + 2i\gamma\delta}{(\gamma^2 + \delta^2)^2}. \tag{WBR13}$$

Since $g(1/2) > 0$, $z \neq 0$, so $z \mapsto z^2$ has nonzero derivative and preserves the local zero order. The two reflected points $\rho, 1 - \rho$ supply one zero α of that order. Conjugation preserves the orders and sends α, β to their conjugates. For real v , $F(-v^2) = g(1/2 - v) > 0$. Thus no nonpositive real zero occurs, and RH is equivalent to every β_j being positive real. An off-line zero has $\delta \neq 0$, while positivity of g on the real axis gives $\gamma \neq 0$; its reciprocal coordinate is therefore nonreal by (WBR13).

182.4 WBR4. Finite criterion and full infinite-tail proof

For $P(X) = \sum_{r=0}^d c_r X^r$, with real coefficients, put

$$H_d = (b_{r+s})_{0 \leq r, s \leq d}, \quad \mathcal{L}(P^2) = c^T H_d c = \sum_j m_j \beta_j P(\beta_j)^2. \quad (\text{WBR14})$$

The reciprocal zeros together with zero form a compact set. Thus boundedness of P and (WBR10) prove absolute convergence. Conjugate terms make the sum real. Under RH its terms are nonnegative, proving $H_d \succeq 0$. The square retained in this formula is the algebraic $P(\beta)^2$.

For the converse, choose a nonreal reciprocal zero β of order m , and its conjugate. Set $r = |\beta|/2$. Among the finitely many distinct reciprocal zeros of modulus at least r , remove these two and call the remaining set $\mathcal{A}$. Define

$$B(X) = \prod_{\gamma \in \mathcal{A}} (X - \gamma), \quad B_0 = \prod_{\gamma \in \mathcal{A}} (r + |\gamma|). \quad (\text{WBR15})$$

The empty products are one. Conjugation permutes $\mathcal{A}$, so B is real and $B(\beta) \neq 0$. Choose either root c of $\beta c^2 = -1$. For an integer $N \geq 0$, put

$$w_N = \frac{c}{\beta^N B(\beta)}, \quad v_N = \frac{\Im w_N}{\Im \beta}, \quad u_N = \Re w_N - (\Re \beta) v_N, \quad P_N(X) = X^N B(X)(u_N + v_N X). \quad (\text{WBR16})$$

The coefficients are real, $u_N + v_N \beta = w_N$, and hence $P_N(\beta) = c$ and $P_N(\bar{\beta}) = \bar{c}$. The selected contributions total $-2m$. Every other point of modulus at least r contributes zero, regardless of its multiplicity.

The remaining infinite tail has the explicit constants

$$C = \frac{|c|B_0}{|B(\beta)|} \left(1 + \frac{|\Re \beta| + r}{|\Im \beta|} \right), \quad T = \sum_{|\beta_j| < r} m_j |\beta_j|. \quad (\text{WBR17})$$

Indeed $|v_N| \leq |w_N|/|\Im \beta|$ and $|u_N| \leq |w_N|(1 + |\Re \beta|/|\Im \beta|)$. For $|X| \leq r$, $|B(X)| \leq B_0$, giving $|P_N(X)| \leq C 2^{-N}$. Therefore

$$\left| \sum_{|\beta_j| < r} m_j \beta_j P_N(\beta_j)^2 \right| \leq C^2 T 4^{-N}, \quad \mathcal{L}(P_N^2) \leq -2m + C^2 T 4^{-N}. \quad (\text{WBR18})$$

The tail is real by conjugation, which justifies the ordered inequality. If $T = 0$, take $N = 0$. If $T > 0$, the explicit choice

$$N = \max \left(0, 1 + \left\lfloor \log_4 \left(\frac{C^2 T}{2m} \right) \right\rfloor \right) \quad (\text{WBR19})$$

satisfies $4^N > C^2 T / (2m)$. This yields a finite negative direction of degree at most $N + |\mathcal{A}| + 1$, proving

$$\text{RH} \iff H_d \succeq 0 \quad \text{for every } d \geq 0. \quad (\text{WBR20})$$

Every actual zero and every multiplicity is included in this proof. The degree depends on the specified pair and tail; no uniform degree or actual off-line zero is thereby supplied.

For a strict negative vector c , set $M = \max_{i,j} |(H_d)_{ij}|$ and $n = d + 1$. If $\|\tilde{c} - c\|_\infty \leq \varepsilon$, expansion gives

$$|\tilde{c}^T H_d \tilde{c} - c^T H_d c| \leq M(2\|c\|_1 n \varepsilon + n^2 \varepsilon^2). \quad (\text{WBR21})$$

If the original value is $-\mu < 0$, choose ε making the right side less than μ , then choose rational coefficients within that distance. This proves the rational-witness assertion with the original matrix fixed. The shifted family has quadratic form $\sum m_j \beta_j^2 P(\beta_j)^2$, and is also nonnegative under RH.

182.5 WBR5. Actual packet and its complete representative

Let Z be a nonempty finite set of actual nontrivial zeros of g , stable under reflection and conjugation, with every full order retained. Write

$$h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}, \quad d_h = \deg h, \quad E_h = \mathbb{C}[s]/(h), \quad A_h = M_s, \quad \nu_h = g/h, \quad \eta_h = j_h(1/\nu_h). \quad (\text{WBR22})$$

The map j_h keeps all Taylor coefficients through orders $m_\rho - 1$. The element η_h is a unit because every order in h is the full order in g . Let $R_Z(u)$ be the unique polynomial of degree below d_h representing $\eta_h u$.

The original Euler inverse on a zero Mellin value is

$$S_\rho F(x) = x^{-\rho} \int_x^\infty F(y) y^{\rho-1} dy, \quad (D - \rho)S_\rho F = F, \quad \mathcal{M}S_\rho F(s) = \frac{\mathcal{M}F(s)}{s - \rho}. \quad (\text{WBR23})$$

The zero Mellin value makes the upper integral the negative lower integral. At infinity the bound $F(x) \leq Cx^{-N}$ yields $C/(N - \Re \rho)$; at zero $F(x) \leq C'x^N$ yields $C'/(N + \Re \rho)$, when the denominators are positive. These inequalities, and $DS_\rho F = \rho S_\rho F + F$, prove every required seminorm bound. The homogeneous function $x^{-\rho}$ is excluded by the two-ended decay, so the inverse is unique and $D - \rho$ is injective. Iteration gives S_h on the vanishing full Mellin jets, independent of inversion order by uniqueness.

The actual section and observation are

$$R_{\text{ref}}u = S_h \Theta(R_Z(u)(D)\phi_*), \quad \sigma_h u = [R_{\text{ref}}u] \in Q, \quad J_h F = j_h \mathcal{M}F, \\ \mathcal{M}R_{\text{ref}}u = \nu_h R_Z(u), \quad J_h R_{\text{ref}} = 1_{E_h}, \quad J_h \Theta = 0. \quad (\text{WBR24})$$

The transform $gR_Z(u)$ has all the zero jets needed by S_h . The section identity is $j_h \nu_h \eta_h = 1$. Thus σ_h is injective. Polynomial division gives

$$DR_{\text{ref}} - R_{\text{ref}}A_h = f_0 \ell_h, \quad \ell_h(u) = [s^{d_h-1}]R_Z(u). \quad (\text{WBR25})$$

Indeed $sR_Z(u) - R_Z(su) = h(s)\ell_h(u)$; the two sides of (WBR25) have equal Mellin transforms. Mellin injectivity follows from Fourier injectivity in logarithmic coordinates. Passing to the original quotient proves $D_Q \sigma_h = \sigma_h A_h$.

The source sequence cited by the package is

$$0 \longrightarrow Q[h(D)] \longrightarrow E_h \xrightarrow{\times j_h g} E_h \longrightarrow Q/h(D)Q \longrightarrow 0. \quad (\text{WBR26})$$

Its complete proof, including the source Euler inverse, full-jet surjectivity and the actual arrows, is included verbatim in dependencies/arithmetic_input.tex, (A5)–(A10). Equations (WBR23)–(WBR25) also prove directly every packet inclusion and operator identity used by this witness, with the full η_h .

182.6 WBR6. Reciprocal action, inverse jet, and literal theta boundary

Since $g(1/2) > 0$, $A_h - \frac{1}{2}I$ is invertible. Define on this finite packet

$$T_h = -(A_h - \frac{1}{2}I)^{-2}. \quad (\text{WBR27})$$

Through σ_h , this is also an endomorphism of the actual finite image in Q . The construction has this precise domain; no inverse on unrelated quotient classes is required.

At a primary block write $\lambda_\rho = \rho - 1/2$ and $A_h = \rho I + N_\rho$, with full nilpotent length m_ρ . The exact finite expansion is

$$T_h = \sum_{j=0}^{m_\rho-1} (-1)^{j+1} (j+1) \lambda_\rho^{-j-2} N_\rho^j. \quad (\text{WBR28})$$

This is the product $-\lambda_\rho^{-2}(1 + N_\rho/\lambda_\rho)^{-2}$. Multiplying the series by $(\lambda_\rho + N_\rho)^2$ gives constant -1 and zero at every positive degree below m_ρ , which proves the identity in the truncated algebra.

Put $\beta_\rho = -\lambda_\rho^{-2}$ and $Y_\rho = T_h - \beta_\rho I$. The coefficient of N_ρ is $2\lambda_\rho^{-3} \neq 0$. The complete inverse coordinate is

$$N_\rho = \lambda_\rho \sum_{j=1}^{m_\rho-1} \binom{-1/2}{j} (Y_\rho/\beta_\rho)^j. \quad (\text{WBR29})$$

This is a finite algebra identity without any analytic branch choice. In the truncated algebra the element U with constant term one and $U^2(1 + Y_\rho/\beta_\rho) = 1$ is unique: each successive coefficient has leading scalar 2. The displayed binomial coefficients solve these recursive equations. The element $1 + N_\rho/\lambda_\rho$ solves the same equation since $T_h/\beta_\rho = (1 + N_\rho/\lambda_\rho)^{-2}$, proving (WBR29). For $m_\rho = 1$, the positive-degree sums are empty and $N_\rho = 0$. Thus every original local length is retained.

There is a literal original-source representative of this action. Let $t_h(s)$ be the unique polynomial of degree below d_h representing $-(s - 1/2)^{-2}$ in E_h . For a polynomial P , let $p_h(s)$ be the degree-below- d_h representative of $P(t_h(s))$. Define

$$K_{P,h}(u; s) = \frac{p_h(s)R_Z(u)(s) - R_Z(P(T_h)u)(s)}{h(s)}. \quad (\text{WBR30})$$

The numerator vanishes modulo h because multiplication by η_h commutes with $P(T_h)$. Thus the quotient is a polynomial in the original variable s . Mellin transformation gives the exact original boundary

$$p_h(D)R_{\text{ref}}u - R_{\text{ref}}P(T_h)u = \Theta(K_{P,h}(u; D)\phi_*). \quad (\text{WBR31})$$

Both transforms are $gK_{P,h}(u; s)$, proving the formula and every sign. It specifies the difference of representatives before passing to Q , and proves the finite packet intertwining there. The support lift keeps the label of that theta boundary fixed.

182.7 WBR7. Full finite algebra, half-trace, and scalar radical

Let $\mathcal{B}_Z$ be the set of distinct reciprocal coordinates in this packet. A fibre of $\rho \mapsto \beta_\rho$ consists exactly of the distinct pair $\rho, 1 - \rho$: equality of the reciprocal squares gives equality or negation of $\rho - 1/2$. Their orders agree by reflection. Call this common order m_β , and put

$$f_Z(X) = \prod_{\beta \in \mathcal{B}_Z} (X - \beta)^{m_\beta}, \quad \mathcal{A}_Z = \mathbb{C}[X]/(f_Z). \quad (\text{WBR32})$$

The map $P \mapsto P(T_h)$ has kernel exactly (f_Z) . On each primary block, the inverse (WBR29) identifies the local algebra with $\mathbb{C}[Y]/Y^{m_\rho}$. Consequently the action vanishes precisely when every Taylor coefficient of P at β_ρ below that order is zero. Intersecting the coprime primary ideals proves the stated kernel and the embedding $\mathcal{A}_Z = \mathbb{C}[T_h] \subset \text{End}(E_h)$.

Choose one point of each reflected pair to write coordinates. Applying (WBR29) on both primary blocks and then Chinese remainders gives an explicit $\mathcal{A}_Z$ -module isomorphism

$$E_h \simeq \mathcal{A}_Z \oplus \mathcal{A}_Z. \quad (\text{WBR33})$$

The action of X on each copy is multiplication by X . Both reflected blocks remain in this display. Changing the coordinate choice swaps the corresponding two components without altering E_h or T_h .

On the local basis $1, Y, \dots, Y^{m_\beta-1}$, multiplication by $Q(\beta+Y)$ is triangular with constant diagonal $Q(\beta)$. Therefore

$$\begin{aligned} \frac{1}{2} \operatorname{Tr}_{E_h} Q(T_h) &= \operatorname{Tr}_{\mathcal{A}_Z} M_Q = \sum_{\beta \in \mathcal{B}_Z} m_\beta Q(\beta), \\ \frac{1}{2} \operatorname{Tr}_{E_h} (T_h P(T_h)^2) &= \sum_{\beta \in \mathcal{B}_Z} m_\beta \beta P(\beta)^2. \end{aligned} \quad (\text{WBR34})$$

This proves the original factor $1/2$, the full multiplicity and the source-to-scalar map. Exhaustion by finite stable packets converges to (WBR14) by (WBR10).

The precise scalar information loss is also computable. On $\mathcal{A}_Z$, define the bilinear form

$$\mathfrak{b}_Z(U, V) = \operatorname{Tr}_{\mathcal{A}_Z} M_{XUV} = \sum_{\beta} m_\beta \beta U(\beta) V(\beta). \quad (\text{WBR35})$$

Its radical is exactly

$$\mathfrak{n}_Z = \{U : U(\beta) = 0 \text{ for every } \beta\} = (\operatorname{rad} f_Z)/(f_Z). \quad (\text{WBR36})$$

One inclusion follows from (WBR35). If $U(\beta_0) \neq 0$, choose a polynomial V equal to one at β_0 and zero at every other node, by Lagrange interpolation. Then the bilinear value is $m_{\beta_0} \beta_0 U(\beta_0) \neq 0$, proving the other inclusion. Thus the scalar form factors through the exact quotient $\mathcal{A}_Z \rightarrow \prod_{\beta} \mathbb{C}$, whose kernel is the displayed nilradical. Before that quotient, (WBR28)–(WBR33) retain every nilpotent coefficient; the trace weights retain every algebraic multiplicity. This specifies the full map relating the local algebra to its scalar observation.

182.8 WBR8. Exact critical-line comparison

The inherited source map is

$$\Gamma : Q \longrightarrow Q_{\text{crit}} = \mathcal{S}(\mathbb{R})/\overline{\zeta(1/2+it)\mathcal{S}(\mathbb{R})}, \quad \Gamma[F] = [\mathcal{M}F(1/2+it)]. \quad (\text{WBR37})$$

Its construction and range are included whole in dependencies/HOCHSCHILD_COMPARISON.md, (H16)–(H25). For $\Re \rho \neq 1/2$, multiplication by $(1/2+it-\rho)^{-1}$ is a continuous Schwartz multiplier, preserves the displayed relation and its closure, and inverts $M_{1/2+it-\rho}$ on Q_{crit} . Intertwining by D therefore sends every full generalized ρ -block to zero under $\Gamma\sigma_h$.

At a critical zero $\rho = 1/2 + i\gamma$ of full order m , the continuous jet map

$$[f] \longmapsto \sum_{j=0}^{m-1} \frac{i^{-j} f^{(j)}(\gamma)}{j!} \epsilon^j \quad (\text{WBR38})$$

vanishes on the relation and its closure. On $\Gamma[R_{\text{ref}}u]$, it equals $j_\rho u$: each t -derivative gives the factor i^j in the Mellin derivative. Together these jet maps invert every critical block. Thus

$$\ker(\Gamma\sigma_h) = E_{h,\text{off}}. \quad (\text{WBR39})$$

In the reciprocal algebra, the corresponding actual map is the Chinese-remainder projection

$$\pi_{\text{crit}} : \mathcal{A}_Z \longrightarrow \mathcal{A}_{Z,\text{crit}}, \quad \ker \pi_{\text{crit}} = \mathcal{A}_{Z,\text{off}}. \quad (\text{WBR40})$$

The functional (WBR34) decomposes into its critical and off-critical summands. If an off-critical node β occurs, its primary idempotent e_β , equal to one on its entire local block and zero on the others, belongs to $\ker \pi_{\text{crit}}$, yet has $\operatorname{Tr}_{\mathcal{A}_Z} M_{Xe_\beta} = m_\beta \beta \neq 0$. Hence in that case the full functional does not factor through π_{crit} . Its exact omitted part is the displayed weighted trace on $\mathcal{A}_{Z,\text{off}}$. On real polynomials the two-value interpolation (WBR16) selects the conjugate pair and kills every other finite packet node, giving the value $-2m$; the actual infinite arithmetic tail is controlled by (WBR18).

All these maps lift with the source label fixed. Thus an off-critical vector maps to $(\ell, 0)$ under the split lift of $\Gamma\sigma_h$, while remaining the input (ℓ, v) of the full source operator and its trace. The exact maps (WBR29)–(WBR40) relate the arithmetic source, the scalar witness and the receiving quotient.

182.9 WBR9. Computation and integration record

The original integral in the numerical script is

$$M_{2j} = 4 \sum_{n \geq 1} \int_0^\infty y^{2j} (4\pi^2 n^4 e^{9y/2} - 6\pi n^2 e^{5y/2}) e^{-\pi n^2 e^{2y}} dy. \quad (\text{WBR41})$$

The factor four is the two in Θ and the two half-lines under reflection. The supplied script retains these constants. It uses finite theta sums and the interval $0 \leq y \leq 4$. Its two high-precision runs have no validated enclosure of the finite quadrature or omitted tails.

The finite independent replay verifies the saved decimal matrices by exact rational LDL arithmetic. Those matrices are positive through dimension 16 in both shifts. This is a theorem about the specified decimal rational matrices. The map from those matrices to actual H_d requires coefficient enclosures; none is supplied by agreement between two floating runs.

The supplied verifier also permits negative shift values, using Python negative indices, and the coefficient recurrence uses floating division when passed integer inputs. These narrow input-contract defects do not affect the archived default runs or the mathematical recurrence. The additive strict verifier accepts explicit exact rationals, validates nonnegative integral indices and interval order, and leaves the archive unchanged. The full replay report, exact tests and machine receipts accompany this proof.

The source NOTE equations (1)–(23), with the explicit $\nu_N = u_N$ symbol repair above, are accepted with their stated standard Hadamard input. For cumulative integration, include its entire original LaTeX, this entire proof, the complete finite replay and both inherited dependency files. Place the reciprocal action after the original arithmetic packet, and its Hankel scalar after the original theta moments. Its source class remains available to the ongoing metric and absolute-base geometric calculations.

Classical context was checked directly at [Zhang’s author record](#). This lies in the established power-sum approach. The current proof makes no novelty claim for that general approach and does not depend on an uninspected theorem from that paper.

183 Complete product proof for the original theta entire function

This appendix proves the genus-zero factorization used in the counterfactual workbench. It is a proof of the classical special case, included to make the application’s analytic dependencies explicit.

183.1 A sublinear growth bound and its zeros

Let F be entire, $F(0) \neq 0$, and suppose that for some $0 < \alpha < 1$ and constants $C, R_0 > 0$,

$$\log \max_{|z| \leq R} |F(z)| \leq CR^\alpha \quad (R \geq R_0). \quad (\text{GF1})$$

The workbench’s original F satisfies this with $\alpha = 3/4$: its explicitly proved bound $\log M_F(R) = O(\sqrt{R} \log R)$ implies (GF1) because $\log R/R^{1/4}$ is bounded for $R \geq 1$. Let the nonzero zeros be a_j , repeated with multiplicity, and let $n(r)$ count those with $|a_j| \leq r$.

We first prove the required counting formula. Choose a circle $|z| = R$ containing no zero. There are finitely many zeros in its closed disk, since otherwise an accumulation point would force the nonzero entire function to vanish identically. Divide F by their linear factors; the resulting holomorphic nonvanishing function on a neighborhood of the disk has a holomorphic logarithm there. Indeed its logarithmic derivative is holomorphic on the disk and has a primitive, as follows by termwise integration of its Taylor series on concentric smaller disks. The exponential of that primitive has the

same logarithmic derivative; their quotient is constant, giving the logarithm after choosing the constant at zero. The real part of this logarithm has its value at zero as its circle mean, by integrating its Taylor series. For $|a| < R$,

$$\frac{1}{2\pi} \int_0^{2\pi} \log |Re^{it} - a| dt = \log R. \quad (\text{GF2})$$

To see this, expand $\log(1 - ae^{-it}/R) = -\sum_{\ell \geq 1} (a/R)^\ell e^{-i\ell t}/\ell$, which converges uniformly on the circle; each term has zero mean. Taking the logarithm of the removed factors now gives

$$\frac{1}{2\pi} \int_0^{2\pi} \log |F(Re^{it})| dt - \log |F(0)| = \sum_{|a_j| < R} \log \frac{R}{|a_j|}. \quad (\text{GF3})$$

For any sufficiently large r , choose $R \in (2r, 3r)$ containing no zero. All terms are nonnegative and every zero with $|a_j| \leq r$ contributes at least $\log 2$. Equations (GF1)–(GF3) therefore imply $n(r) \leq C_1 r^\alpha$, for a fixed positive C_1 and all sufficiently large r .

Choose a positive r_0 smaller than the modulus of every zero; such a radius exists since $F(0) \neq 0$. After enlarging C_1 , the inequality $n(r) \leq C_1 r^\alpha$ holds for every $r \geq r_0$. The sum over successive dyadic annuli gives

$$\sum_j \frac{1}{|a_j|} \leq \sum_{\ell \geq 0} \frac{n(2^{\ell+1}r_0)}{2^\ell r_0} \leq C_1 2^\alpha r_0^{\alpha-1} \sum_{\ell \geq 0} 2^{(\alpha-1)\ell} < \infty. \quad (\text{GF4})$$

The inequalities can overcount zeros and still give the stated upper bound. If the zero set is empty, every sum is zero.

183.2 The product and a lower bound on selected circles

Define the literal product

$$P(z) = \prod_j (1 - z/a_j). \quad (\text{GF5})$$

On a fixed disk $|z| \leq A$, all sufficiently late factors have $|z/a_j| \leq 1/2$. The power series logarithm satisfies $|\log(1 - z/a_j)| \leq 2|z/a_j|$, so (GF4) makes its tail uniformly convergent there. The finite preceding factors and that exponential tail define an entire function, locally uniformly independent of the ordering. Its zeros and their multiplicities are exactly the a_j , and $P(0) = 1$. Thus

$$H(z) = F(z)/P(z) \quad (\text{GF6})$$

extends through every zero to a nonvanishing entire function. An entire primitive of H'/H , obtained by integrating its entire power series, gives an entire logarithm h with $H = e^h$ after adjusting its constant.

We prove h constant without assuming any growth bound for $1/P$ away from the following selected circles. Let t be sufficiently large, put $N_t = n(4t)$, and set $\delta_t = t/[4(N_t + 1)]$. Delete from $[t, 2t]$ each open interval of radius δ_t about a number $|a_j| \leq 4t$. Their total length is at most $2N_t\delta_t < t/2$. Hence a radius $R_t \in [t, 2t]$ remains with $|R_t - |a_j|| \geq \delta_t$ for every such zero. For $|z| = R_t$,

$$|1 - z/a_j| \geq \frac{\delta_t}{4t} = \frac{1}{16(N_t + 1)} \quad (|a_j| \leq 4t). \quad (\text{GF7})$$

For the remaining zeros, $|z/a_j| \leq 1/2$, and the same logarithm estimate used for (GF5) gives $\log |1 - z/a_j| \geq -2|z|/|a_j|$. Another dyadic estimate, retaining only $|a_j| > 4t$, gives

$$\sum_{|a_j| > 4t} \frac{1}{|a_j|} \leq \sum_{\ell \geq 0} \frac{n(2^{\ell+1}4t)}{2^\ell 4t} \leq C_2 t^{\alpha-1}, \quad (\text{GF8})$$

where $C_2 = C_1 2^\alpha 4^{\alpha-1} / (1 - 2^{\alpha-1})$ is positive and fixed. Summing the logarithms of (GF7) and the uniformly convergent tail proves, on the entire selected circle,

$$\log |P(z)| \geq -N_t \log(16(N_t + 1)) - 2R_t C_2 t^{\alpha-1} \geq -C_3 t^\alpha \log t \quad (\text{GF9})$$

for another fixed constant $C_3 > 0$ and all large t . This estimate keeps every zero, including repetitions.

183.3 The zero-free factor is constant

Combining (GF1), (GF6), and (GF9) shows that $\Re h(z) \leq C_4 t^\alpha \log t$ on $|z| = R_t$. Write $h(z) = \sum_{\ell \geq 0} d_\ell z^\ell$ and put $B_t = C_4 t^\alpha \log t$, enlarged if necessary so that the bound holds on every selected circle under consideration. The Taylor series, uniformly convergent on a circle, gives

$$d_\ell R_t^\ell = \frac{1}{\pi} \int_0^{2\pi} \Re h(R_t e^{i\theta}) e^{-i\ell\theta} d\theta \quad (\ell \geq 1). \quad (\text{GF10})$$

The integral of the constant B_t against $e^{-i\ell\theta}$ is zero. Because $B_t - \Re h \geq 0$ on the circle, its mean and the mean-value identity yield

$$|d_\ell| R_t^\ell \leq \frac{1}{\pi} \int_0^{2\pi} (B_t - \Re h(R_t e^{i\theta})) d\theta = 2(B_t - \Re h(0)). \quad (\text{GF11})$$

Since $R_t \geq t$ and $\alpha < 1$, the right side divided by R_t^ℓ tends to zero for every integer $\ell \geq 1$. Thus every such d_ℓ is zero. It follows that H is constant. Evaluating at zero now proves the full factorization

$$F(z) = F(0) \prod_j (1 - z/a_j). \quad (\text{GF12})$$

This also covers finitely many zeros and the empty zero set.

183.4 Logarithmic coefficients with their full multiplicities

Group equal zeros in (GF12), writing distinct reciprocals $\beta_j = a_j^{-1}$ and multiplicities m_j . Equation (GF4) becomes $\sum_j m_j |\beta_j| < \infty$. Their supremum is finite. Choose a sufficiently small positive r such that $r|\beta_j| \leq 1/2$ for all j . The derivative series $\sum_j m_j \beta_j / (1 - \beta_j z)$ converges uniformly on $|z| \leq r$, by domination with $2 \sum_j m_j |\beta_j|$. It is the negative logarithmic derivative of (GF12), by termwise differentiation of its locally uniformly convergent logarithm, or by integrating the uniformly convergent derivative series and matching its value at zero. Expanding each denominator and interchanging absolutely convergent sums gives

$$-\frac{F'(z)}{F(z)} = \sum_j \frac{m_j \beta_j}{1 - \beta_j z} = \sum_{n \geq 0} \left(\sum_j m_j \beta_j^{n+1} \right) z^n. \quad (\text{GF13})$$

Every series interchange is justified by $\sum_j m_j |\beta_j| / (1 - r|\beta_j|) < \infty$. Equations (GF12)–(GF13) prove exactly the product and power-sum input used in the workbench and (TC16), with the unchanged $F(0) = g(1/2)$.

This calculation continues the supplied *RH Counterfactual Workbench*. It keeps its original $g = 2\xi$, theta source, Fourier coordinate, unscaled mass, reciprocal-zero multiplicities, and monomial matrices. The accompanying workbench gives the full arithmetic packet and support comparison. Here the infinite theta integral receives explicit truncation bounds, and the negative-witness construction receives quantitative rational approximation and finite interval verification. The computational certificate uses these bounds to prove positivity of both original matrices of dimension 16. This finite result has the same matrix definitions as the workbench's exploratory calculation.

184 The original integral and its two omitted regions

Retain

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad f_0(x) = 2 \sum_{n \geq 1} \phi_*(nx), \quad \psi(y) = e^{y/2} f_0(e^y). \quad (\text{TC1})$$

The original reflection and Mellin calculation give $\psi(-y) = \psi(y)$ and $g(1/2 + iz) = \int_{\mathbb{R}} \psi(y) e^{izy} dy$. For every even integer $J \geq 0$, write $M_J = \int_{\mathbb{R}} y^J \psi(y) dy$. Substitution of (TC1), with its theta factor two and reflection factor two, gives

$$M_J = \int_0^\infty I_J(y) dy, \quad I_J(y) = 4y^J \sum_{n \geq 1} \left(4\pi^2 n^4 e^{9y/2} - 6\pi n^2 e^{5y/2} \right) e^{-\pi n^2 e^{2y}}. \quad (\text{TC2})$$

At $y \geq 0$, each summand is nonnegative; it is strictly positive at $y > 0$, because $2\pi n^2 e^{2y} - 3 > 0$. This also proves positivity of every M_J once convergence is established below.

For an integer $N \geq 1$ and a real $L > 0$, retain exactly the terms $1 \leq n < N$ on $0 \leq y \leq L$. Denote their integral by $M_J^{N,L}$. Thus N is the first omitted integer. Set

$$r_N = e^{4/N - 2\pi N}, \quad r_1 = e^{4 - 2\pi}, \quad \lambda_J(L) = 2\pi e^{2L} - \frac{9}{2} - \frac{J}{L}. \quad (\text{TC3})$$

Both r_N and r_1 lie strictly between zero and one.

Theorem 184.1 (Two explicit positive tails). *For $\lambda_J(L) > 0$ the full original moment satisfies*

$$0 \leq M_J - M_J^{N,L} \leq T_{J,N,L} + Y_{J,L}, \quad (\text{TC4})$$

where every factor is retained in

$$T_{J,N,L} = \frac{16\pi^2 L^{J+1} e^{9L/2} N^4 e^{-\pi N^2}}{1 - r_N}, \quad Y_{J,L} = \frac{16\pi^2 L^J e^{9L/2 - \pi e^{2L}}}{(1 - r_1) \lambda_J(L)}. \quad (\text{TC5})$$

Proof. For $n = N + \ell$, $\ell \geq 0$, use $(N + \ell)^4 \leq N^4 e^{4\ell/N}$, which follows from $\log(1 + x) \leq x$ for $x \geq 0$, and $(N + \ell)^2 \geq N^2 + 2N\ell$. For $y \geq 0$ these imply

$$\sum_{n \geq N} n^4 e^{-\pi n^2 e^{2y}} \leq \frac{N^4 e^{-\pi N^2 e^{2y}}}{1 - e^{4/N - 2\pi N e^{2y}}} \leq \frac{N^4 e^{-\pi N^2}}{1 - r_N}. \quad (\text{TC6})$$

The negative term in each parenthesis of (TC2) can be dropped for an upper bound. On $[0, L]$ one has $y^J \leq L^J$ and $e^{9y/2} \leq e^{9L/2}$. Integrating that bound over an interval of length L proves the first expression in (TC5).

For the second region, apply the first bound in (TC6) with $N = 1$, retaining its numerator's dependence on y and bounding its denominator below by $1 - r_1$. Consequently

$$0 \leq I_J(y) \leq \frac{16\pi^2}{1 - r_1} y^J e^{9y/2 - \pi e^{2y}} \quad (y \geq 0). \quad (\text{TC7})$$

Write $y = L + v$ with $v \geq 0$. The elementary inequalities $(L + v)^J \leq L^J e^{Jv/L}$ and $e^{2(L+v)} \geq e^{2L}(1 + 2v)$ yield

$$y^J e^{9y/2 - \pi e^{2y}} \leq L^J e^{9L/2 - \pi e^{2L}} e^{-\lambda_J(L)v}. \quad (\text{TC8})$$

Its integral for $v \geq 0$ is the numerator divided by $\lambda_J(L)$, proving the second bound. The two omitted regions are disjoint: the first has $0 \leq y \leq L$ and $n \geq N$; the second has $y > L$ and every $n \geq 1$. Every omitted summand is nonnegative. Tonelli's theorem therefore justifies all exchanges before convergence is known; the finite upper bounds then prove convergence and (TC4). $\square$

For every fixed J , the bounds tend to zero by first increasing L and then increasing N . Indeed (TC8) is dominated by the negative double exponential as $L \rightarrow \infty$, while for fixed L the factor $N^4 e^{-\pi N^2}$ tends to zero and $r_N \rightarrow 0$. The finite integrand

$$y^J e^{y/2} \sum_{n=1}^{N-1} (16x_n(y)^2 - 24x_n(y)) e^{-x_n(y)}, \quad x_n(y) = \pi n^2 e^{2y}, \quad (\text{TC9})$$

is entire as a function of the original complex coordinate y . Expanding x_n shows that it is exactly the retained integrand of (TC2); no scalar factor or negative term has been changed. This entire extension supplies the analyticity condition for validated complex-ball quadrature on the finite real intervals.

185 Exact propagation to the original Hankel matrices

Define, in the original coefficient convention,

$$a_j = \frac{(-1)^j M_{2j}}{(2j)!}, \quad F(w) = \sum_{j \geq 0} a_j w^j, \quad -\frac{F'(w)}{F(w)} = \sum_{n \geq 0} b_n w^n. \quad (\text{TC10})$$

The original entire-function comparison is $F(z^2) = g(1/2 + iz)$, and $a_0 = M_0 > 0$. Multiplication of the last identity by F and extraction of the coefficient of w^n prove the complete recurrence

$$b_n = \frac{-(n+1)a_{n+1} - \sum_{j=1}^n a_j b_{n-j}}{a_0}. \quad (\text{TC11})$$

In particular the original mass remains in every division by a_0 . The two real symmetric matrices of dimension $d+1$ are

$$H_d = (b_{r+s})_{0 \leq r, s \leq d}, \quad H_d^{(1)} = (b_{r+s+1})_{0 \leq r, s \leq d}. \quad (\text{TC12})$$

Proposition 185.1 (Finite enclosures and signs). *Suppose that closed rational intervals enclose the finite integrals and upper bounds in (TC4)–(TC5). Adding the interval $[0, T_{J,N,L} + Y_{J,L}]$ with outward upper endpoints gives rational enclosures of the full moments. Applying (TC10)–(TC11) by interval arithmetic, with an enclosure of a_0 having positive lower endpoint, gives enclosures of every required b_n . An interval LDL^T recursion whose every pivot has positive lower endpoint proves positive definiteness of the original matrix in (TC12).*

Proof. Addition, subtraction, multiplication and division by an interval excluding zero each contain the exact operation on contained arguments. This follows for multiplication from the extrema of a bilinear function on a rectangle; division reduces to multiplication by the interval reciprocal. Induction in (TC11) proves the assertion. No independence of the interval arguments is required for enclosure.

For a symmetric matrix A , the exact recursion in the unchanged coordinate order is

$$D_j = A_{jj} - \sum_{k < j} L_{jk}^2 D_k, \quad (\text{TC13})$$

$$L_{jj} = 1, \quad L_{ij} = \frac{A_{ij} - \sum_{k < j} L_{ik} L_{jk} D_k}{D_j} \quad (i > j), \quad L_{ij} = 0 \quad (i < j).$$

If the interval pivots have positive lower endpoints, induction shows that every exact D_j is positive and every division is defined. Formula (TC13) makes $A_{ij} = \sum_k L_{ik} D_k L_{jk}$ for all $i \geq j$; symmetry gives the remaining entries. Thus $A = LDL^T$. The triangular L is invertible with determinant one. For every nonzero real vector v , $v^T A v = \sum_j D_j ((L^T v)_j)^2 > 0$. The same equality for complex vectors uses the conjugate transpose and squared moduli and proves Hermitian positive definiteness. $\square$

For a specified rational vector $c = (c_0, \dots, c_d)$ let $\gamma_n = \sum_{r+s=n} c_r c_s \in \mathbb{Q}$. The exact signed witness is

$$c^\top H_d c = \sum_{n=0}^{2d} \gamma_n b_n. \quad (\text{TC14})$$

If $b_n \in [\ell_n, u_n]$, its upper endpoint is

$$U(c) = \sum_{\gamma_n \geq 0} \gamma_n u_n + \sum_{\gamma_n < 0} \gamma_n \ell_n. \quad (\text{TC15})$$

Every comparison here is rational. A strict inequality $U(c) < 0$ is a finite negative certificate. If $\widehat{b}_n$ have errors $|b_n - \widehat{b}_n| \leq \epsilon_n$, the exact error in (TC14) is at most $\sum_n |\gamma_n| \epsilon_n$, by the triangle inequality. These statements include all mixed matrix entries.

186 Quantitative rational form of the counterfactual separator

We record the full argument to show precisely how a negative counterfactual form becomes a rational certificate. The entire factorization in the supplied workbench gives the distinct reciprocal zeros β_j of F , with positive integer multiplicities m_j , and

$$\sum_j m_j |\beta_j| < \infty, \quad b_n = \sum_j m_j \beta_j^{n+1}. \quad (\text{TC16})$$

No reciprocal zero is zero. The multiset is stable under complex conjugation. The actual map from a zeta zero $\rho = 1/2 + \delta + i\gamma$ is

$$\beta = -\frac{1}{(\rho - 1/2)^2} = \frac{\gamma^2 - \delta^2 + 2i\gamma\delta}{(\gamma^2 + \delta^2)^2}. \quad (\text{TC17})$$

The reflected pair $\rho, 1 - \rho$ corresponds to a single zero of F with the same multiplicity. Both primary blocks remain in the original packet before taking its half-trace.

Let

$$S_* = \sum_j m_j |\beta_j|, \quad R_* = \max\{1, \sup_j |\beta_j|\} < \infty, \quad \|P\|_{R_*} = \sum_{r=0}^{\deg P} |p_r| R_*^r \quad (\text{TC18})$$

for $P(X) = \sum p_r X^r$. This coefficient norm is an explicit error-control map; it changes neither P nor the original Hankel form. Define

$$\mathcal{Q}(P) = \sum_j m_j \beta_j P(\beta_j)^2 = p^\top H_{\deg P} p. \quad (\text{TC19})$$

Absolute convergence follows from $|P(\beta_j)| \leq \|P\|_{R_*}$ and (TC16). The sum is real for real P because conjugate terms pair, and real reciprocal terms are real. The equality with the finite matrix follows by expanding the finite polynomial product and using (TC16).

Lemma 186.1 (Coefficient perturbation with the full reciprocal tail). *For real polynomials P, E one has*

$$|\mathcal{Q}(P + E) - \mathcal{Q}(P)| \leq S_* \|E\|_{R_*} (2\|P\|_{R_*} + \|E\|_{R_*}). \quad (\text{TC20})$$

Proof. The polynomial identity $(P + E)^2 - P^2 = 2PE + E^2$ holds at every β_j including every multiplicity. Take absolute values term by term in the absolutely convergent series (TC19), bound $|P(\beta_j)|$ and $|E(\beta_j)|$ by (TC18), and sum $m_j |\beta_j|$. This gives (TC20). $\square$

Theorem 186.2 (Explicit finite degree and rational coefficient accuracy). *Choose any nonreal reciprocal zero β and its conjugate of multiplicity m . Put $r = |\beta|/2$. Let $\mathcal{A}$ be the finite set of all other distinct reciprocal zeros of modulus at least r , and set*

$$B(X) = \prod_{\alpha \in \mathcal{A}} (X - \alpha), \quad B_0 = \prod_{\alpha \in \mathcal{A}} (r + |\alpha|), \quad T_* = \sum_{|\beta_j| < r} m_j |\beta_j|. \quad (\text{TC21})$$

Choose either $c \in \mathbb{C}$ satisfying $\beta c^2 = -1$ and define

$$C_* = \frac{|c|B_0}{|B(\beta)|} \left(1 + \frac{|\Re\beta| + r}{|\Im\beta|} \right). \quad (\text{TC22})$$

If $T_* = 0$, take $N_* = 0$. Otherwise take the explicit integer

$$N_* = \max \left\{ 0, 1 + \left\lfloor \frac{\log(C_*^2 T_*/m)}{\log 4} \right\rfloor \right\}. \quad (\text{TC23})$$

For any integer $N \geq N_*$ put

$$w_N = \frac{c}{\beta^N B(\beta)}, \quad v_N = \frac{\Im w_N}{\Im \beta}, \quad u_N = \Re w_N - (\Re \beta) v_N, \quad P_N(X) = X^N B(X)(u_N + v_N X). \quad (\text{TC24})$$

Then $\mathcal{Q}(P_N) \leq -m$. A rational polynomial $\tilde{P}_N$ of degree at most $D = N + \#\mathcal{A} + 1$ can be obtained by rounding each of the $D + 1$ original coefficients to a nearest multiple of $1/H$, with either choice allowed at a tie, for any positive integer H with

$$\frac{\sum_{r'=0}^D R_*^{r'}}{2H} \leq \min \left\{ 1, \frac{m}{2S_*(2\|P_N\|_{R_*} + 1)} \right\}. \quad (\text{TC25})$$

Every such rounding satisfies $\mathcal{Q}(\tilde{P}_N) \leq -m/2 < 0$.

Proof. Absolute summability in (TC16) makes $\mathcal{A}$ finite. It is conjugation stable; hence B has real coefficients, $B(\beta) \neq 0$, and u_N, v_N are real. Evaluation of their formulas gives $u_N + v_N \beta = w_N$ and therefore $P_N(\beta) = c$ and $P_N(\bar{\beta}) = \bar{c}$. The selected two terms of (TC19) sum to $-2m$ exactly. All other terms with modulus at least r vanish.

For $|X| \leq r$, one has $|B(X)| \leq B_0$ and

$$|u_N + v_N X| \leq |w_N| \left(1 + \frac{|\Re\beta| + r}{|\Im\beta|} \right).$$

Consequently $|P_N(X)| \leq C_* 2^{-N}$. The absolute sum of all remaining terms is at most $C_*^2 T_* 4^{-N}$, so

$$\mathcal{Q}(P_N) \leq -2m + C_*^2 T_* 4^{-N}. \quad (\text{TC26})$$

The chosen integer (TC23) makes the last summand at most m ; if $T_* = 0$ it is zero. This proves the first assertion. The coefficient rounding error $E = \tilde{P}_N - P_N$ has each coefficient at most $1/(2H)$ in absolute value. Thus $\|E\|_{R_*} \leq \sum_{r'=0}^D R_*^{r'}/(2H)$. The bound in (TC25) and (TC20) make the change in the quadratic form at most $m/2$, proving the strict negative result. Every original coefficient slot is included in the error bound. A nonzero coefficient may round to zero; an original zero coefficient remains an exact zero. $\square$

All constants in this counterfactual degree bound retain their dependence on the chosen actual zero and on the full reciprocal set. It supplies no universal dimension for an off-critical witness. Once a rational polynomial is specified, however, (TC14)–(TC15) require only finitely many original moments. As their enclosing intervals shrink, their propagated intervals shrink to the exact coefficients: (TC11) is a finite composition of continuous rational operations with denominator $a_0 > 0$. The strict margin in (TC25) therefore eventually yields a strictly negative rational upper bound in (TC15).

187 The completed finite certificate

The supplied computation uses $N = 20$, $L = 4$, and $J = 0, 2, \dots, 64$. It keeps all nineteen original theta terms on each of the eight intervals $[j/2, (j+1)/2]$, $0 \leq j < 8$. The omitted two regions are enclosed by (TC5). For these parameters every $\lambda_J(L)$ is positive: already $\pi > 3$ and $e^8 > 1 + 8 + 8^2/2 = 41$ give $2\pi e^8 - 9/2 - J/4 > 246 - 9/2 - 16 > 0$. The actual computation retains ball enclosures of the complete expressions, rather than replacing them by that rough inequality.

The finite integrations use python-flint 0.9.0's validated `acb.integral`, at 1024 bits and target 850 bits. The callback is exactly (TC9); its entire expression satisfies the integration routine's analytic-ball contract. Each returned real interval is enlarged by the positive tails. All endpoints are exported as exact dyadic rational numerators and denominators. The complete a_j, b_n, L_{ij}, D_j enclosures and the individual integration intervals are retained in the machine-readable certificate. All thirty-two computed pivots have strictly positive lower endpoints, proving

$$H_{15} > 0, \quad H_{15}^{(1)} > 0. \quad (\text{TC27})$$

Every smaller leading principal matrix inherits positivity. For orientation, the readable enclosures include

$$\det H_1 \in [1.9493355548191422147398782191721395 \times 10^{-9} \pm 5.60 \times 10^{-45}]. \quad (\text{TC28})$$

The actual certificate contains the more precise exact rational endpoints. Its last pivots are positive intervals centered at $6.1698420811114408502314906319786538 \times 10^{-107}$ and $7.1026100619440799659087832255229554 \times 10^{-111}$, respectively. The original a_0 remains centered at $0.99424155637662821982554747937079544$. These values are given to identify the checked objects; the strict signs are decided by the enclosing rational endpoints.

The complete workbench proves that positivity for every unshifted dimension is equivalent to RH. Equation (TC27) settles the displayed finite dimensions and makes no assertion about larger dimensions. The packet trace still evaluates the retained arithmetic source before any critical-only comparison, and its support maps retain τ and every receiving supported zero exactly as in the included packet proofs.

Original marked-product note: literal source and reading corrections

The following appendix preserves the complete original body, including its abstract and scope statements. Only its document wrapper, `\maketitle` and `\tableofcontents` controls are removed here. The separate `MARKED_PRODUCT_ORIGINAL_NOTE.tex` is byte exact. The original frequency symbol is y in $S = k/2 + iy$; the deformation parameter is u . In the original analytic displays, the measure written du after defining a density in y is read as dy , and the frequency arguments written $c + iu$ are read as

$c + iy$. These are distinct original variables, and this correction does not specialize or replace either one.

The sentence following original equation (64) overstates positivity of the relative derivative. For the literal positive source Grams $M(0)$ and $M(1)$, the identities

$$M(0)(M(0)^{-1}M(1)) = M(1), \quad M(0)(M(0)^{-1}(M(1) - M(0))) = M(1) - M(0)$$

prove that the first endomorphism is positive and self-adjoint in the $M(0)$ metric and that the second is self-adjoint. The second need not be positive: when $M(1) = M(0)/2$, it equals $-I/2$. Its original operator norm and the resulting midpoint enclosure remain meaningful without the extra positivity assertion.

The two nonnegative source/relation operators whose densities occur in the signed four-endpoint cancellation each have trace $2q$. Their rank is $q + 1$, with spectrum $1, 2, \dots, 2, 1$ on their range (the multiplicity of 2 is $q - 1$). The earlier AW7 proves this from the actual nested source and relation projections; SP6–SP8 reproduce that spectrum on the identical operators proved above. Thus a kernel mass $2q$ is read as that trace, not as rank $2q$. The complete exact cancellation is retained in SP1–SP13. Its final bound is the earlier AW14, whose full-spectrum refinement AW13 is also included; the additional overlap and common-range refinement is SP8–SP10.

The marked τ -base, weight-matched external products,
and the signed arithmetic four-endpoint correction

Original abstract. We continue the original marked Split-Zero construction, retaining its absolute pointed base, supported zero, amplitude and support observations, full theta complex, and pre-quotient norms. We construct the external product of the original packet’s polynomial-exponential complex. Its top cohomology has rank d^k , its special fibre is the full tensor packet, and its diagonal parameter operator specializes to the original sum action. Its finite-field realization has weight k under Deligne’s actual hypotheses. An explicit coefficient and source diagram connects this family to the original theta complex; no Frobenius intertwiner is assumed. We then calculate the signed arithmetic/Gamma correction simultaneously at all four original endpoints. The result is a single integral of the actual multiplier against a signed difference of two equal-rank source/relation projection densities. Its differentiated sections are original relations, their complete quadratic contribution is calculated, and a finite quadrature error bound is proved. A closed formula for the first conjugate-pair calculation retains the exact cancellation $|h|^2 w_h = |2\xi|^2/(2\pi)$. These results do not prove the remaining uniform upper bound.

188 Scope and fixed inputs

The earlier audit constrains particular auxiliary implications. It is not a no-go theorem for geometry over $\mathbb{F}_1$ or for this marked τ -base. We retain its valid examples and its exact arithmetic/Gamma decomposition. We do not use an arbitrary test polynomial as an arithmetic zero packet. Everywhere below, an arithmetic packet means a nonempty finite set of actual nontrivial zeros of $g = 2\xi$, with each selected zero included to its complete order.

The current formal integration distinguishes an original relation module from the larger kernel of a finite observation, and distinguishes a source-section defect from a coefficient-action defect. Those distinctions are used below. Analytic period invertibility and the analytic theta constructions remain written results, not assertions of a new Lean run.

189 The original absolute base and its actual fibres

For a commutative ring R , retain the semiring

$$G(R) = \{\tau\} \sqcup R^\bullet, \quad e_R = 0_R^\bullet, \quad \tau + x = x, \quad r^\bullet + s^\bullet = (r + s)^\bullet, \quad \tau x = \tau, \quad r^\bullet s^\bullet = (rs)^\bullet. \quad (1)$$

The multiplicative unit is $1_R^\bullet$, including when R is the zero ring. Define

$$p_R(\tau) = 0, \quad p_R(r^\bullet) = r, \quad b_R(\tau) = 0, \quad b_R(r^\bullet) = 1 \in \mathbb{B}. \quad (2)$$

Both are semiring maps. The pair (p_R, b_R) is injective: support distinguishes τ from every represented element, and amplitude distinguishes represented elements. In particular e_R has observations $(0, 1)$, while τ has observations $(0, 0)$.

Let $\mathbb{F}_{1,\tau} = \{\tau_0, 1_0\}$ be the pointed commutative monoid. Its finite-word preaddition identifies precisely words having the same number of 1_0 terms; τ_0 terms can be deleted. Thus $[] \sim [\tau_0]$, but $[1_0, 1_0] \not\sim [1_0]$. There is a unique pointed multiplicative structural map

$$j_R : \mathbb{F}_{1,\tau} \longrightarrow G(R), \quad \tau_0 \mapsto \tau, \quad 1_0 \mapsto 1_R^\bullet. \quad (3)$$

It preserves the preaddition because the image of a word is its integer number of units in $G(R)$. Its base spectrum $\mathfrak{b}_\tau$ has exactly one multiplicative prime, $\{\tau_0\}$.

We work in marked monoidal spaces carrying their original semiring sheaf and the two observations (2), and in their specified coefficient-support diagrams. The structural maps are local pointed-monoid maps. This declares the category actually used; it does not identify a finite chart with a finite-type arithmetic scheme or assume a general six-functor formalism for semirings.

For a nonzero integral domain R , the semiring prime ideals are

$$P_\tau = \{\tau\}, \quad P_{\mathfrak{p}} = \{\tau\} \sqcup \mathfrak{p}^\bullet \quad (\mathfrak{p} \in \operatorname{Spec} R). \quad (4)$$

Indeed, an ideal containing any $a^\bullet$ contains $e_R = a^\bullet + (-a)^\bullet$. Its represented part is a ring ideal, and primality reduces to ring primality. The remaining ideal $\{\tau\}$ is prime since a product of represented elements is represented. Thus

$$P_e = \{\tau, e_R\}, \quad V(e_R) \simeq \operatorname{Spec} R, \quad D(e_R) = \{P_\tau\}. \quad (5)$$

Here P_e is the supported-zero prime, P_τ is a point in the enlarged source, and the unique point of $\mathfrak{b}_\tau$ is the structural target. Their connecting maps are the closed inclusion induced by p_R , the inclusion of $D(e_R)$, and the structural map $a_R : X_R \rightarrow \mathfrak{b}_\tau$.

One explicit sheaf presentation is obtained by adjoining P_τ to every nonempty open of $\operatorname{Spec} R$. On $U \cup \{P_\tau\}$ its value is $G(\mathcal{O}_R(U))$, and on $\{P_\tau\}$ its value is $G(0) \simeq \mathbb{B}$. The restriction to that point is b_R . Compatible sections on a cover have the same support because all opens meet at P_τ ; represented amplitudes then glue by the ring sheaf, and absent sections glue to τ . This proves the sheaf property. It agrees with the displayed localizations on principal opens, including localization at e_R .

Consequently the direct image and its further restriction are

$$(a_{R*} \mathcal{S}_R)(\mathfrak{b}_\tau) = G(R) \xrightarrow{b_R} G(R)[e_R^{-1}] \simeq \mathbb{B}. \quad (6)$$

We retain the left-hand object. The absolute structural fibre is the whole marked source; it is not replaced by the Boolean stalk. The original arithmetic square is

$$\begin{array}{ccc} G(\mathbb{Z}) & \xrightarrow{G(\iota)} & G(\mathbb{C}) \\ p_{\mathbb{Z}} \downarrow & & \downarrow p_{\mathbb{C}} \\ \mathbb{Z} & \xrightarrow{\iota} & \mathbb{C}. \end{array} \quad (7)$$

Its integer target is infinite. For every ring ideal I , the square with $G(R/I)$ commutes; $G(R \rightarrow R/I)^{-1}(e_{R/I}) = I^\bullet$ and its inverse image of τ is $\{\tau\}$. In particular the ordinary finite ideal norms $|R/I|$ are retained by the arithmetic observation; no finite Euler factor is assigned to the infinite quotient by the zero ideal.

For a coefficient vector space V , write $S(V) = \{\tau\} \sqcup V^\bullet$. A linear map lifts by $\tau \mapsto \tau$ and $v^\bullet \mapsto f(v)^\bullet$. For an original join-support diagram, the same formula is applied fibrewise and uses its specified transport maps. On fixed nonbottom labels,

$$\tilde{f}^{-1}(e) = (\ker f)^\bullet, \quad \tilde{f}^{-1}(\tau) = \{\tau\}. \quad (8)$$

For general support-changing maps, this nonabsence assertion is made only when the receiving label is nonbottom. The current reconstruction allows nontrivial bottom coefficient fibres; that case is not silently treated as the disjoint single-fibre model.

190 The theta complex over the marked point

Retain the original Fréchet spaces and seminorms

$$V = \{\phi \in \mathcal{S}(\mathbb{R})_{\text{ev}} : \phi(0) = 0, \int_{\mathbb{R}} \phi = 0\},$$

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |D^m F(x)| < \infty \text{ for every } b \in \mathbb{Z}, m \geq 0\}, \quad D = -x\partial_x. \quad (9)$$

The Fourier and Mellin maps are

$$\hat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx, \quad \Theta\phi(x) = 2 \sum_{n \geq 1} \phi(nx), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}. \quad (10)$$

The original source proofs establish continuity and injectivity of Θ , $D\Theta = \Theta D$, and

$$\Theta\hat{\phi}(x) = x^{-1}\Theta\phi(1/x), \quad \mathcal{M}\Theta\phi = gH_\phi, \quad g(s) = 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s). \quad (11)$$

Here

$$H_\phi(s) = \frac{2\pi^{s/2}}{s(s-1)\Gamma(s/2)} \int_0^\infty \phi(x) x^s \frac{dx}{x}, \quad \phi_* = (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2}, \quad H_{\phi_*} = 1. \quad (12)$$

Every constant in (10)–(12) is retained.

The four-point chart P has $+\langle \eta < \sigma$ and $-\langle \eta < \sigma$. Its coefficient sheaf has values $V, V, \mathcal{B}, 0$, restrictions $\Theta, \Theta\mathcal{F}$ into η , and zero restrictions into σ . Its structural map to $X_{\mathbb{C}}$ sends the first three points to P_e and σ to P_τ , then to $\mathfrak{b}_\tau$. The coefficient scalar restriction at σ is the specified $G(\mathbb{C}) \rightarrow \mathbb{B}$; reconstructing the zero coefficient fibre leaves its supported zero and absence.

The projective-diagram resolution

$$0 \rightarrow P_\eta \xrightarrow{x \mapsto (x, -x)} P_+ \oplus P_- \xrightarrow{(x, y) \mapsto x+y} \underline{\mathbb{C}} \rightarrow 0 \quad (13)$$

is exact at every chart point. Applying the sheaf Hom functor gives the actual global-coefficient complex

$$C_{+-} = [V \oplus V \xrightarrow{\Theta(v-\hat{w})} \mathcal{B}]. \quad (14)$$

The map $(v, w) \mapsto (v - \hat{w}, w)$ with inverse $(a, w) \mapsto (a + \hat{w}, w)$ identifies it with $C_+ \oplus V[0]$, where $C_+ = [V \xrightarrow{\Theta} \mathcal{B}]$. Thus $H^1(C_+) = Q = \mathcal{B}/\Theta V$, while the entire additional degree-zero cycle is retained in (14). This is a coefficient-complex calculation over the marked base, not a replacement of that base by $\text{Spec } \mathbb{C}$.

190.1 Actual packets and the finite observation kernel

For $h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}$, with the stipulated full orders, set

$$E_h = \mathbb{C}[s]/h, \quad A_h = M_s, \quad v_h = g/h, \quad v_h = j_h v_h \in E_h^\times. \quad (15)$$

The original Euler inverse

$$S_\rho F(x) = x^{-\rho} \int_x^\infty F(y) y^{\rho-1} dy \quad (16)$$

on its zero-Mellin-value domain is continuous in the stated spaces. Its iterations supply $F_h = S_h(\Theta\phi_*) \in \mathcal{B}$ with $\mathcal{M}F_h = v_h$. They give the actual square and exact sequence

$$\begin{array}{ccc} V/h(D)V & \xrightarrow{\Theta} & \mathcal{B}/h(D)\mathcal{B} \\ j_h H \downarrow \wr & & \wr \downarrow j_h \mathcal{M} \\ E_h & \xrightarrow{\times j_h g} & E_h, \end{array} \quad 0 \rightarrow Q[h(D)] \rightarrow E_h \xrightarrow{\times j_h g} E_h \rightarrow Q/h(D)Q \rightarrow 0. \quad (17)$$

For the actual packet $j_h g = 0$ and v_h is a unit. The canonical finite observation $J_h F = j_h \mathcal{M}F$ and source section

$$r_h u = \mathcal{T}_h(\text{rem}_h(v_h^{-1}u)), \quad \mathcal{T}_h P = P(D)F_h, \quad \alpha_h P = P(D)\phi_* \quad (18)$$

satisfy

$$\mathcal{T}_h(hP) = \Theta\alpha_h P, \quad J_h \mathcal{T}_h P = v_h[P]_h, \quad J_h r_h = 1, \quad J_h \Theta = 0. \quad (19)$$

Thus the coefficient complex $[\mathbb{C}[s] \xrightarrow{h} \mathbb{C}[s]ds]$ maps to the original C_+ by $(\alpha_h, \mathcal{T}_h)$. Its H^1 map is $\sigma_h M_{v_h} : E_h \hookrightarrow Q$, where $\sigma_h = [r_h]$. Its cone retains $Q/\sigma_h E_h$ in degree one. On the entire source the observation kernel remains $\ker J_h/\Theta V$; equality with zero is asserted only on the stated finite packet image.

191 The complete dilation and relation action

For $a > 0$ retain $U_a F(x) = F(x/a)$. Mellin transformation gives $\mathcal{M}U_a F(s) = a^s \mathcal{M}F(s)$ and $U_a \Theta = \Theta U_a$. Fourier transformation gives

$$\widehat{U_a \phi} = a U_{1/a} \widehat{\phi}. \quad (20)$$

Therefore the two-leg action is $(U_a, aU_{1/a})$ and its generators are $(D, 1 - D)$. On E_h the exact action is multiplication by $j_h(a^s)$; on a primary block it is

$$a^{A_h}|_{E_\rho} = a^\rho \sum_{j=0}^{m_\rho-1} \frac{(\log a)^j}{j!} N_\rho^j. \quad (21)$$

The full v_h commutes with this multiplication. Thus $J_h U_a = a^{A_h} J_h$ and the finite inclusion into Q intertwines the same action.

There is a source primitive for the representative defect. Put $P_u = \text{rem}_h(v_h^{-1}u)$ and $\tilde{P}_u = \text{rem}_h(j_h(a^s)P_u)$. Then

$$K_a u = S_h^V (U_a \alpha_h P_u - \alpha_h \tilde{P}_u), \quad U_a r_h - r_h a^{A_h} = \Theta K_a. \quad (22)$$

The input to S_h^V has every required zero jet by construction. Applying the injective $h(D)$ proves the second equation. Injectivity of Θ also proves

$$K_{ab} = U_a K_b + K_a b^{A_h}. \quad (23)$$

Polynomial source spans are preserved by D , not generally by every U_a ; (22) is the explicit map into the full original source which supplies the latter comparison.

On the ordered k -fold tensor complex, $D^{(k)} = \sum_i D_i$, the finite action is $A_k = \sum_i A_{h,i}$, and

$$a^{A_k} = \bigotimes_{i=1}^k a^{A_{h,i}}. \quad (24)$$

This retains every term in the exponential of $N_1 + \cdots + N_k$. A primitive for the tensor difference is the sum whose i -th term is

$$(-1)^{i-1} (U_a r_h)^{\otimes(i-1)} \otimes K_a \otimes (r_h a^{A_h})^{\otimes(k-i)}. \quad (25)$$

The tensor differential contributes the second $(-1)^{i-1}$, giving the positive telescoping difference. All primitives remain in their original tensor support labels, with the specified join when terms are added.

192 The weight-matched external family over the same base

Write $d = \deg h$ and $h(s) = s^d + \sum_{b < d} h_b s^b$. Define

$$\Phi_h(s) = \frac{s^{d+1}}{d+1} + \sum_{b=0}^{d-1} \frac{h_b s^{b+1}}{b+1}. \quad (26)$$

Its constant is fixed to zero; $\Phi'_h = h$. Let $R = \mathbb{C}[u, t_1, \dots, t_k]$. On $R[s_1, \dots, s_k] \otimes \bigwedge^\bullet(ds_1, \dots, ds_k)$ define

$$\mathcal{D} = \sum_{i=1}^k (u \partial_{s_i} + h(s_i) - t_i) ds_i \wedge (-). \quad (27)$$

The coefficient operators commute, and the wedge signs give $\mathcal{D}^2 = 0$.

Theorem 192.1 (The full external-product fibre). *The complex (27) has cohomology only in degree k . That cohomology is free over R with the retained basis $s_1^{a_1} \cdots s_k^{a_k} ds_1 \wedge \cdots \wedge ds_k$, $0 \leq a_i < d$, and has rank d^k . At the coefficient specialization $u = t_1 = \cdots = t_k = 0$, it is $E_h^{\otimes k}$ with its full nilpotent structure.*

Proof. In one variable, $(u \partial_s + h - t)P$ has degree $\deg P + d$ and the same leading coefficient as P . It is injective, and successive leading-term subtraction gives a unique remainder of degree below d . This splits the one-factor complex, as an R -module complex, into its free remainder in degree one and a contractible pair. Tensor those explicit splittings. Every summand having a contractible factor is contractible, with the usual tensor-homotopy signs. The sole remaining summand is the stated tensor remainder in degree k . Since all splittings are over R , the result survives the displayed coefficient specialization, without a derived-fibre Tor term. $\square$

This family has an explicit original-source realization. The coefficient maps α_h and $\mathcal{T}_h$ are injective; denote their images by V_* and $\mathcal{B}_h$. Transport the one-variable family differential to them:

$$d_{u,t}^\theta = \Theta|_{V_*} + u \mathcal{T}_h \partial_s \alpha_h^{-1} - t \mathcal{T}_h \alpha_h^{-1} : V_*[u, t] \rightarrow \mathcal{B}_h[u, t]. \quad (28)$$

Then $d_{u,t}^\theta \alpha_h = \mathcal{T}_h(u \partial_s + h - t)$. Thus (28), not an asserted unidentified complex, is a deformation of the original polynomial subcomplex. The derivative is also realized by the original logarithmic multiplier:

$$\mathcal{T}_h(P') = (\log x)P(D)F_h - P(D)((\log x)F_h). \quad (29)$$

This follows from $[\log x, D] = 1$. Its Mellin proof retains both terms $v'_h P + v_h P'$; the $v'_h P$ term is not dropped.

Tensor (28) in the original order and then include at the marked specialization in $C_+^{\otimes k}$. The resulting cohomology map is

$$E_h^{\otimes k} \xrightarrow{M_{v_h^{\otimes k}}} E_h^{\otimes k} \xrightarrow{\sigma_h^{\otimes k}} Q^{\otimes k}. \quad (30)$$

Over $\mathbb{C}$ these are literal algebraic tensor complexes. On the inherited completed projective tensor realization, the same maps apply to the finite packet and its continuous sections. A new exactness theorem for arbitrary completed tensor products is not assumed.

The scalar structural maps and specialization are

$$\mathbb{F}_{1,\tau} \rightarrow G(R), \quad G(R) \xrightarrow{G(\text{ev}_0)} G(\mathbb{C}). \quad (31)$$

They commute with (7). The images of the represented u, t_i are e , while τ maps to τ . The original source chart, the family, and the marked fibre remain over the same unique point of $\mathfrak{b}_\tau$. Evaluation in (31) is a coefficient specialization over that point; it does not identify the absolute base with an extra complex parameter value.

192.1 The cyclic inclusion and its complete family defect

Let $\chi = \chi_{h,k}$ be the minimal polynomial of the sum on $E_h^{\otimes k}$ and let $E = \mathbb{C}[S]/\chi$. The algebra injection $\alpha[P] = P(\sum_i s_i)1$ and weighted module injection

$$\eta = M_{v_h^{\otimes k}} \alpha : E \hookrightarrow E_h^{\otimes k} \quad (32)$$

are retained. Their sum actions intertwine. The quotient $E_h^{\otimes k}/\eta E$ and its induced marked action remain; the word “cyclic” is not a deletion of this quotient.

Fixed-order monic division gives, for each $P(S)$,

$$\chi(S)P(S) = \sum_{i=1}^k h(s_i)Q_i(\mathbf{s}), \quad S = \sum_i s_i. \quad (33)$$

At the special fibre its actual primitive is $\sum_i (-1)^{i-1} Q_i ds_1 \wedge \cdots \widehat{ds_i} \cdots \wedge ds_k$. At general parameters (27) gives instead the exact equation

$$[\chi(S)P(S)]_{\mathcal{H}} = \sum_i [t_i Q_i - u \partial_{s_i} Q_i]_{\mathcal{H}}. \quad (34)$$

Thus the original cyclic annihilator is a marked-fibre relation. The full free family retains the correction (34), rather than declaring that annihilator constant throughout the family.

193 Deligne’s step, with the actual parameter and action maps

For $u \neq 0$, the one-factor connection is

$$\nabla_{t_i} = \partial_{t_i} - \frac{A_{h,i}(t_i)}{u}, \quad A_h(t) = A_h + t\mathcal{R}_h, \quad \mathcal{R}_h = 1 \otimes [S^{d-1}] \text{rem}_h. \quad (35)$$

On the diagonal $t_i = t$, the operator is

$$\nabla_t = \partial_t - \frac{A_k + t \sum_i \mathcal{R}_{h,i}}{u}, \quad (-u \nabla_t) \bmod (u, t) = A_k. \quad (36)$$

The coefficient commutators prove descent of (35): $[u\partial_s + h - t, \partial_t] = 1$ and $[u\partial_s + h - t, -s/u] = -1$. Formula (36) is an operator on the full tensor coefficient module; on ηE its transverse term is the explicitly retained composite

$$E \xrightarrow{\eta} E_h^{\otimes k} \xrightarrow{\sum_i \mathcal{R}_{h,i}} E_h^{\otimes k} \xrightarrow{\pi_\eta} E_h^{\otimes k} / \eta E. \quad (37)$$

It is not presumed zero.

Let $R_0 \subset \mathbb{C}$ be the finitely generated coefficient ring containing the coefficients of h , the finitely many coefficients of v_h and its inverse in the retained remainder basis, and $1/(d+1)!$. Thus the finite Taylor-unit multiplication and its inverse also specialize through this same coefficient model; no finite-field interpretation of the entire analytic function g is asserted. At a specified finite-field specialization of characteristic $p > d+1$, and $u \neq 0$, take

$$\mathcal{L}_\psi \left(\frac{\sum_i \Phi_h(s_i) - \sum_i t_i s_i}{u} \right) \quad \text{on } \mathbb{A}^k. \quad (38)$$

Its highest homogeneous part is $\sum_i s_i^{d+1}/((d+1)u)$. The projective hypersurface is smooth: its partial derivatives are s_i^d/u , which cannot vanish simultaneously at a projective point. Deligne's exponential-sum theorem, Weil II 3.7.2.3, therefore gives compact-support cohomology only in degree k , of dimension d^k , pure of weight k . Equivalently, the actual external-product sheaf and compact Künneth map give the tensor product of the k degree-one, weight-one factors. Repeated critical roots do not remove smoothness of the leading homogeneous part.

This uses the product of the original degree- d packet family. The rank- q , weight-one exponential family constructed from the sum annihilator has a different specified map and is not substituted for (38). The current correction resolves the citation as Roman I.8.11 to Weil I, retains strict < 2 , and retains lisse/mixed hypotheses for propagation. The algebraic fibre (31) is not automatically a lisse fibre of the $u \neq 0$ exponential system.

For completeness the complex periods use the original ordered rays

$$\begin{aligned} \vartheta_j &= \frac{\arg u + \pi}{d+1} + \frac{2\pi j}{d+1}, \quad \Gamma_j = -\ell_0 + \ell_j, \quad 1 \leq j \leq d, \\ (\Pi_h)_{jb}(u, t) &= \int_{\Gamma_j} e^{(\Phi_h(s) - ts)/u} s^b ds, \quad 0 \leq b < d. \end{aligned} \quad (39)$$

The leading exponent is $-r^{d+1}/((d+1)|u|)$, proving absolute convergence on those rays and differentiation on compact parameter sets. At the monomial member the matrix is a nonzero gamma-column factor times $(\exp(2\pi i j(b+1)/(d+1)) - 1)_{jb}$. A polynomial of degree at most d vanishing at all $d+1$ roots of unity proves that last matrix invertible. Coefficient differentiation and unique differential remainder yield a matrix equation $\Pi' = \Pi B$ along a coefficient path; hence $(\det \Pi)' = \text{Tr}(B) \det \Pi$, proving invertibility at every parameter, including collisions.

The ordered external period map is exactly

$$\Pi_k(u, \mathbf{t}) = \bigotimes_i \Pi_h(u, t_i) : \mathcal{H}_{u, \mathbf{t}}^k \xrightarrow{\sim} \mathbb{C}^{d^k}. \quad (40)$$

Fubini proves the product formula with the ordered product contours and $ds_1 \wedge \cdots \wedge ds_k$. The cyclic map is the actual rectangular map $\Pi_k \eta$. On its image it has the inverse induced by $\eta^{-1} \Pi_k^{-1}$. On the full source its observation kernel is unchanged by invertibility of Π_k .

In particular the complete base diagram is the split lift of

$$\mathcal{H}^k/(u, \mathbf{t}) \mathcal{H}^k \simeq E_h^{\otimes k} \xrightarrow{\sigma_h^{\otimes k} M_{v_h^{\otimes k}}} Q^{\otimes k}, \quad E \xrightarrow{\eta} E_h^{\otimes k} \xrightarrow{\Pi_k} \mathbb{C}^{d^k}. \quad (41)$$

Every arrow is defined above, and (21), (24), (35)–(37) specify its action. The finite-field branch of (38) has its own Frobenius on that realization. No faithful Frobenius comparison with a^{A_k} is added to (41).

194 The original boundary pairing, before its supported quotient

For the canonical cyclic section $r_N = \mathcal{V}C_N : E \rightarrow \mathcal{B}^{\widehat{\otimes} k}$, retain

$$J^{(k)}r_N = \eta, \quad [r_N] = \sigma_h^{\otimes k}\eta, \quad D^{(k)}r_N - r_N A = dK_N, \quad G_N = r_N^* r_N. \quad (42)$$

Here C_N is the coefficient minimum for the actual source norm. Integration by parts, including the vanishing endpoint $[x\overline{F}H]_0^\infty$, proves

$$W_N = A^*G_N + G_N A - kG_N = -r_N^* dK_N - (dK_N)^* r_N. \quad (43)$$

For $a = e^t$ the original dilation defect is the convergent finite-interval source integral

$$U_a^{\otimes k} r_N - r_N a^A = d \int_0^t U_{e^{t-v}}^{\otimes k} K_N e^{vA} dv. \quad (44)$$

Differentiation of $U_{e^{t-v}} r_N e^{vA}$ verifies the sign and both endpoints. All factors in e^{vA} on every nilpotent block remain as in (21).

The new tensor family uses (42) through the finite source deformation $D_{\mathbf{t}} = D^{(k)} + \sum_i t_i r_{\text{full}} \mathcal{R}_{h,i} j_{\text{full}}$ on the full packet presentation. Its finite observation is $A_k + \sum_i t_i \mathcal{R}_{h,i}$; its representative theta primitive is unchanged. For a cyclic restriction the additional term (37) remains in the full quotient. On changing packet or support, the current integration's exact identity is used:

$$D(h)\widehat{a}_i - \widehat{a}_j D(h) = \Delta_h a_i J_i + r_j(E(h)a_i - a_j E(h))J_i. \quad (45)$$

Thus neither equal finite jets nor a coefficient basis change is used to manufacture source naturality.

The arithmetic content of the relation norm is more explicit than positivity. From (33), let $s_l = 1/2 + it_l$ and put

$$Z_i(P; \mathbf{t}) = g(s_i) \prod_{l \neq i} v_h(s_l) Q_i(P; \mathbf{s}).$$

Then full Mellin–Plancherel gives

$$\|\mathcal{V}(\chi P)\|^2 = \frac{1}{(2\pi)^k} \sum_{i,j=1}^k \int_{\mathbb{R}^k} \overline{Z_i(P; \mathbf{t})} Z_j(P; \mathbf{t}) d\mathbf{t}. \quad (46)$$

For two different inputs use the corresponding polarized formula. The terms $i \neq j$ are retained. This formula uses the actual identities $h v_h = g$ and $j_h g = 0$. It does not replace g/h by a generic bounded function. All its integrals converge, since each displayed multiplier is the Mellin transform of its specified original theta-source function.

195 One common source for the signed arithmetic/Gamma correction

Use the original sum-frequency coordinate $S = k/2 + iy$ in the analytic calculation. The Gamma reference is the retained density

$$r_\lambda(t) = \frac{|\Gamma(\lambda + it/2)|^2}{2\pi}, \quad c_\lambda = 2^{1-2\lambda} \Gamma(2\lambda), \quad r_{\lambda,k} = r_\lambda^{*k} = \frac{c_\lambda^k}{c_{k\lambda}} r_{k\lambda}. \quad (47)$$

We use $\lambda = 1/4$ for the original reference, keeping $\int r_{1/4,k} = (2\pi)^{k/2}$. An explicit half-line reference vector is

$$F_\lambda^\Gamma(x) = 2x^{2\lambda-1/2} e^{-x^2}, \quad \mathcal{M}F_\lambda^\Gamma(1/2 + it) = \Gamma(\lambda + it/2), \quad \|F_\lambda^\Gamma\|_{L^2(dx)}^2 = c_\lambda. \quad (47a)$$

Substitution $y = x^2$ proves the Mellin identity and the norm, including their factors two. It is an auxiliary weighted L^2 reference, mapped to the same polynomial coefficient source; it is not declared an element of the original strong-Schwartz space. Its polynomial-dilation columns have the weighted $x^{\pm 2a}$ norms needed for holonomy comparison whenever $0 < a < 2\lambda$. The actual density is

$$w_h(t) = \frac{|v_h(1/2 + it)|^2}{2\pi}, \quad m(y) = w_h^{*k}(y), \quad r(y) = r_{1/4,k}(y). \quad (48)$$

No mass is set to one. The ratio $b(y) = m(y)/r(y)$ is the actual arithmetic multiplier. For $k = 1$ its isolated zeros are retained; for $k \geq 2$ its convolution is positive everywhere.

Let $c = k/2$ and use the common source $\mathcal{P}_{2q}$, $q = \deg \chi$. For $0 \leq x \leq 1$ set

$$d\mu_x(y) = ((1-x)r(y) + xm(y))du, \quad \dot{\mu}(y) = m(y) - r(y). \quad (49)$$

This is the Gram of the explicit map

$$P \mapsto (\sqrt{1-x} P(c + iu), \sqrt{x} \mathcal{V}P) \quad (50)$$

into the direct sum of the Gamma reference Hilbert space and the original arithmetic source Hilbert space. Their original norms are used. All finite source Grams $M_N(x)$ are positive definite, including the endpoints: a nonzero polynomial cannot vanish on a positive-measure part of either original measure.

Every quotient map $J_N : \mathcal{P}_N \rightarrow E$ and every relation inclusion $B_N = M_\chi : \mathcal{P}_{N-q} \rightarrow \mathcal{P}_N$ is unchanged as x varies. Define

$$G_N(x) = (J_N M_N(x)^{-1} J_N^*)^{-1}, \quad C_N(x) = M_N(x)^{-1} J_N^* G_N(x), \quad V_N(x) = \det G_N(x). \quad (51)$$

At $x = 0, 1$ these are precisely the reference and arithmetic canonical objects, not just matrices chosen to have their dimensions.

The underlying coefficient complex $[B_N \hookrightarrow \mathcal{P}_N]$ over $\mathfrak{b}_\tau$ is constant in (49). Its degree-one image is always the same supported E . The Hermitian forms in (50) are varying observations of that common source; they do not change the cochain relations.

196 An exact signed four-endpoint calculation

Let $v_N(y)$ be the row $(1, c + iu, \dots, (c + iu)^N)$. Define the source and original-relation projection densities

$$K_N(x, y) = v_N(y) M_N(x)^{-1} v_N(y)^*, \\ K_N^{\text{rel}}(x, y) = v_N(y) B_N (B_N^* M_N(x) B_N)^{-1} B_N^* v_N(y)^*, \quad (52)$$

with the second expression zero at $N = q - 1$. Their residual is

$$L_N(x, y) = K_N - K_N^{\text{rel}} = v_N C_N G_N^{-1} C_N^* v_N^* \geq 0. \quad (53)$$

The inverse identity in (53) follows by block inversion in the retained basis of quotient lifts followed by the relation columns. In that ordering the monic relation matrix has determinant one. Passing to the conventional relation-first determinant order would contribute $(-1)^{q(N-q+1)}$; its phase is not a change of metric.

Theorem 196.1 (Signed arithmetic correction on a common source). *Define*

$$F(x) = \log \frac{V_{q-1}(x) V_q(x)}{V_{2q-1}(x) V_{2q}(x)}, \quad \Delta_{h,k} = F(1) - F(0).$$

Then

$$\Delta_{h,k} = \int_0^1 \int_{\mathbb{R}} \dot{\mu}(y) (L_{q-1} + L_q - L_{2q-1} - L_{2q})(x, y) dy dx. \quad (54)$$

This is exactly

$$\mathcal{B}_{h,k}^{\text{ar}} - \mathcal{B}_{h,k}^{\Gamma} = \log \frac{T_{k,q-1} T_{k,q}}{T_{k,2q-1} T_{k,2q}}, \quad T_{k,N} = V_N(1)/V_N(0). \quad (55)$$

Proof. Differentiate $J_N C_N = I$ and $B_N^* M_N C_N = 0$. Since C'_N lies in the original kernel of J_N ,

$$C'_N = -B_N (B_N^* M_N B_N)^{-1} B_N^* \dot{M}_N C_N. \quad (56)$$

All derivatives are in the fixed original coordinates. Orthogonality eliminates both derivative-section cross terms in $G_N = C_N^* \dot{M}_N C_N$, so

$$G'_N = C_N^* \dot{M}_N C_N, \quad (\log V_N)' = \text{Tr}(G_N^{-1} C_N^* \dot{M}_N C_N) = \int \dot{\mu} L_N. \quad (57)$$

The four finite matrices are smooth on the compact interval and have positive minimum eigenvalues; their polynomial integrands have the moments supplied by (48). This justifies the finite differentiation and integrations. Add the four expressions with their displayed signs and integrate in x . $\square$

The derivative section (56) is not merely killed by the finite observation: it is explicitly in $\chi \mathcal{P}_{N-q}$. Equation (33) supplies its theta primitive. The lift sends this derivative relation to the receiving supported zero while retaining its original source norm.

196.1 The equal-rank cancellation is calculated before estimation

Let $K_n^\chi(x, y)$ denote the ordinary polynomial kernel of degree at most n for the measure $|\chi(c + iu)|^2 d\mu_x$. Set

$$\begin{aligned} \mathbf{R}_x(y) &= |\chi(c + iu)|^2 (K_{q-1}^\chi + K_q^\chi - K_0^\chi)(x, y), \\ \mathbf{P}_x(y) &= (K_{2q-1} - K_{q-1} + K_{2q} - K_q)(x, y). \end{aligned} \quad (58)$$

Both are nonnegative. Differences of consecutive polynomial-kernel projections are positive, so the first is the sum of the degree-0 through degree- $(q-1)$ relation kernel and the degree-1 through degree- q relation kernel. Their exact integrals are

$$\int \mathbf{R}_x d\mu_x = 2q, \quad \int \mathbf{P}_x d\mu_x = 2q. \quad (59)$$

Substitution in (53) proves, without estimating the terms independently,

$$L_{q-1} + L_q - L_{2q-1} - L_{2q} = \mathbf{R}_x - \mathbf{P}_x. \quad (60)$$

In particular every constant contrast cancels from the signed derivative. More explicitly, put $f_x = (m - r)/((1 - x)r + xm)$ where defined. The endpoint values at isolated zeros are read in the integrable products, not by an assumed bounded pointwise logarithmic derivative. Then

$$F'(x) = \frac{1}{2q} \iint (f_x(y) - f_x(v)) \mathbf{R}_x(y) \mathbf{P}_x(v) d\mu_x(y) d\mu_x(v). \quad (61)$$

The factor $1/(2q)$ follows from the two actual masses in (59); neither source measure is rescaled. Formulas (46), (54), and (58) calculate this signed term using the original g/h , its convolution, and the relation multiplication by g .

197 The retained quadratic term and a finite upper certificate

Set $H_N = B_N^* M_N B_N$. A second derivative of (57) gives the exact matrix equation

$$\boxed{G_N'' = -2C_N^* \dot{M}_N B_N H_N^{-1} B_N^* \dot{M}_N C_N.} \quad (62)$$

Thus

$$(\log V_N)'' = -\text{Tr}((G_N^{-1} G_N')^2) - 2\text{Tr}(G_N^{-1} C_N^* \dot{M}_N B_N H_N^{-1} B_N^* \dot{M}_N C_N). \quad (63)$$

Both terms are nonnegative before their minus signs. The second is the squared norm of the literal original relation correction (56). The signed four-endpoint sum contains all four occurrences with their original signs; separate concavity does not assert a sign for that sum.

There is a fully finite error bound for calculating (54), including all inverses. Work in the original top-source metric $M_{2q}(0)$. Let

$$\delta = \|M_{2q}(0)^{-1}(M_{2q}(1) - M_{2q}(0))\|_{M_{2q}(0)}, \quad a = \min\{1, \lambda_{\min}(M_{2q}(0)^{-1}M_{2q}(1))\} > 0. \quad (64)$$

The indicated endomorphism is positive self-adjoint for the stated metric; (64) does not choose a new metric. Every source and relation restriction inherits $M(x) \succeq aM(0)$ and relative derivative norm at most δ/a .

For a fixed full-column-rank inclusion U , its Gram $H(x) = U^* M(x) U$ is affine in x , and

$$\frac{d^3}{dx^3} \log \det H(x) = 2\text{Tr}((H(x)^{-1} H'(x))^3). \quad (65)$$

The four source ranks sum to $6q + 2$, and their four relation ranks sum to $2q + 2$. Therefore

$$|F'''(x)| \leq 2(8q + 4)(\delta/a)^3. \quad (66)$$

Composite midpoint quadrature applied to F' proves the explicit two-sided enclosure

$$\boxed{\left| \Delta_{h,k} - \frac{1}{m} \sum_{j=0}^{m-1} F'\left(\frac{j+1/2}{m}\right) \right| \leq \frac{8q+4}{12m^2} (\delta/a)^3.} \quad (67)$$

The proof of the midpoint constant is the second-order Taylor integral remainder on each interval of length $1/m$: its absolute integral is at most $\sup |F'''|/(24m^3)$, then sum the m intervals. Arithmetic moment enclosures must still be propagated into (64) and the sampled traces. Formula (67) is a finite analytic certificate, not a uniform asymptotic bound on its constants.

198 All inputs are the actual one-factor arithmetic moments

Define without rescaling

$$\mu_{h,n} = \frac{1}{2\pi} \int_{\mathbb{R}} t^n |g(1/2 + it)/h(1/2 + it)|^2 dt. \quad (68)$$

Every selected apparent singularity is filled by the entire quotient g/h , using the stipulated full multiplicity. Exponential Gamma decay and polynomial bounds for ζ give convergence of every finite moment. For the sum density,

$$\int y^n m_{h,k}(y) dy = \sum_{n_1 + \dots + n_k = n} \frac{n!}{\prod_i n_i!} \prod_i \mu_{h,n_i}. \quad (69)$$

The source entries in the retained S -basis are

$$(M_N^{\text{ar}})_{ab} = \sum_{r=0}^a \sum_{s=0}^b \binom{a}{r} \binom{b}{s} c^{a+b-r-s} (-i)^r i^s \int y^{r+s} m_{h,k}(y) dy. \quad (70)$$

Relation matrices are $B_N^* M_N^{\text{ar}} B_N$, with B_N the actual coefficient matrix of multiplication by χ . The four endpoints use the single moment list through degree $4q$. Equation (46) is the additional, arithmetic source identity behind those relation entries; their interpretation is not supplied by generic positivity.

The Gamma input has the exact Laplace transform

$$\int e^{\theta y} r_{1/4,k}(y) dy = (2\pi)^{k/2} (\cos \theta)^{-k/2}, \quad |\theta| < \pi/2. \quad (71)$$

Its derivatives supply the other entries in the same common matrix. Thus (54)–(67) are executable using one original arithmetic moment list, the same χ and unit, and exact Gamma moments.

198.1 A closed first-pair calculation with the original relation cancellation

Take $k = 1$ and an actual simple conjugate pair $1/2 \pm i\gamma$. Then

$$h(S) = (S - 1/2)^2 + \gamma^2, \quad |h(1/2 + it)|^2 w_h(t) = w_1(t) = |g(1/2 + it)|^2 / (2\pi). \quad (72)$$

Let $a_j = \mu_{h,2j}$, $0 \leq j \leq 4$, and $b_j = \mu_{1,2j}$, $0 \leq j \leq 2$. They satisfy the exact arithmetic identities

$$b_0 = \gamma^4 a_0 - 2\gamma^2 a_1 + a_2, \quad b_1 = \gamma^4 a_1 - 2\gamma^2 a_2 + a_3, \quad b_2 = \gamma^4 a_2 - 2\gamma^2 a_3 + a_4. \quad (73)$$

Put

$$E_3 = \det \begin{pmatrix} a_0 & a_1 & a_2 \\ a_1 & a_2 & a_3 \\ a_2 & a_3 & a_4 \end{pmatrix}.$$

Parity separates the source Hankel matrices into their even and odd blocks. Their Schur quotient by the original relation gives

$$\exp(\mathcal{B}_{h,1}^{\text{ar}}) = \frac{a_0 a_1^2 b_1^2 (b_0 b_2 - b_1^2)}{E_3 (a_1 a_3 - a_2^2)^2}. \quad (74)$$

For example the four individual volumes are

$$V_1 = a_0 a_1, \quad V_2 = \frac{a_1(a_0 a_2 - a_1^2)}{b_0}, \quad V_3 = \frac{(a_0 a_2 - a_1^2)(a_1 a_3 - a_2^2)}{b_0 b_1}, \quad (75)$$

$$V_4 = \frac{E_3(a_1 a_3 - a_2^2)}{b_1(b_0 b_2 - b_1^2)}.$$

Substitution proves (74), including every mass factor. The Gamma comparison uses the same h and (73), but the actual reference moment list is

$$(a_0^\Gamma, a_1^\Gamma, a_2^\Gamma, a_3^\Gamma, a_4^\Gamma) = \sqrt{2\pi} \left(1, \frac{1}{2}, \frac{7}{4}, \frac{139}{8}, \frac{5473}{16} \right). \quad (76)$$

The difference of the logarithms of (74) for these two inputs is the original signed four-endpoint correction. The supplied numerical script evaluates (68) for an approximation to the first actual pair, keeping the removable value and the unmodified 2ξ . It is a numerical evaluation, not an interval proof of the root, its simplicity, the infinite tail, or the final sign. A number is not promoted from an unfinished earlier run into a proved result.

199 Holonomy recovery and the exact original metric correction

The retained all-holonomy transform is

$$(\mathcal{Z}_{L,\theta}\psi)(r) = \sum_{a \in \mathbb{Z}} e^{ia\theta} \psi(r + aL), \quad \widehat{\mathcal{Z}_{L,\theta}\psi}(n) = L^{-1/2} \widehat{\psi}((2\pi n + \theta)/L). \quad (77)$$

It uses the original half-density map and all relative variables. Fourier inversion in a gives an exact unitary direct integral, hence the original source mean $\int M_\theta d\theta/(2\pi) = M$. The zero mode is retained.

For the same finite J and relation columns B , the existing sections obey

$$C - C_\theta = BX_\theta, \quad G = \overline{G} + \int X_\theta^* B^* M_\theta B X_\theta \frac{d\theta}{2\pi}. \quad (78)$$

Thus no interchange of quotient minimization with phase averaging is made in (54). At each interpolation value x , the same formula applies to the direct-sum source (50). Its discrepancy is again an explicit original relation. If the already calculated source-relative holonomy errors are at most $\eta < 1$, the established quadratic comparison gives $(1 - \eta^2)G_N(x) \preceq \overline{G}_N(x) \preceq G_N(x)$. Applying determinant bounds at both endpoints of (54) supplies a total signed-correction error at most

$$4q \log \frac{1}{1 - \eta^2}. \quad (79)$$

This is a proved finite transport allowance once the original weighted-source constants and sampling errors have been evaluated. It is not the missing asymptotic estimate. Completing a fixed-phase Hilbert quotient first remains a further map with kernel $(p_{L,\theta})/(\chi)$; that operation is not used here.

200 What is newly established and what remains

The marked-base and scalar inputs are retained, and the new constructions are (27)–(41), the original-source relation norm (46), the signed common-source formula (54)–(61), its complete differentiated relation cost (62)–(63), the finite enclosure (67), and the arithmetic first-pair formula (72)–(76). They use actual packets rather than arbitrary polynomials as arithmetic data. The Gamma model remains a specified norm comparison of the same coefficient source.

Deligne’s theorem now applies to a concrete external family with degree, rank, and finite-field weight matched to the original tensor packet. Its special-fibre arrow and the cyclic transverse correction are calculated. This is an additional geometric construction over the original τ -base, not a deduction of arithmetic purity from the word “absolute” or from auxiliary finite-field purity.

The retained audit shows that auxiliary purity alone is insufficient; it does not establish failure of the marked programme. The original endpoint identity is still

$$\mathcal{B}_{h,k}^{\text{ar}} = \mathcal{B}_{h,k}^\Gamma + \Delta_{h,k}. \quad (80)$$

The signed term is now a single explicit arithmetic source/relation integral and admits finite error control. What remains unproved is a uniform upper estimate on (80) below the inherited off-line quartet threshold $4q_k \log k$ along the required growing packet/tensor family, or an independently proved faithful action-and-metric transfer producing that estimate. Neither a numerical first-pair calculation nor the finite-field weight- k statement is represented as that result.

Source and execution scope

The owner’s uploaded `arithmetic_input.tex`, `coherent_tensor_integration.tex`, `toda_cv_exact_bridge.tex`, SGA trace/period note, marked-base recovery, holonomy note, and

dated Deligne primary-source correction supply the specified inherited inputs. The repo's `tau-split-integration/RESEARCH_NOTE.md` supplies the current source/coefficient-defect distinction. The current work preserves those meanings and does not claim a new Lean or full-primary-source audit.

Deligne, *La conjecture de Weil II*, Publ. Math. IHES 52 (1980), especially 3.3.6 and 3.7.2–3.7.4, supplies the cited finite-field statements at their actual hypotheses. Standard finite-dimensional Schur complements, determinant differentiation, tensor-complex signs, and polynomial moment facts are proved here at the displayed map types; no general novelty claim is made for them.

The package's symbolic checks are finite regression tests. Numerical quadrature is separately labelled and is not an interval certificate. The execution record, rather than this prose, reports which supplied scripts actually ran.

Part III

Complete source, dual and transcript calculations

201 Verified typed maps in the original τ -base construction

This is an independent source-map verification for the transcript continuation audit. It reads the entire primary note and the entire canonical source route. It does not claim to audit the whole shared transcript or the analytic arithmetic estimates. It does not duplicate the homotopy-fibre/right-adjoint continuation assigned elsewhere.

201.1 Source pins and exact scope

1. output/split_zero_rh_tandem_2026-09-12/sources/Tau_Base_Cohomology_2026-09-12/NOTE.md, 25,512 bytes, SHA-256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3. All 611 lines read. Equation locators below refer to this body.
2. work/f1_geometry_current_source_route_20260913.md, SHA-256 a8cdd18817a2c3596778c60a04ef9d76125a03ae5404759835a2bc2b18fa4c74. Entire body read. Its dependencies were not thereby deemed independently reread.
3. output/split_zero_rh_tandem_2026-09-12/tex/support_diagrams.tex, SHA-256 7586ac17247456a55bdacfcf8b46c196c29eafd3b57846a71792e918704e069b. Entire body read to check the kernel types and support-index transport. Its labels D1–D8 are used below.

The primary note explicitly works in the algebraic category

$$\mathcal{A} = \text{Fun}(P, \text{Vect}_E), \quad E = \mathbb{C}, \quad + < \eta < \sigma, \quad - < \eta < \sigma.$$

The topology is the upper-set topology; diagrams are covariant. The calculations below keep that category, its arrows, and its cohomological degrees. The source does not replace the Schwartz topology by a theorem about its continuous dual: it calculates an algebraic right adjoint, and says so.

201.2 1. The structural map does not perform Boolean localization

Primary equations (2)–(3), lines 33–45, use the blueprint map

$$j_R : \mathbf{F}_{1,\tau} = \{\tau, 1\} \longrightarrow B_R, \quad j_R(\tau) = \tau, \quad j_R(1) = 1_R^\bullet.$$

The only additional additive relation imposed by the source blueprint is that its empty sum represents τ . The target retains that relation, its own addition relations, and its original multiplicative monoid, so the displayed map preserves all source relations. Every proper prime contains τ and excludes the unit. Its inverse image is consequently exactly $\{\tau\}$. This proves the structural map to the one-point base.

Primary equations (6)–(7), lines 64–80, concern a separate map $\chi_R : G(R) \rightarrow \mathbb{B}$, with $\chi_R(\tau) = 0$, $\chi_R(r^\bullet) = 1$, and localization at $e = 0_R^\bullet$. Inverting the idempotent e gives $e=1$; then $er^\bullet = e$ gives $r^\bullet = 1$. No cancellation with τ occurs. The source already proves this localization, and does not use it as the definition of the structural base pushforward.

The canonical route supplies the exact comparison for every $G(R)$ -semimodule M :

$$\Phi : \mathbb{B} \otimes_{G(R)} M \longrightarrow eM, \quad b \otimes m \longmapsto b \cdot em.$$

Here eM is a Boolean semimodule under its original addition. For a supported scalar a , $ea = e$, so both sides of the balancing relation map to $b \cdot em$; for $a=\tau$ both map to the global zero. Additivity in m follows from distributivity of e . Additivity in b uses $em + em = em$. Its inverse is

$$\Psi : eM \longrightarrow \mathbb{B} \otimes_{G(R)} M, \quad l \longmapsto 1 \otimes l.$$

Indeed $\Phi\Psi(l) = el = l$, and $\Psi\Phi(1 \otimes m) = 1 \otimes em = \chi_R(e) \otimes m = 1 \otimes m$; tensors with Boolean coefficient 0 vanish. Both formulas commute with every split-linear map. The comparison is therefore a natural isomorphism, not a claimed lack of relation between the two constructions.

201.3 2. The global pushforward and its canonical derived restriction

Primary equations (17)–(20), lines 200–242, are correct with their displayed domains and signs.

For x in P , $P_x(y) = E$ when $x \leq y$, and 0 otherwise, with identity maps on nonzero arrows. A natural transformation $P_x \rightarrow F$ is determined by the image v of 1 at x ; at y above x its value must be $r_{xy}v$. Conversely those values are natural. Thus

$$\mathrm{Hom}_{\mathcal{A}}(P_x, F) = F_x.$$

Evaluation is exact because kernels and cokernels in the diagram category are computed at each point. This proves projectivity of P_x .

The source resolution is

$$0 \longrightarrow P_\eta \xrightarrow{\delta} P_+ \oplus P_- \xrightarrow{\varepsilon} \mathbf{E} \longrightarrow 0, \quad \delta(v) = (v, -v), \quad \varepsilon(u, v) = u + v.$$

At $+$ its sequence is $0 \rightarrow 0 \rightarrow E \xrightarrow{1} E \rightarrow 0$, and at $-$ it is the same sequence in the second summand. At η and σ its sequence is $0 \rightarrow E \rightarrow E^2 \rightarrow E \rightarrow 0$, with kernel of addition exactly $\{(v, -v) : v \in E\}$. Restriction maps commute with both displayed maps because each nonzero component is an identity. This checks exactness and naturality on every point and arrow.

Compatible global sections of F are determined by $(u, v) \in F_+ \oplus F_-$ with $r_+u = r_-v$. Their η -value is this common vector and their σ -value is its image under $r_{\eta\sigma}$. Hence $\Gamma(P, F) = \mathrm{Hom}(\mathbf{E}, F)$, and the resolution computes

$$A_\tau(F) = R\Gamma(P, F) \simeq C_F, \quad C_F^0 = F_+ \oplus F_-, \quad C_F^1 = F_\eta, \quad d_F(u, v) = r_+u - r_-v.$$

The convention is the displayed resolution coboundary by precomposition. The degrees and the differential are those of the source, not an identification with F_σ .

Put $r = r_{\eta\sigma}$. The two maps $c_+, c_- : C_F \rightarrow F_\sigma[0]$ have degree-zero parts

$$c_+^0(u, v) = rr_+u, \quad c_-^0(u, v) = rr_-v,$$

and degree-one parts 0. They are chain maps because the target has no term in degree 1. With degree -1 homotopy h defined by $h^1 = r : F_\eta \rightarrow F_\sigma$,

$$(c_+ - c_-)^0 = h^1 d_F, \quad (c_+ - c_-)^1 = 0 = d_{F_\sigma} h^1.$$

They therefore give a single canonical derived morphism $\mathrm{res}_\sigma : A_\tau(F) \rightarrow F_\sigma[0]$. Its action on a global compatible section is its actual σ -value. This proves the comparison, including its sign, without substituting the target for the source.

201.4 3. The actual arithmetic cohomology and its three support fibres

Primary equations (10)–(15), (21)–(25), retain

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi \text{ even}, \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx,$$

$$\mathcal{B} = \left\{ F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^k F(x)| < \infty \text{ for all } b \in \mathbb{Z}, k \geq 0 \right\},$$

$$\Theta\phi(x) = \sum_{n \neq 0} \phi(nx), \quad JF(x) = x^{-1}F(1/x), \quad J\Theta = \Theta\mathcal{F}.$$

Its joint diagram is $(V, V, \mathcal{B}, 0)$, with differential

$$d(\phi, \psi) = \Theta\phi - J\Theta\psi = \Theta(\phi - \widehat{\psi}).$$

Consequently its image is exactly ΘV : one inclusion follows from Fourier invariance of V , and the reverse inclusion follows by using $(\phi, 0)$. Fourier invariance follows from evenness and $\mathcal{F}^2\phi(x) = \phi(-x)$, which exchanges the two vanishing moments and gives $\mathcal{F}^2 = 1$ on V . Using the source's established injectivity of Θ gives

$$\ker d = \{(\widehat{\psi}, \psi) : \psi \in V\}, \quad H^1 C_{\mathcal{T}} = Q = \mathcal{B}/\Theta V.$$

This verifier does not replace the source's Mellin/Poisson proof of injectivity by an independent analytic claim. The algebraic identification just made uses that named source result at its exact place.

For the $+$ singleton mask the differential is Θ . For the $-$ singleton mask it is $-J\Theta = -\Theta\mathcal{F}$. Each is injective, and each has image ΘV , so its H^0 is 0 and its H^1 is Q . The inclusions from either singleton to the joint mask are coordinate inclusions in degree 0 and identity in degree 1; they are chain maps since the joint differential restricts to the indicated signed singleton differential. Their induced H^1 maps are the identity of Q . The empty support diagram is zero.

Thus the entire H^1 support diagram has zero bottom fibre and Q at all three nonempty masks, with identity transitions among nonempty comparable masks. Its reconstruction is exactly

$$M = \widetilde{H}_{\mathcal{T}}^1 = \{\tau\} \sqcup \coprod_{\emptyset \neq A \subseteq \{+, -\}} \{A\} \times Q.$$

The linear map induced by res_{σ} on H^1 is $Q \rightarrow H^1(0[0]) = 0$ at each nonempty mask. Reconstructing that same-mask diagram map gives

$$\epsilon_M : M \longrightarrow eM, \quad \tau \longmapsto \tau, \quad (A, q) \longmapsto (A, 0).$$

This is the precise typed reading of the source's statement immediately after (25), at lines 283–288. It is not a degree-one map to the unshifted linear stalk treated as if that stalk had nonzero H^1 . The supported skeleton is obtained by the explicit support reconstruction. Its fibres are

$$\epsilon_M^{-1}(\tau) = \{\tau\}, \quad \epsilon_M^{-1}(A, 0) = \{A\} \times Q \quad (A \neq \emptyset).$$

Every arithmetic amplitude remains in its recorded fibre. The projection and its section $(A, 0) \mapsto (A, 0)$ prove the relation to the boundary skeleton exactly.

201.5 4. The right adjoint is computed algebraically on that same chart

Primary equations (26)–(30), lines 294–347, give the correct right-adjoint object.

Define $I_x(W)(y) = W$ if $y \leq x$ and 0 otherwise. A map $F \rightarrow I_x(W)$ is uniquely determined by $\ell : F_x \rightarrow W$: its y -component for $y \leq x$ is ℓr_{yx} , and its other components are 0. These components are natural on every arrow. Therefore

$$\mathrm{Hom}_{\mathcal{A}}(F, I_x(W)) = \mathrm{Hom}_E(F_x, W).$$

Every vector space is injective: a linear map defined on a subspace extends after extending a basis of that subspace to a basis of the whole space. Evaluation at x is exact, so $I_x(W)$ is injective in $\mathcal{A}$.

The source complex is

$$K_\tau(W)^{-1} = I_\eta(W), \quad K_\tau(W)^0 = I_+(W) \oplus I_-(W), \quad d_K = (+\mathrm{res}, -\mathrm{res}).$$

A bounded complex of injectives calculates the derived Hom from a sheaf here. Evaluation of its Hom complex gives

$$R\mathrm{Hom}_{\mathcal{A}}(F, K_\tau(W)) = \left[\mathrm{Hom}_E(F_\eta, W) \xrightarrow{\ell \mapsto (\ell r_+, -\ell r_-)} \mathrm{Hom}_E(F_+, W) \oplus \mathrm{Hom}_E(F_-, W) \right],$$

in degrees -1 and 0 . The ordinary Hom complex from C_F to $W[0]$ has exactly these terms. For a degree -1 map ℓ its differential is $-(-1)^{-1} \ell d_F = \ell d_F$, giving exactly the displayed pair. This proves the chain isomorphism in (28), naturally in F and W , and hence the stated adjunction.

For bounded coefficient complexes the same result follows by taking the finite total complexes, preserving the original differential of W . An explicit convention is

$$K_\tau(W)^n = I_\eta(W^{n+1}) \oplus I_+(W^n) \oplus I_-(W^n), \quad d(s, u, v) = (-d_W s, \mathrm{res}_+ s + d_W u, -\mathrm{res}_- s + d_W v).$$

Its square is zero: the first component is $d_W^2 s$, and each other component cancels its two restriction-of- $d_W s$ terms, leaving $d_W^2 u$ or $d_W^2 v$. This is the signed totalization of the displayed two-term adjoint.

At $+$, $-$, η , σ , respectively, the W -vector-space stalk complexes are

$$[W \xrightarrow{1} W], \quad [W \xrightarrow{-1} W], \quad W[1], \quad 0.$$

The inclusion $S_\eta W[1] \rightarrow K_\tau(W)$, identity at η and zero at the other points, is natural: at each arrow entering η its source is zero; at arrows leaving η its target is zero; all other squares have a zero entry on the source side. It induces an isomorphism in cohomology at every stalk, since the $\pm$ complexes have invertible differentials. Hence

$$K_\tau(W) \simeq S_\eta W[1]$$

by an explicit quasi-isomorphism. In particular $K_\tau(W)_\sigma = 0$ does not imply that the right adjoint is zero, nor that its Hom from the arithmetic sheaf is zero. Its degree -1 Hom cohomology is

$$\{\ell : \mathcal{B} \rightarrow W : \ell \Theta V = 0\} \cong \mathrm{Hom}_E(Q, W).$$

The inverse correspondence sends a quotient functional $\lambda : Q \rightarrow W$ to $\lambda \circ q$; the forward correspondence sends ℓ to $[F] \mapsto \ell(F)$. Equality of values on representatives is exactly $\ell \Theta V = 0$.

This verifies the target of the full finite-jet/residue morphism (43), whose source has been retained as $\overline{A_Z}$ and whose codomain is $H^{-1} R\mathrm{Hom}_{\mathcal{A}}(\mathcal{T}, K_\tau(\mathcal{L}_1))$. The source's surjective $J_Z : Q \rightarrow A_Z$ and perfect finite residue pairing are the specified reasons its precomposition map is injective. Neither a continuous-dual identification nor involutive Verdier duality is supplied by this algebraic adjunction.

201.6 5. Exact categorical and all-support kernels

Use D1–D8 with $M = \mathcal{T}(L, V)$, $N = \mathcal{T}(L', W)$, and a split-linear map

$$F = \mathcal{T}(\alpha, f), \quad F(l, x) = (\alpha(l), f_l x).$$

The target's global zero is $(\perp', 0)$, while its support skeleton consists of all $(k, 0)$. Consequently

$$F(l, x) = 0_N \iff \alpha(l) = \perp' \text{ and } f_l x = 0,$$

$$F(l, x) \in eN \iff f_l x = 0.$$

Writing $L_0 = \alpha^{-1}(\perp')$, these equalities give

$$\ker_{G(R)} F = \mathcal{T}(L_0, (\ker f_l)_{l \in L_0}),$$

$$F^{-1}(eN) = \mathcal{T}(L, (\ker f_l)_{l \in L}) = M \times_N eN.$$

The original transition maps restrict to these kernels: naturality gives $f_k \rho_{lk} x = \rho'_{\alpha(l), \alpha(k)} f_l x = 0$. Also L_0 is closed under joins because α preserves joins. Therefore both displayed carriers are sub-semimodules. Any map with the corresponding vanishing property has its image in the indicated carrier and hence factors uniquely through the inclusion. This proves the two universal properties, not just set identities. Their exact comparison is the inclusion induced by $L_0 \hookrightarrow L$.

For ϵ_M above, α is the identity and every fibre map is the zero map $Q \rightarrow 0$. Its bottom fibre is zero. Thus

$$\ker_{G(E)} \epsilon_M = \{\tau\}, \quad M \times_{eM} eM = M.$$

A trivial categorical kernel here cannot establish disappearance of supported arithmetic cohomology: the second displayed object is the entire original arithmetic carrier. The formula states the scope of the trivial-kernel result exactly.

The quotient q at a fixed nonempty mask has source $\mathcal{B}$, boundary subspace ΘV , and target Q . Its supported form sends (A, F) to $(A, [F])$. In the all-support sense its kernel fibre is ΘV , while every boundary maps to $(A, 0)$, never τ . This follows from $[F] = 0 \iff F \in \Theta V$. More generally, a cochain map has

$$\ker H(f) = \{z \in \ker d_C : fz \in \text{im } d_D\} / \text{im } d_C.$$

The map sends the class of z to its cohomology class. It is well-defined because boundaries map to boundaries, onto because every cohomology class has a cycle representative, and injective because the zero class is precisely a boundary. This is D7, and reconstructing it at every label gives the all-support object in D8.

201.7 6. Dual support arrows: the exact reversal and its limit

Primary equation (31), lines 349–356, retains the correct map for every inclusion $A \subseteq B$:

$$\rho_{AB}^\vee : \text{Hom}_E(H_B, W) \longrightarrow \text{Hom}_E(H_A, W), \quad \ell \longmapsto \ell \rho_{AB}.$$

For $A \subseteq B \subseteq C$, $\rho_{AB}^\vee(\rho_{BC}^\vee \ell) = \ell \rho_{BC} \rho_{AB} = \ell \rho_{AC}$, proving functoriality on L^{op} . The identity arrow acts as the identity. Thus the exact dual-index diagram exists.

It is not a covariant diagram on the original inclusion-ordered L with the same arrow directions. The source does not assert that it is. A further reconstruction into split semimodules must declare its index semilattice. For the finite Boolean lattice in this source, L^{op} itself has join given by intersection and bottom $\{+, -\}$. Applying D1–D5 to this opposite lattice is valid and keeps the dual arrows, but its bottom fibre is then $\text{Hom}_E(H_{\{+, -\}}, W)$, not the original empty-mask fibre. In degree 1 this is $\text{Hom}_E(Q, W)$. D1–D5 explicitly allow such nonzero bottom fibres. Thus an argument that applies a theorem requiring a singleton bottom fibre to this reconstructed dual has changed a hypothesis and must calculate the actual bottom fibre. The original dual map (43), formed label by label with precomposition, does not require that unsupported identification.

201.8 7. A completed exact jet map that makes the eigenline wording precise

Primary (40), (44)–(45), and (49) retain full nilpotent jets. The phrase “residue-value eigenvector” in (49) is read through the following exact maps, so it does not discard the nilpotents of (40).

At an actual zero ρ of multiplicity m , keep the original coordinate $z = s - \rho$ and factor

$$g(\rho + z) = u(z)z^m, \quad u(0) \neq 0.$$

Then $A_\rho = \mathcal{O}_\rho/(g) = \mathcal{O}_\rho/(z^m)$, with the identity on germs giving the latter equality of ideals because u is a unit. Its reduction map is

$$q_\rho : A_\rho \longrightarrow E, \quad [h] \longmapsto h(\rho).$$

The endomorphism J_g of (44) factors as an actual quotient followed by an injection:

$$A_\rho \xrightarrow{q_\rho} E \xrightarrow{t_\rho} A_\rho, \quad t_\rho(c) = c[g'], \quad J_g = t_\rho q_\rho.$$

Indeed

$$g' = u'(z)z^m + mu(z)z^{m-1} \equiv mu(0)z^{m-1} \pmod{z^m}.$$

Writing $h = h(0) + z\tilde{h}$, multiplication by $[g']$ kills the second summand, so $[g'h] = h(0)[g']$, proving factorization. Since $mu(0) \neq 0$, $[g'] \neq 0$; therefore t_ρ is injective. Its image is exactly

$$\text{Ann}_{A_\rho}(z) = Ez^{m-1}.$$

To verify this equality, multiply $\sum_{j=0}^{m-1} c_j z^j$ by z . The product is zero modulo z^m exactly when $c_0 = \dots = c_{m-2} = 0$. This includes $m=1$, when the annihilator is all of $A_\rho = E$. Consequently

$$\ker J_g = \ker q_\rho = zA_\rho, \quad \text{im } J_g = \text{Ann}_{A_\rho}(z).$$

The actual scaling operator remains

$$U_a = a^\rho \sum_{j=0}^{m-1} \frac{(\log a)^j}{j!} N^j, \quad N[z^j] = [z^{j+1}], \quad a > 0.$$

Reduction gives $q_\rho U_a = a^\rho q_\rho$, since every $j>0$ term has zero constant coefficient. Multiplication of $t_\rho(c)$, which lies in Ez^{m-1} , by a $j>0$ term is zero, so $U_a t_\rho(c) = t_\rho(a^\rho c)$. Both maps are equivariant. Thus the residue-value representation and its socle image inside the full jet are linked by the explicit nonzero map t_ρ . When $m > 1$, the constant lift 1 of a residue value is not generally an eigenvector of U_a for $a \neq 1$, because its z coefficient is $a^\rho \log a \neq 0$. The socle image $t_\rho(1)$ is an actual eigenvector. No full jet was replaced by its reduction in proving that fact.

The tensor of r copies of this explicit eigenvector is nonzero in $A_\rho^{\otimes Er}$: the coefficient of $(z^{m-1})^{\otimes r}$ is $(mu(0))^r \neq 0$. Its action on that finite tensor quotient is exactly $a^{r\rho}$. Its precise relation to primary (47) is the equivariant surjection

$$Q^{\otimes Er} \xrightarrow{(\text{pr}_\rho J_Z)^{\otimes r}} A_\rho^{\otimes Er}.$$

Here Z contains ρ , $J_Z : Q \rightarrow A_Z$ is the source’s full jet quotient, and pr_ρ is its block projection. Each map is equivariant by the full jet scaling formula (40). The first is surjective by the source’s jet-surjectivity result, the block projection is surjective, and their tensor is surjective because each simple target tensor has a tensor of preimages and such tensors span the target. This proves the exact relation to $Q^{\otimes r}$.

The quotient-and-socle argument of this subsection, taken alone, does not establish an equivariant lift to Q . The original arithmetic section supplies that additional map: Subsection 201.10 below retains its full Taylor unit and proves its scaling equivariance, giving the actual eigenline inside Q

and its tensor inside $Q^{\otimes r}$. Thus this is a completed source lift, with the quotient-only argument and the additional original section both specified. On the finite quotient the tensor modulus expression is

$$\log \frac{|a^{r\rho}|^2}{a^r} = r(2 \operatorname{Re} \rho - 1) \log a \quad (a > 1),$$

with its original action and coefficient line. This is an identity on the actual eigenline embedded in $A_\rho^{\otimes r}$, which is a quotient of the tensor cohomology in (47); it proves no upper bound on that identity. At every nonempty supported mask, q_ρ , t_ρ , and J_g lift by retaining the mask, so a killed nilpotent maps to the supported zero of its mask.

201.9 Audit uses

The source already contains the structural base, global pushforward, derived restriction, right adjoint, full supported Q , dual-index arrows, and the finite-jet morphism into that right adjoint. A passage that calls any of these missing must be tested against the equation locators above. The algebraic calculation does not supply analytic bounds; that limitation has the exact scope stated in the primary note. A boundary-stalk vanishing or a trivial categorical kernel does not reach the original supported Q , because the explicit maps above retain the whole Q fibre. A duality argument must retain the dual arrow direction, its coefficient line, and its actual algebraic category. A tensor argument can use the exact socle embedding into the finite tensor quotient above while retaining every nilpotent in that ambient jet object; it must retain the displayed quotient map from the full tensor cohomology. Subsection 201.10 constructs the source eigenvector using the original arithmetic section and its proved finite scaling cocycle, rather than inferring it from the quotient alone.

201.10 8. The original arithmetic section completes the source eigenline lift

The section used here is already constructed in the retained arithmetic source, equations (A7)–(A11) of output/split_zero_rh_tandem_2026-09-12/tex/arithmetic_input.tex, SHA-256 a50b0fb587b644c4ea94dba45b2b423d038f2bfbef7fef188543939ba850e58d2. The group-level source integral is proved in Sections 2–3, equations (9)–(19), of output/tau_f1_transcript_audit_2026-09-13/proofs/theta_scaling_cocycle.md, SHA-256 5aae80114cbf3cb0c3bec25e4e655b37117a932c1a92132161c162393b7ea377. We retain their maps and give the source-lift proof explicitly. The earlier quotient calculation did not prove this additional map, but the map is present in the original construction and is completed here at the full scaling-group level.

The original packet and its unit. Let Z be a nonempty finite set of actual nontrivial zeros of the original $g = 2\xi$, with each complete multiplicity m_ρ , and set

$$h(X) = \prod_{\rho \in Z} (X - \rho)^{m_\rho}, \quad d = \deg h, \quad E_h = \mathbb{C}[X]/(h), \quad A = M_X.$$

The letter X here is the original polynomial variable denoted t in (A10)–(A11); the notation E_h distinguishes that source's finite packet E from the ground field $E = \mathbb{C}$ used earlier in this verification. The complex Mellin coordinate remains s . At each selected zero, the quotient

$$v(s) = g(s)/h(s), \quad \varepsilon = j_h(h/g) \in E_h$$

is holomorphic and nonzero. Indeed, in the original coordinate $z = s - \rho$, both g and h have order exactly m_ρ , so their quotient has a nonzero constant coefficient. A truncated power series with nonzero constant coefficient is invertible by recursively solving for its inverse coefficients. The Chinese-remainder decomposition therefore makes ε a unit, with $j_h(v)\varepsilon = 1$. No coefficient of this unit is replaced by 1. For $u \in E_h$, let $R_Z(u)$ be the unique polynomial of degree less than d representing εu . Polynomial division by the monic h proves this existence and uniqueness.

The retained source is

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad \mathcal{M}\Theta(P(D)\phi_*) = gP.$$

Its moments and this Mellin identity are the proved original (A3), with the same Fourier convention and both factors of two retained. Write

$$D = -x\partial_x, \quad p_{b,k}(F) = \sup_{x>0} x^b |D^k F(x)|, \quad b \in \mathbb{Z}, \quad k \geq 0.$$

These are the defining seminorms of the original $\mathcal{B}$. The operator inverse is the actual inverse

$$S_h^{\mathcal{B}} : \ker(j_h \mathcal{M}) \longrightarrow \mathcal{B} \quad \text{of} \quad h(D) : \mathcal{B} \longrightarrow \ker(j_h \mathcal{M}).$$

Equations (A5)–(A7), or equation (9) in the finite-cocycle chapter, prove its range, injectivity, and continuity. The explicit one-factor inverse used in that proof is

$$S_\rho F(x) = x^{-\rho} \int_x^\infty F(y) y^{\rho-1} dy, \quad \mathcal{M}F(\rho) = 0.$$

It satisfies $(D-\rho)S_\rho F = F$. The zero moment writes its upper integral as the negative lower integral; these two expressions give, respectively, all decay bounds at infinity and zero. More explicitly, for $N > \operatorname{Re} \rho$ and $N + \operatorname{Re} \rho > 0$,

$$|S_\rho F(x)| \leq \frac{p_{N,0}(F)}{N - \operatorname{Re} \rho} x^{-N}, \quad |S_\rho F(x)| \leq \frac{p_{-N,0}(F)}{N + \operatorname{Re} \rho} x^N.$$

Using the first bound for $x \geq 1$, the second for $x \leq 1$, and $DS_\rho F = \rho S_\rho F + F$ proves every defining derivative seminorm bound. The homogeneous solution $cx^{-\rho}$ belongs to $\mathcal{B}$ only when $c = 0$. Integration by parts gives $\mathcal{M}S_\rho F(s) = \mathcal{M}F(s)/(s - \rho)$, with the removable value filled in. Iteration removes one of the prescribed zero factors at each step and preserves every other vanishing order. This proves the stated inverse on the complete jet kernel and injectivity of $h(D)$, without assuming an unproved operator range.

Define the original section exactly as in (A10):

$$R_{\text{ref}} u = S_h^{\mathcal{B}} \Theta(R_Z(u)(D)\phi_*), \quad J_Z F = j_h \mathcal{M}F, \quad q : \mathcal{B} \longrightarrow Q = \mathcal{B}/\Theta V, \quad \sigma = qR_{\text{ref}}.$$

The input to $S_h^{\mathcal{B}}$ has Mellin transform $gR_Z(u)$, which has all required zero jets, so this definition has the stated domain for every u . The inverse formula gives

$$\mathcal{M}R_{\text{ref}} u = vR_Z(u), \quad J_Z R_{\text{ref}} u = j_h(v)\varepsilon u = u.$$

For $\phi \in V$, the original Mellin identity $\mathcal{M}\Theta\phi = gH_\phi$, with H_ϕ holomorphic at the selected zeros, gives $J_Z\Theta\phi = 0$. Thus J_Z factors as $\overline{J}_Z q$, and

$$\overline{J}_Z \sigma = 1_{E_h}, \quad h(D)\sigma(u) = q\Theta(R_Z(u)(D)\phi_*) = 0.$$

The displayed left inverse proves that $\sigma : E_h \hookrightarrow Q[h(D)]$ is injective. This is an actual section inside the arithmetic cohomology, not a section inferred from finite-dimensional quotient data alone.

All positive dilations act equivariantly after the original boundary. Set $\ell(u) = [X^{d-1}]R_Z(u)$. Since multiplication by X commutes with the unit ε , the polynomial $XR_Z(u) - R_Z(Au)$ is divisible by h . Its degree is at most d ; its leading coefficient is $\ell(u)$. Hence the exact polynomial identity is

$$XR_Z(u) - R_Z(Au) = h(X)\ell(u).$$

Applying the defining inverse, or multiplying by the injective $h(D)$, gives the original boundary coefficient (A11):

$$DR_{\text{ref}} - R_{\text{ref}}A = \Theta\phi_*\ell.$$

For a single simple zero this coefficient is $\ell(u) = u/g'(\rho) = u/(2\xi'(\rho))$; its arithmetic unit and factor of two remain present.

For $a > 0$ let $\lambda = \log a$, $T_r = e^{rA}$, and retain $U_a F(x) = F(x/a)$. Define

$$c_a(u) = \int_0^\lambda U_{e^{\lambda-r}} \phi_* \ell(T_r u) dr \in V.$$

When $\lambda < 0$ this is the oriented integral $\int_0^\lambda = -\int_\lambda^0$. No orientation changes are hidden. Fix any norm on the finite-dimensional E_h , only for this convergence estimate, with the induced operator norms for A and ℓ . For the original Schwartz seminorms $q_{N,k}(\phi) = \sup_x (1 + |x|)^N |\partial_x^k \phi(x)|$,

$$q_{N,k}(U_b \phi) \leq b^{-k} \max(1, b)^N q_{N,k}(\phi).$$

On the interval between 0 and λ , this inequality and $\|T_r\| \leq e^{|r|\|A\|}$ give

$$q_{N,k}(c_a(u)) \leq |\lambda| e^{(N+k+\|A\|)|\lambda|} q_{N,k}(\phi_*) \|\ell\| \|u\|.$$

The integrand is continuous in every seminorm. Its Riemann sums converge in the complete closed Schwartz subspace V : uniform continuity on the compact parameter interval makes them Cauchy in each seminorm, and their limits retain evenness and both zero moments. Differentiating dilation is legitimate in every seminorm, as the difference quotient's integral remainder is bounded by finitely many seminorms of $D^2\phi$ on that compact interval. The same argument applies in $\mathcal{B}$, using $p_{b,k}(U_a F) = a^b p_{b,k}(F)$. Consequently

$$\frac{d}{dr}(U_{e^{\lambda-r}} R_{\text{ref}} T_r u) = -U_{e^{\lambda-r}} (DR_{\text{ref}} - R_{\text{ref}}A) T_r u = -\Theta U_{e^{\lambda-r}} \phi_* \ell(T_r u).$$

Integrating in the actual $\mathcal{B}$ seminorms and using continuity of Θ proves, for every $a > 0$,

$$U_a R_{\text{ref}} - R_{\text{ref}} a^A = \Theta c_a, \quad a^A = e^{(\log a)A}.$$

This is precisely equation (15) of the finite-cocycle calculation. The original relation space is invariant because $U_a \Theta = \Theta U_a$, so U_a induces $\overline{U}_a$ on Q . Applying q to the identity gives the required full intertwining

$$\boxed{\overline{U}_a \sigma = \sigma a^A \quad \text{for every } a > 0.}$$

Inserting $U_a R_{\text{ref}} a^A$ into the defect for ab and using injectivity of Θ also gives the retained cocycle law $c_{ab} = U_a \circ c_b + c_a \circ b^A$. This proves group equivariance of the section in Q ; it does not assert strict equivariance of R_{ref} in $\mathcal{B}$. Indeed the displayed boundary is exactly what connects those two maps.

The exact full-jet insertion and the source eigenline. The identity on germs gives the Chinese-remainder isomorphism

$$E_h \xrightarrow{\sim} \bigoplus_{\nu \in Z} A_\nu, \quad A_\nu = \mathcal{O}_\nu / (g) = \mathcal{O}_\nu / ((s - \nu)^{m_\nu}).$$

At each centre the ideals generated by h and g both equal the displayed power ideal, since their remaining factors are units. For a fixed $\rho \in Z$, let $\iota_\rho : A_\rho \hookrightarrow E_h$ be the inverse Chinese-remainder map with all other blocks zero. An explicit formula, retaining all Taylor coefficients, uses $H_\rho(X) = h(X)/(X - \rho)^{m_\rho}$: for a germ representative f ,

$$\iota_\rho[f] = \left[H_\rho(X) \sum_{j=0}^{m_\rho-1} \frac{1}{j!} \frac{d^j}{dX^j} \left(\frac{f(X)}{H_\rho(X)} \right) \right]_{X=\rho} (X - \rho)^j \Big|_h.$$

At ρ its jet is f ; at every other selected centre the factor H_ρ gives all required zero jets. A change of representative f by a germ of order at least m_ρ leaves the displayed derivatives unchanged. These facts prove that this is the exact well-defined insertion, inverse to its block projection. In each block,

$$A|_\nu = \nu I + N_\nu, \quad a^A|_\nu = a^\nu \sum_{j=0}^{m_\nu-1} \frac{(\log a)^j}{j!} N_\nu^j.$$

Thus ι_ρ intertwines the full block scaling; it does not replace that block by its residue-value quotient.

Retain the preceding subsection's actual factorization $g(\rho + z) = u_\rho(z)z^m$, $m = m_\rho$, and put

$$t_\rho : \mathbb{C} \longrightarrow A_\rho, \quad t_\rho(c) = c[g'] = cmu_\rho(0)z^{m-1}.$$

Its domain has action $c \mapsto a^\rho c$. The previous calculation proves that t_ρ is an injective intertwiner, since $mu_\rho(0) \neq 0$ and $N_\rho z^{m-1} = 0$. Therefore the complete original source lift is

$$L_\rho = \sigma \iota_\rho t_\rho : (\mathbb{C}, a^\rho) \hookrightarrow (Q, \bar{U}_a), \quad w_\rho = L_\rho(1).$$

Its equivariance follows by composing the three proved intertwiners. Its nonvanishing follows without any choice of a quotient representative: $\bar{J}_Z w_\rho = \iota_\rho[g'] \neq 0$. For an explicit left inverse, let pr_ρ denote the block projection and set

$$\Lambda_\rho(q_0) = \frac{[z^{m-1}] \text{pr}_\rho \bar{J}_Z(q_0)}{mu_\rho(0)}.$$

Then $\Lambda_\rho L_\rho = 1_{\mathbb{C}}$. This linear left inverse is used to certify injectivity; no equivariance of Λ_ρ on the whole Q is asserted. In particular, for $m > 1$ it is not residue evaluation, which would vanish on the socle. The construction keeps precisely the nilpotent coefficient required for a nonzero lift.

The full tensor lift in the original top cohomology. For every integer $r \geq 1$, tensor over $\mathbb{C}$ to obtain

$$L_\rho^{\otimes r} = \sigma^{\otimes r} \iota_\rho^{\otimes r} t_\rho^{\otimes r} : \mathbb{C}^{\otimes r} \hookrightarrow Q^{\otimes r}, \quad w_\rho^{\otimes r} = L_\rho^{\otimes r}(1^{\otimes r}).$$

The map $\Lambda_\rho^{\otimes r}$ is a left inverse, since the tensor of the identities $\Lambda_\rho L_\rho = 1$ is the identity. Thus this is a nonzero tensor in the source cohomology, not only in its finite quotient. Composing the exact scaling intertwiners gives

$$\bar{U}_a^{\otimes r} w_\rho^{\otimes r} = a^{r\rho} w_\rho^{\otimes r} \quad (a > 0).$$

The top-degree comparison in primary (47) identifies this tensor with an actual class of $H^r \mathbf{A}_{\tau,r}(\mathcal{T}^{\boxtimes r})$. Explicitly, put

$$b_\rho = R_{\text{ref}} \iota_\rho[g'] \in \mathcal{B}.$$

Its representative in the original tensor complex is $b_\rho^{\otimes r} \in \mathcal{B}^{\otimes r}$. Top boundaries are sums of tensors with a ΘV factor. The map $J_Z^{\otimes r}$ kills every such tensor, whereas it sends this representative to $(\iota_\rho[g'])^{\otimes r} \neq 0$. This also proves its nonzero top cohomology class directly in the original complex.

The group action on this representative has the original source boundary and tensor signs. Put $c = c_a(\iota_\rho[g'])$. Then $U_a b_\rho - a^\rho b_\rho = \Theta c$. In the joint two-leg complex, $d(c, 0) = \Theta c$. With each $\mathcal{B}$ factor in degree one, form the degree $r - 1$ tensor

$$H_{a,r} = \sum_{j=1}^r (-1)^{j-1} (U_a b_\rho)^{\otimes(j-1)} \otimes (c, 0) \otimes (a^\rho b_\rho)^{\otimes(r-j)}.$$

Only the degree-zero factor contributes to its differential, with sign $(-1)^{j-1}$ from its preceding degree-one factors. It cancels the displayed coefficient. The resulting sum telescopes, giving

$$dH_{a,r} = (U_a b_\rho)^{\otimes r} - (a^\rho b_\rho)^{\otimes r}.$$

This is the cochain-level proof of the stated tensor eigencharacter on the original complex, retaining its source boundary rather than postulating a strict invariant representative.

Finally, the source character now has the exact original modulus identity

$$\log \frac{|a^{r\rho}|^2}{a^r} = r(2 \operatorname{Re} \rho - 1) \log a \quad (a > 1)$$

on the nonzero class $w_\rho^{\otimes r}$ itself. The actual moment line still has character a ; no norm or mass has been changed. This identity supplies the source eigenline requested by the tensor construction. It does not supply an upper estimate for its modulus. At each original nonempty support mask, σ , ι_ρ , and t_ρ lift by keeping that mask and its labelled zero. Their cohomological lifts commute with the identity transports among the nonempty Q -fibres; external τ remains external absence. The joint tensor class above therefore belongs to the retained supported arithmetic cohomology over the same absolute base.

202 Scope and source pins

This calculation completes the specific promise in transcript A1545, node bacc895-0427-42ee-b6f6-4c61752dfde2, to compute “the full τ -chart dual, including bottom fibers created by reversed support arrows.” It uses the actual four-point chart, coefficient spaces, differential, and right adjoint of the retained *Arithmetic cohomology over the τ -base*, NOTE.md, SHA-256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e5702c27db97e7b63c3. The complete transcript segment U0041–U0054 has SHA-256 e79b46722d9a2ee95b68ae6512f37a19fd41e4b3ecc4e53583cd357d0442c251. The reconstruction convention allowing a nonzero bottom fibre is the fully read `tex/support_diagrams.tex`, equations (D1)–(D8). No generic-stalk restriction replaces global cohomology here.

203 1. Original objects, signs, and both index sets

Retain $E = \mathbb{C}$, the even Schwartz space

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx,$$

and

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^k F(x)| < \infty \quad (b \in \mathbb{Z}, k \geq 0)\}.$$

Write $\mathcal{F} : V \rightarrow V$ for this Fourier transform; on this even space $\mathcal{F}^{-1} = \mathcal{F}$. Retain

$$\Theta\phi(x) = \sum_{n \neq 0} \phi(nx), \quad JF(x) = x^{-1}F(1/x), \quad J\Theta = \Theta\mathcal{F}, \quad Q = \mathcal{B}/\Theta V,$$

and denote the quotient by $q : \mathcal{B} \rightarrow Q$. The source proves injectivity of Θ from its Mellin identity in $\Re s > 1$; no zero in the critical strip is assumed absent.

The geometric index poset remains $P = \{+, -, \eta, \sigma\}$, with $+ < \eta < \sigma$ and $- < \eta < \sigma$. The support index poset is separately

$$L = \{\emptyset, +, -, J_0\}, \quad J_0 = \{+, -\},$$

ordered by inclusion. The symbol J_0 denotes a support mask; J above denotes the original inversion operator. At active mask A , the coefficient diagram $\mathcal{T}_A$ retains precisely the source legs belonging to A , has overlap $\mathcal{B}$, and has zero vector stalk at σ . At the empty mask it is the zero diagram. The source computes

$$\mathbf{A}_\tau(F) = R\Gamma(P, F) \simeq [F_+ \oplus F_- \xrightarrow{r_+ - r_-} F_\eta], \quad K_\tau(W) = [I_\eta(W) \longrightarrow I_+(W) \oplus I_-(W)],$$

with degrees 0, 1 and $-1, 0$, respectively, and differential signs $+$, $-$. Its proved adjunction gives

$$D_A(W) := R\mathrm{Hom}_{\mathrm{Fun}(P, \mathrm{Vect}_E)}(\mathcal{T}_A, K_\tau(W)) \cong R\mathrm{Hom}_E(\mathbf{A}_\tau(\mathcal{T}_A), W).$$

Here W is an ordinary coefficient vector space, and $X^\vee = \mathrm{Hom}_E(X, W)$ throughout the algebraic calculation.

204 2. The complete complexes and every support arrow

The following are literal representatives, not just their cohomology:

A	D_A^{-1}	D_A^0	δ_A
$\emptyset$	0	0	0
$+$	$\mathcal{B}^\vee$	$V^\vee$	$\ell \mapsto \ell\Theta$
$-$	$\mathcal{B}^\vee$	$V^\vee$	$\ell \mapsto -\ell\Theta\mathcal{F}$
J_0	$\mathcal{B}^\vee$	$V^\vee \oplus V^\vee$	$\ell \mapsto (\ell\Theta, -\ell\Theta\mathcal{F})$.

For $A \subseteq A'$, the arrow $D_{A'} \rightarrow D_A$ is precomposition with the original coefficient inclusion. On degree -1 it is the identity between active masks. On degree zero the arrows $J_0 \rightarrow +$ and $J_0 \rightarrow -$ are respectively

$$(a, b) \mapsto a, \quad (a, b) \mapsto b.$$

Both leaf-to-empty arrows are zero, as is the direct joint-to-empty arrow. Applying either coordinate projection to $\delta_{J_0}\ell$ gives the corresponding displayed leaf differential; the maps therefore commute with the differentials. Both composites from joint to empty are zero. These checks prove all naturality and composition identities in $\mathrm{Fun}(L^{\mathrm{op}}, \mathrm{Ch}(E))$.

205 3. Cohomology, with an explicit quotient and inverse

For every active mask, the degree- -1 kernel is

$$\{\ell \in \mathcal{B}^\vee : \ell\Theta = 0\} \xleftarrow{q^\vee} Q^\vee, \quad q^\vee(\lambda) = \lambda q.$$

The inverse sends ℓ to $[F] \mapsto \ell(F)$. It is well-defined precisely because $\ell\Theta = 0$. The Fourier isomorphism makes the condition on the minus face equivalent to the same equation. All active transition maps on this kernel are the identity in these $Q^\vee$ coordinates.

On either single leg, the degree-zero cohomology is zero. Indeed any linear functional on V extends to $\mathcal{B}$ through the injective map Θ . More concretely, the global retraction constructed in transcript A1694, fully reproved with explicit fixed cutoffs and estimates in Appendix A below, is a continuous linear map $\Lambda : \mathcal{B} \rightarrow V$ with $\Lambda\Theta = 1$. Then $a\Lambda$ lifts $a \in V^\vee$ on the plus face and $-b\mathcal{F}^{-1}\Lambda$ lifts $b \in V^\vee$ on the minus face.

At the joint mask define

$$\pi_0 : V^\vee \oplus V^\vee \longrightarrow V^\vee, \quad \pi_0(a, b) = a\mathcal{F} + b.$$

This evaluates the functional on the original cycle $\psi \mapsto (\mathcal{F}\psi, \psi)$. The composite $\pi_0\delta_{J_0}$ is zero. Conversely, if $a\mathcal{F} + b = 0$, then $b = -a\mathcal{F}$, and

$$\delta_{J_0}(a\Lambda) = (a, -a\mathcal{F}) = (a, b).$$

The quotient map is surjective, with representative $c \mapsto (0, c)$. Its inverse on the quotient sends c to the class of $(0, c)$: subtracting this representative from (a, b) gives

$$(a, b) - (0, a\mathcal{F} + b) = (a, -a\mathcal{F}) = \delta_{J_0}(a\Lambda).$$

This proves both inverse identities. Consequently the entire cohomology diagram is

$$\begin{array}{c|ccc} A & J_0 & + & - & \emptyset \\ \hline H^{-1}D_A & Q^\vee & Q^\vee & Q^\vee & 0 \\ H^0D_A & V^\vee & 0 & 0 & 0. \end{array}$$

The arrows in degree -1 are identity from joint to either leaf and zero to the empty mask. Every arrow in degree zero is zero. No degree-zero joint class is discarded.

In particular $V^\vee \neq 0$ when $W = E$. A concrete continuous functional is $\phi \mapsto \phi(1)$. It is nonzero on

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2} \in V.$$

The function is even, Schwartz, and vanishes at zero. Integration by parts gives $\int x^4 e^{-\pi x^2} dx = \frac{3}{2\pi} \int x^2 e^{-\pi x^2} dx$, proving its integral is zero; its value at one is $2\pi(2\pi - 3)e^{-\pi} \neq 0$.

206 4. What the reversed bottom actually contains

In L^{op} the bottom is J_0 , the join operation is original intersection, and the top is the original empty mask. Thus the dual's bottom cohomology fibres are exactly $Q^\vee$ in degree -1 and $V^\vee$ in degree zero. In particular the latter is nonzero for $W = E$. The rule “every bottom fibre is zero” is therefore incompatible with this calculation.

The source's full reconstruction retains these fibres. For either cohomology diagram $H^i D$, it is

$$M^i = \coprod_{A \in L^{\text{op}}} H^i D_A,$$

with

$$(A, u) + (B, v) = (A \cap B, \rho_{A, A \cap B} u + \rho_{B, A \cap B} v), \quad r^\bullet(A, u) = (A, ru), \quad \tau(A, u) = (J_0, 0).$$

The global additive zero is $(J_0, 0)$, and $e(A, u) = (A, 0)$. Associativity transports three amplitudes to $A \cap B \cap C$; equality of the two iterated transports proves the two sums agree. The zero law uses the unique map from the bottom and its zero value. Linearity of transitions proves distributivity, and the fibrewise vector-space scalar laws prove the remaining semimodule laws. This is the exact reconstruction, including nonzero vectors in the fibre of its global zero under multiplication by e .

If an additional external-absence label is desired while retaining every original reversed label, it can also be constructed explicitly: adjoin a new bottom $\perp_\dagger < L^{\text{op}}$, put zero fibre there, and retain all old fibres and arrows. The new external zero is $(\perp_\dagger, 0)$. The label map sending $\perp_\dagger$ and J_0 both to J_0 , and fixing every other label, preserves joins and bottom. With identity maps on old fibres and the zero map on the new fibre it reconstructs a surjective split-linear comparison to M^i . Its only additional identification is between the new external zero and the zero vector at the old bottom J_0 . It does not remove any nonzero bottom vector. This proves the exact relation between the two declared conventions; it does not silently impose a zero bottom fibre on the original reversed diagram.

207 5. Strict natural splitting fails, but the derived splitting has a concrete roof

Let $C = V^\vee$, let Z_C be the diagram supported at the bottom J_0 with value C , and let H be the degree- -1 cohomology diagram just calculated. The maps $q^\vee : H[1] \rightarrow D$ and $\pi : D \rightarrow Z_C[0]$, where π is π_0 only at the joint mask in degree zero, are natural cochain maps.

There is no strict natural cochain section $s : Z_C[0] \rightarrow D$ of π when $C \neq 0$. At the joint mask write $s(c) = (a(c), b(c))$. Naturality to the plus leaf forces $a(c) = 0$, since the source at that leaf is zero.

Naturality to the minus leaf forces $b(c) = 0$. Hence $\pi s = 0$, contradicting $\pi s = 1_C$. This is exactly a strict-section obstruction.

It is not a derived nonsplitting statement. Here is the actual surviving derived map. Write $b = J_0, x = +, y = -, t = \emptyset$ in the reversed diamond. For a vertex v , define the projective diagram

$$P_v(C)(w) = \begin{cases} C, & v \leq w, \\ 0, & v \not\leq w. \end{cases}$$

The augmented resolution of Z_C is

$$\mathcal{R}_C : P_t(C) \xrightarrow{c \mapsto (c, -c)} P_x(C) \oplus P_y(C) \xrightarrow{(a,b) \mapsto a+b} P_b(C) \xrightarrow{\epsilon} Z_C,$$

with degrees $-2, -1, 0$ before the augmentation. At b , the augmentation is identity. At either leaf the preceding map is identity and the augmented stalk is zero. At t , the stalk sequence is $0 \rightarrow C \rightarrow C^2 \rightarrow C \rightarrow 0$, with the displayed anti-diagonal and sum. This proves exactness stalkwise and on all arrows. Each $P_v(C)$ is projective because its Hom functor is $\text{Hom}_E(C, -_v)$, an exact functor over a field. Thus $\epsilon : \mathcal{R}_C \rightarrow Z_C[0]$ is a quasi-isomorphism.

Define $f : \mathcal{R}_C \rightarrow D$ as follows. In degree zero it is determined by

$$f_b^0(c) = (0, c), \quad f_x^0(c) = 0, \quad f_y^0(c) = c, \quad f_t^0(c) = 0.$$

In degree -1 , its map from $P_x(C)$ is zero, and its map from $P_y(C)$ is determined at y by

$$f_y^{-1}(c) = -c\mathcal{F}^{-1}\Lambda \in \mathcal{B}^\vee.$$

At t it is zero; in degree -2 it is zero. These maps are natural by their projective-source definitions and the zero target at t . At y , the chain equation is

$$\delta_y(-c\mathcal{F}^{-1}\Lambda) = c\mathcal{F}^{-1}\Lambda\Theta\mathcal{F} = c.$$

At x both sides are zero, and at t both sides are zero. These verify every chain equation. Finally $\pi f = \epsilon$, so

$$Z_C[0] \xleftarrow[\simeq]{\epsilon} \mathcal{R}_C \xrightarrow{f} D$$

is an explicit right inverse of π in the derived category. The combined cochain map

$$H[1] \oplus \mathcal{R}_C \longrightarrow D, \quad (h, r) \longmapsto q^\vee h + f(r),$$

induces identity on degree -1 cohomology and the displayed isomorphism on degree zero cohomology. It is therefore a quasi-isomorphism. This proves the full derived relationship without replacing the original support arrows by equalities.

208 6. The original action and the actual defect of this roof

For $a > 0$, retain $U_a F(x) = F(x/a)$. On the source plus and minus legs the actions are U_a and $aU_{1/a}$. On $\mathcal{B}$ the action is U_a . Let $W = \mathcal{L}_w$ carry a^w , where the source supplies $w = 0, 1$. Then on the displayed dual complex the action is

$$\ell \longmapsto a^w \ell U_{1/a}, \quad (\alpha, \beta) \longmapsto (a^w \alpha U_{1/a}, a^{w-1} \beta U_a).$$

The source identities $\Theta U_a = U_a \Theta$ and $\mathcal{F} U_a = aU_{1/a} \mathcal{F}$ verify directly that these operators commute with every differential and support arrow. On cohomology they give

$$H^{-1} : \lambda \longmapsto a^w \lambda \bar{U}_{1/a}, \quad H^0 : c \longmapsto a^{w-1} c U_a.$$

For $w = 1$, these are the original weight-one dual action on $Q^\vee$ and the explicit action $c \mapsto cU_a$ on the retained bottom $V^\vee$.

The roof above need not be strictly equivariant because Λ is not asserted equivariant. Its degree-zero component is equivariant. At the minus generator of degree -1 , its exact failure is

$$U_a^D f_y^{-1}(c) - f_y^{-1}(U_a^C c) = a^w c \mathcal{F}^{-1}(U_{1/a} \Lambda - \Lambda U_{1/a}).$$

Here the first $U_{1/a}$ in parentheses acts on V , and the second on $\mathcal{B}$. The formula follows by substitution and $U_a \mathcal{F}^{-1} = a \mathcal{F}^{-1} U_{1/a}$. Its precomposition with Θ is zero, using $\Lambda \Theta = 1$ and the theta intertwining. It consequently factors through the exact injection $q^\vee : Q^\vee \rightarrow \mathcal{B}^\vee$, with functional

$$[F] \mapsto a^w c \mathcal{F}^{-1}(U_{1/a} \Lambda - \Lambda U_{1/a}) F.$$

This is the computed relation between the original action, the chosen derived roof, and the retained $Q^\vee$ fibre. No equivariant splitting is inferred by erasing this term. In this statement each projective $P_v(C)$ carries the displayed coefficient action $c \mapsto a^{w-1} c U_a$ at every nonzero stalk, and its restriction maps are identities; its resolution maps therefore intertwine the actions.

The derived class of this defect is also computable. Applying $\text{Hom}(-, H)$ to the displayed projective resolution gives the complex

$$\text{Hom}_E(C, Q^\vee) \xrightarrow{\ell \mapsto (\ell, \ell)} \text{Hom}_E(C, Q^\vee)^2 \longrightarrow 0.$$

The last term is zero because $H_t = 0$. Thus

$$\text{Ext}^1(Z_C, H) \cong \text{Hom}_E(C, Q^\vee), \quad [(u, v)] \mapsto v - u, \quad d \mapsto [(0, d)].$$

The two maps are inverse: their first composite is identity, and subtracting $(0, v - u)$ from (u, v) gives the diagonal pair (u, u) . The action defect of the chosen roof has zero plus component and minus component $q^\vee d_a$, where

$$d_a(c)([F]) = a^w c \mathcal{F}^{-1}(U_{1/a} \Lambda - \Lambda U_{1/a}) F.$$

It therefore has the exact Ext class d_a . Equivalently, a nullhomotopy would be a degree- -1 map from $P_b(C)$ to D , represented by the same functional on both leaves; its degree-zero equation forces that functional to annihilate ΘV . The leaf equations require its two copies to equal $(0, q^\vee d_a)$. Such a map exists exactly when $d_a = 0$. This proves that this particular derived section intertwines the action exactly when the displayed class vanishes; it does not assert that no other equivariant section can exist.

The class is the transpose of the original global theta cocycle by an exact formula. Put

$$s[F] = (1 - \Theta \Lambda) F, \quad k_b = \Lambda U_b s.$$

Every F has its original decomposition $F = \Theta \Lambda F + s q F$. Substitution, with $\Lambda \Theta = 1$ and $U_b \Theta = \Theta U_b$, gives

$$U_b \Lambda - \Lambda U_b = -k_b q.$$

Consequently the same class is

$$\boxed{d_a(c) = -a^w c \mathcal{F}^{-1} k_{1/a} : Q \longrightarrow W.}$$

The minus sign, Fourier inverse, reciprocal parameter, and coefficient action are retained. The reversed-support defect and the source's scaling boundary are thus connected by a proved morphism.

209 7. Continuity and the finite residue inclusion remain attached

For $W = E$, all the formulas also hold for continuous duals with their strong topologies. The maps $\Theta, \mathcal{F}, q$ and the source's explicit Λ are continuous, and $\Lambda\Theta = 1$ splits the original topological sequence. Thus the plus and minus lifts used above are continuous; all quotient and inverse maps are continuous on the displayed finite products. Precomposition by a continuous linear map is strongly continuous because it takes bounded subsets to bounded subsets. This verifies the asserted topology of every displayed dual transport. The derived roof assertion in Section 5 is in the declared algebraic diagram category; no undeclared derived category of all locally convex spaces is used.

The explicit inverse pair on strong duals is

$$\mathcal{B}'_b \longrightarrow V'_b \oplus Q'_b, \quad \ell \longmapsto (\ell\Theta, \ell s), \quad (\alpha, \lambda) \longmapsto \alpha\Lambda + \lambda q.$$

Its composites are identity by $\Lambda\Theta = 1, qs = 1, \Lambda s = 0, q\Theta = 0$, and $\Theta\Lambda + sq = 1$. Strong continuity follows directly from $p_B(T'\ell) = p_{T(B)}(\ell)$ for a bounded subset B and continuous linear T . In particular q' identifies Q'_b with the annihilator of ΘV , with continuous inverse $\ell \mapsto \ell s$. The joint relation subspace is the closed kernel of π_0 , and $c \mapsto [(0, c)]$ is its continuous quotient inverse.

For the original reflection-stable finite arithmetic packet A_Z , keep $g = 2\xi$, every actual multiplicity, the complete jet map $J_Z : Q \rightarrow A_Z$, and the full residue form

$$R_Z(f, h) = \sum_{\rho \in Z} \text{Res}_{s=\rho} \frac{f^\dagger(s)h(s)}{g(s)} ds, \quad f^\dagger(s) = \overline{f(1-\bar{s})}.$$

The source proves its perfectness, J_Z 's surjectivity and continuity, and its covariance with $\mathcal{L}_1$. Therefore the map

$$\overline{A_Z} \longrightarrow Q'_b, \quad \bar{f} \longmapsto ([F] \mapsto R_Z(f, J_Z[F]))$$

is the same injective continuous residue map at each active vertex of $H^{-1}D$. The active support arrows are identities, so its three naturality squares commute exactly; at the empty vertex both maps are zero. Every nilpotent remains in the full A_Z and residue pairing. The new bottom $H^0 = V'_b$, the action defect of Section 6, and the original arithmetic residue inclusion now coexist in one completely specified reversed support calculation.

For the continuous-jet assertion one can retain an explicit estimate. Write $r = \Re \rho$ and choose an integer $n > |r|$. Differentiating the Mellin integral and splitting it at one gives, for every $j \geq 0$,

$$|(\mathcal{M}F)^{(j)}(\rho)| \leq j! \left(\frac{p_{n,0}(F)}{(n-r)^{j+1}} + \frac{p_{-n,0}(F)}{(n+r)^{j+1}} \right).$$

The two integrals used here are respectively $\int_1^\infty x^{r-n}(\log x)^j dx/x = j!/(n-r)^{j+1}$ and $\int_0^1 x^{r+n}|\log x|^j dx/x = j!/(n+r)^{j+1}$. They follow from substitution $y = |\log x|$ and j integrations by parts. Thus every derivative in the finite jet is continuous, with its actual order retained. The map descends by the original quotient topology since it annihilates ΘV .

The finished result is the explicit dual diagram, its nonzero bottom degree-zero fibre, the precise strict-section obstruction, the constructed derived roof that survives that obstruction, and its full scaling defect. None of these computations proves a theta weight bound, removes a finite-prime trace term, or replaces A_τ by restriction to σ .

210 Appendix A: complete retraction on the original theta source

210.1 A.1. Original spaces and the fixed auxiliary functions

Work over $\mathbb{C}$, with Fourier convention

$$\widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx.$$

Retain the original spaces, with their indicated seminorm topologies:

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \widehat{\phi}(0) = 0\},$$

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : p_{b,k}(F) = \sup_{x>0} x^b |D^k F(x)| < \infty \quad (b \in \mathbb{Z}, k \geq 0)\}, \quad D = -x\partial_x.$$

Use Schwartz seminorms $\sigma_{m,j}(u) = \sup_{x \in \mathbb{R}} (1 + |x|)^m |u^{(j)}(x)|$. The Fourier transform preserves the even Schwartz space and satisfies $\mathcal{F}^2 \phi(x) = \phi(-x)$. Consequently it preserves V , since $\widehat{\phi}(0) = \int \phi$ and $\int \widehat{\phi} = \phi(0)$.

Fix the following explicit smooth functions for the entire construction:

$$h(t) = \begin{cases} e^{-1/t}, & t > 0, \\ 0, & t \leq 0, \end{cases} \quad \chi(x) = \frac{h(1/16 - x^2)}{h(1/16 - x^2) + h(x^2 - 1/64)}, \quad \alpha = \beta = \chi.$$

All derivatives of h at zero vanish: each derivative for $t > 0$ is a polynomial in $1/t$ times $e^{-1/t}$, which tends to zero. The denominator defining χ never vanishes, since its two arguments cannot both be nonpositive. Thus χ is real, even, smooth, lies in $[0, 1]$, equals one for $|x| \leq 1/8$, and vanishes for $|x| \geq 1/4$. In particular

$$\|\chi\|_2^2 \leq \frac{1}{2}.$$

These are choices of reconstruction data on the original coordinates. The spaces, Fourier convention and arithmetic theta map remain exactly those displayed here.

210.2 A.2. Theta continuity and recovery on both exterior regions

The original maps are

$$\Theta \phi(x) = \sum_{n \neq 0} \phi(nx) = 2 \sum_{n \geq 1} \phi(nx), \quad JF(x) = x^{-1} F(1/x).$$

Poisson summation gives $\Theta \mathcal{F} = J\Theta$ on V . For this identity, periodize the Schwartz function $t \mapsto \phi(xt)$; its Fourier coefficients are $x^{-1} \widehat{\phi}(n/x)$, obtained by integrating over all translated unit intervals. Both the periodization and its Fourier series converge absolutely with derivatives. Evaluation at zero gives $\sum_n \phi(nx) = x^{-1} \sum_n \widehat{\phi}(n/x)$. The two zero-index terms vanish by the original moments.

The theta map is continuous into $\mathcal{B}$. Indeed, for $x \geq 1$, an integer $N > 1$, and $s_{N,k}(\phi) = \sup_{t>0} t^N |D^k \phi(t)|$,

$$|D^k \Theta \phi(x)| \leq 2\zeta(N) s_{N,k}(\phi) x^{-N}.$$

Each $s_{N,k}$ is bounded by finitely many Schwartz seminorms. Choosing $N \geq b$ bounds the part of $p_{b,k}$ on $x \geq 1$. The identities

$$D^k J = J(1 - D)^k, \quad p_{b,k}(JF) \leq \sum_{j=0}^k \binom{k}{j} p_{1-b,j}(F)$$

follow by differentiating $x^{-1} F(1/x)$. For $x \leq 1$, apply the preceding theta estimate to $\widehat{\phi}$ at $1/x$; choosing also $N \geq 1 - b$ bounds this part by $2\zeta(N) \sum_{j=0}^k \binom{k}{j} s_{N,j}(\widehat{\phi})$. This proves every required bound and also continuity of J .

For $x \neq 0$, define the actual arithmetic inverse series

$$\mathcal{U}F(x) = \frac{1}{2} \sum_{n \geq 1} \mu(n) F(n|x|).$$

Here μ is the ordinary Möbius function; the factor $1/2$ inverts the sum over both nonzero integer signs. Put

$$P_j(T) = (-1)^j T(T+1) \cdots (T+j-1), \quad P_0 = 1, \quad C_{N,j}(F) = \sum_{k=0}^j |[T^k]P_j(T)| p_{N,k}(F).$$

The identity $x^j \partial_x^j = P_j(D)$ follows by induction. Therefore, for $x > 0$ and integer $N > 1$,

$$|\partial_x^j \mathcal{U}F(x)| \leq \frac{\zeta(N)}{2} C_{N,j}(F) x^{-N-j}. \quad (1)$$

The same absolute bound holds for negative x . It proves locally uniform convergence of every differentiated series away from zero.

For $\phi \in V$, the divisor rearrangement is legitimate: for fixed $x > 0$, $\sum_{m,n \geq 1} |\phi(mnx)|$ is finite, by a Schwartz bound of degree $N > 1$ and $\sum_{m,n} (mn)^{-N} = \zeta(N)^2$. Thus

$$\mathcal{U}\Theta\phi(x) = \sum_{k \geq 1} \left(\sum_{d|k} \mu(d) \right) \phi(kx) = \phi(x).$$

The divisor sum is one for $k = 1$ and zero otherwise: prime factorization gives the product $\prod_{p|k} (1 - 1)$ when $k > 1$. Evenness gives recovery on negative x , and Poisson summation gives the second exterior recovery:

$$\boxed{\mathcal{U}\Theta\phi = \phi, \quad \mathcal{U}J\Theta\phi = \hat{\phi} \quad (x \neq 0).} \quad (2)$$

In particular Θ is injective, including at zero by continuity. No information about zeros of zeta in a critical strip enters this proof.

210.3 A.3. Fixed contraction and full Schwartz estimates

On $L^2(\mathbb{R}, dx)$, set

$$A = M_\chi, \quad B = \mathcal{F}^{-1} M_\chi \mathcal{F}, \quad T = AB.$$

Its integral kernel is $\chi(x)\check{\chi}(x-y)$. Plancherel and the change of variable $z = x - y$ give

$$\|T\|^2 \leq \|T\|_{\text{HS}}^2 = \|\chi\|_2^2 \|\check{\chi}\|_2^2 = \|\chi\|_2^4 \leq \frac{1}{4}.$$

Consequently the operator-norm convergent series supplies the actual inverse:

$$\boxed{(1 - T)^{-1} = \sum_{n=0}^{\infty} T^n, \quad \|(1 - T)^{-1}\| \leq 2.} \quad (3)$$

Multiplying its partial sums by $1 - T$ leaves $1 - T^{n+1}$, which tends to the identity, proving both inverse identities.

Define exterior functions, extended by zero near the origin, by

$$a_F = (1 - \chi)\mathcal{U}F, \quad b_F = (1 - \chi)\mathcal{U}JF, \quad YF = a_F + \chi\mathcal{F}^{-1}b_F.$$

Here are explicit bounds verifying all their Schwartz seminorms. Write $c_0 = 1$ and $c_r = \|\chi^{(r)}\|_\infty$ for $r \geq 1$. Leibniz's rule and (1), with $N = m + 2$, give

$$\sigma_{m,j}(a_F) \leq \frac{\zeta(m+2)}{2} 9^m \sum_{r=0}^j \binom{j}{r} c_r 8^{2+j-r} C_{m+2,j-r}(F). \quad (4)$$

Indeed every nonzero differentiated term occurs at $|x| \geq 1/8$, where $1 + |x| \leq 9|x|$ and $|x|^{-2-j+r} \leq 8^{2+j-r}$. The same bound holds for b_F with JF in place of F ; the displayed bounds for J express it in finitely many original $p_{b,k}(F)$. Smoothness across the plateau endpoints follows from smoothness of the cutoffs and their identically zero interior factors.

Fourier inversion is continuous on these Schwartz seminorms. Explicitly, integration by parts gives

$$\sigma_{m,j}(\mathcal{F}^{-1}u) \leq \sum_{r=0}^m \binom{m}{r} (2\pi)^{j-r} \|\partial_\xi^r(\xi^j u)\|_1.$$

Each integral on the right is bounded by a finite sum of Schwartz seminorms, using Leibniz's rule and $\int_{\mathbb{R}} (1 + |\xi|)^{-2} d\xi = 2$. Together with (4), this proves that $Y : \mathcal{B} \rightarrow \mathcal{S}^{\text{even}}$ is continuous.

The operator T also maps L^2 continuously to Schwartz space. Put

$$b_j = \|(2\pi\xi)^j \chi(\xi)\|_2 \leq \frac{(\pi/2)^j}{\sqrt{2}}, \quad A_{m,j} = (5/4)^m \sum_{r=0}^j \binom{j}{r} \|\chi^{(r)}\|_\infty b_{j-r}.$$

Cauchy-Schwarz in the Fourier integral bounds $\|\partial^j Bf\|_\infty$ by $b_j \|f\|_2$. Leibniz's rule and the support of χ therefore give

$$\sigma_{m,j}(Tf) \leq A_{m,j} \|f\|_2.$$

Set $\Phi F = (1 - T)^{-1} YF$, initially in L^2 . The equation $\Phi F = YF + T\Phi F$ proves that it is Schwartz, and supplies the explicit continuity estimate

$$\sigma_{m,j}(\Phi F) \leq \sigma_{m,j}(YF) + 2A_{m,j} \|YF\|_2. \quad (5)$$

The final L^2 norm is bounded by $\sqrt{2} \sigma_{1,0}(YF)$. Every operator preserves parity; hence ΦF is even. Equations (2) give

$$Y\Theta\phi = (1 - A)\phi + A(1 - B)\phi = (1 - T)\phi, \quad \Phi\Theta\phi = \phi. \quad (6)$$

210.4 A.4. The original moment correction and exact splitting

Retain

$$\gamma_0(x) = e^{-\pi x^2}, \quad \gamma_2(x) = 2\pi x^2 e^{-\pi x^2}.$$

Their moment columns $(\phi(0), \int_{\mathbb{R}} \phi)$ are $(1, 1)$ and $(0, 1)$. For the integral constants, the square of the Gaussian integral is the planar polar integral $2\pi \int_0^\infty r e^{-\pi r^2} dr = 1$. Integrating $\partial_x(xe^{-\pi x^2})$ then gives $2\pi \int x^2 e^{-\pi x^2} dx = 1$. Thus the continuous projection

$$P_V u = u - u(0)\gamma_0 - \left(\int_{\mathbb{R}} u - u(0) \right) \gamma_2$$

has both original moments zero and is identity on V . Continuity follows from $|u(0)| \leq \sigma_{0,0}(u)$ and $|\int u| \leq 2\sigma_{2,0}(u)$. The required map is therefore

$$\boxed{\Lambda = P_V(1 - T)^{-1}Y : \mathcal{B} \longrightarrow V, \quad \Lambda\Theta = 1_V.} \quad (7)$$

All constants and seminorm dependence have been supplied in (1)–(5). For the original quotient $q : \mathcal{B} \rightarrow Q = \mathcal{B}/\Theta V$, put $K = 1 - \Theta\Lambda$. Equation (7) gives $K^2 = K$, $\ker K = \Theta V$, and $\text{im } K = \ker \Lambda$. The image ΘV is closed because it is the kernel of continuous K . The continuous map K descends by the quotient topology to

$$s : Q \rightarrow \mathcal{B}, \quad s[F] = KF, \quad qs = 1, \quad \Lambda s = 0, \quad \Theta\Lambda + sq = 1.$$

These equations prove the continuous inverse pair

$$V \oplus Q \longrightarrow \mathcal{B}, \quad (\phi, u) \longmapsto \Theta\phi + su, \quad F \longmapsto (\Lambda F, qF).$$

Finally, retain $U_a F(x) = F(x/a)$. It is continuous because $p_{b,k}(U_a F) = a^b p_{b,k}(F)$; its source action preserves V and obeys $U_a \Theta = \Theta U_a$. It therefore induces $\overline{U}_a$ on Q . Put $k_a = \Lambda U_a s$. The decomposition of $U_a s$ gives

$$U_a s = \Theta k_a + s \overline{U}_a, \quad k_{ab} = U_a k_b + k_a \overline{U}_b, \quad k_1 = 0.$$

For the middle identity, substitute the first identity with parameter b into $\Lambda U_a U_b s$, and use $\Lambda U_a \Theta = U_a$ and $\Lambda U_a s = k_a$. Writing $F = \Theta \Lambda F + sqF$ also proves

$$U_a \Lambda - \Lambda U_a = -k_a q.$$

Consequently the reversed-support dual roof's action defect is exactly

$$\boxed{d_a(c) = -a^w c \mathcal{F}^{-1} k_{1/a}.$$

This connects the completed retraction to the original action on the full Q , retaining its Fourier inverse, weight factor, reciprocal parameter and sign. The calculation does not set this cocycle to zero.

This calculation completes the operator comparison left unspecified in shared transcript A0961, node a7bbd422-311c-4380-ba6c-a4bdd61fce2f, §7. It uses the original arithmetic objects of *Arithmetic cohomology over the tau-base*, equations (10)–(14), (19), (27), and (38)–(45). It preserves the actual function $g = 2\xi$, every local unit, multiplicity, coordinate, reflected-germ sign and support mask. The new grading is an explicitly constructed additional action. It is not identified with arithmetic Frobenius or with the original Mellin scaling.

210.5 1. Original arithmetic objects and analytic identities

Write $E = \mathbb{C}$ and retain

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi \text{ even}, \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx.$$

The target is the original Fréchet space

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : p_{b,k}(F) < \infty \text{ for all } b \in \mathbb{Z}, k \geq 0\}, \quad p_{b,k}(F) = \sup_{x>0} x^b |D^k F(x)|, \quad D = -x\partial_x.$$

Its Mellin transform is

$$\mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}.$$

For $F \in \mathcal{B}$ this is entire. Indeed, for any compact set of s and any derivative order, choose integers b_- below every $\Re s$ in that compact set and b_+ above every $\Re s$. On $(0, 1)$ and $(1, \infty)$ respectively, the bounds $|F(x)| \leq p_{b_-,0}(F)x^{-b_-}$ and $|F(x)| \leq p_{b_+,0}(F)x^{-b_+}$ give integrable dominating functions even after multiplication by any power of $|\log x|$. Differentiation under the integral is therefore justified.

Retain the two original maps

$$\Theta\phi(x) = \sum_{n \in \mathbb{Z} \setminus \{0\}} \phi(nx), \quad \mathcal{J}F(x) = x^{-1}F(1/x).$$

For every $\phi \in V$, $\Theta\phi \in \mathcal{B}$. At infinity this follows by termwise Euler differentiation and the Schwartz estimate, choosing a decay exponent greater than one so that its sum over n converges. At zero Poisson summation, with both original vanishing moments, gives

$$\Theta\phi(x) = x^{-1} \Theta \widehat{\phi}(1/x).$$

The same infinity estimates for $\widehat{\phi}$ apply after differentiating this identity; the resulting finite sums of Euler derivatives still decay faster than every power at zero. All sums and differentiated sums converge normally on compact positive intervals. Fourier transformation preserves V , and

$$\mathcal{J}\Theta\psi = \Theta\widehat{\psi}.$$

Thus the original two-leg cochain complex is

$$C_\theta = [V \oplus V \xrightarrow{d} \mathcal{B}], \quad d(\phi, \psi) = \Theta\phi - \mathcal{J}\Theta\psi = \Theta(\phi - \widehat{\psi}),$$

in degrees 0, 1. Its degree-one quotient is $Q = \mathcal{B}/\Theta V$.

For clarity, the exact Mellin factor used below can be proved without replacing g by its leading local monomial. Put

$$g(s) = 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

The entire continuation and reflection identity needed here follow directly from the Gaussian theta integral. With

$$\vartheta(x) = 2 \sum_{n \geq 1} e^{-\pi n^2 x^2},$$

Poisson summation gives $\vartheta(x) = x^{-1}\vartheta(1/x) + x^{-1} - 1$. Mellin integration for $\Re s > 1$, followed by splitting at 1 and substituting $x \mapsto 1/x$ in the lower integral, yields

$$\pi^{-s/2}\Gamma(s/2)\zeta(s) = \frac{1}{s(s-1)} + \int_1^\infty \vartheta(x)(x^s + x^{1-s}) \frac{dx}{x}.$$

The latter integral is entire by Gaussian decay. Consequently

$$g(s) = 1 + s(s-1) \int_1^\infty \vartheta(x)(x^s + x^{1-s}) \frac{dx}{x}, \quad g(1-s) = g(s), \quad \overline{g(\bar{s})} = g(s).$$

In particular g is not zero identically and satisfies $g^\dagger = g$ for the reflection below.

For $\phi \in V$, absolute convergence for $\Re s > 1$ gives the exact factorization

$$\mathcal{M}\Theta\phi(s) = 2\zeta(s)\mathcal{M}\phi(s) = g(s)H_\phi(s), \quad H_\phi(s) = \frac{2\pi^{s/2}\mathcal{M}\phi(s)}{s(s-1)\Gamma(s/2)}.$$

Here $\mathcal{M}\phi$ uses the positive half-line. To verify that H_ϕ is entire, split its integral at 1 and subtract finitely many terms of the even Taylor expansion of ϕ at zero. Since $\phi(0) = 0$, its only possible Mellin poles are simple poles at $s = -2, -4, \dots$, with the corresponding even Taylor coefficients as residues. Each is canceled by the simple zero of $1/\Gamma(s/2)$. At $s = 0$ the same reciprocal gamma factor cancels the displayed factor s . At $s = 1$, $\mathcal{M}\phi(1) = \frac{1}{2} \int_{\mathbb{R}} \phi = \frac{1}{2} \widehat{\phi}(0) = 0$ cancels $s-1$. This proves the asserted entire continuation. The displayed identity then holds everywhere by continuation. No vanishing at an arithmetic zero was assumed in this argument.

210.6 2. Full actual jet packets, reflection, and residue pairing

Fix any finite set Z of actual zeros of this g which is stable under

$$\iota\rho = 1 - \bar{\rho}.$$

If Z is empty, set $A_Z = 0$, $J_Z = 0$, $S = 0$, and $L_q = 1$; all packet identities below are the unique identities on the zero space, and no minimum or maximum over Z is taken. For the remaining construction assume Z is nonempty. Retain the actual order $m_\rho \geq 1$ of each zero and the coordinate $z_\rho = s - \rho$. Write the actual germ, with its unit intact, as

$$g_\rho(z) = g(\rho + z) = u_\rho(z)z^{m_\rho}, \quad u_\rho(0) \neq 0.$$

The coefficient algebra is

$$A_Z = \bigoplus_{\rho \in Z} \mathcal{O}_\rho / (g),$$

where $\mathcal{O}_\rho$ is the ring of holomorphic germs at ρ . Since multiplication by the actual unit u_ρ is invertible, the ideal (g_ρ) equals (z^{m_ρ}) . This equality identifies classes with unique truncated Taylor coordinates; it does not replace the denominator g_ρ in a residue. Define

$$(J_Z F)_\rho = \sum_{j=0}^{m_\rho-1} \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} z_\rho^j.$$

The preceding factorization proves $J_Z \Theta = 0$, so J_Z induces $\bar{J}_Z : Q \rightarrow A_Z$.

Reflection is the conjugate-linear involution

$$(f^\dagger)_\rho(z) = \overline{f_{\iota\rho}(-\bar{z})} = \sum_{j \geq 0} (-1)^j \overline{f_{\iota\rho,j}} z^j.$$

Because $g^\dagger = g$, reflection preserves the defining ideals, $m_{\iota\rho} = m_\rho$, and the actual units satisfy

$$u_\rho(z) = (-1)^{m_\rho} \overline{u_{\iota\rho}(-\bar{z})}.$$

Retain the original residue form, conjugate-linear in its first variable and linear in its second:

$$R_Z(f, h) = \sum_{\rho \in Z} \text{Res}_{z=0} \frac{(f^\dagger)_\rho(z) h_\rho(z)}{u_\rho(z) z^{m_\rho}} dz.$$

Changing either representative by a multiple of its actual g changes the integrand by a holomorphic germ, so this form is well-defined. It is perfect: if a nonzero component of h starts with $h_k z^k$, choose $(f^\dagger)_\rho = z^{m_\rho-1-k}$ and all other components zero. Its residue is $h_k/u_\rho(0) \neq 0$. Reflection is a bijection, so that choice of $f^\dagger$ comes from an f . Finite dimension then gives nondegeneracy in both variables.

The form is **skew-Hermitian**, with no phase change. In fact for a meromorphic germ $a(z) = \sum a_j z^j$, reflection changes its residue coefficient to $-\bar{a}_{-1}$, because $(-1)^{-1} = -1$. Applying that identity, relabeling ρ by $\iota\rho$, and using $g^\dagger = g$ gives

$$R_Z(h, f) = -\overline{R_Z(f, h)}.$$

This sign will not be replaced by a positivity assertion.

210.7 3. The exact additional grading and its inverse

For each real $q > 0$ define componentwise

$$(C_q f)_\rho(z) = f_\rho(z/q) \pmod{g_\rho(z)}.$$

This is an algebra automorphism of the original quotient. To check well-definedness with the original unit retained, compute

$$\frac{g_\rho(z/q)}{g_\rho(z)} = q^{-m_\rho} \frac{u_\rho(z/q)}{u_\rho(z)}.$$

The right side is a holomorphic unit at zero. Thus substitution sends the ideal (g_ρ) onto itself. Its inverse is

$$(C_q^{-1} f)_\rho(z) = f_\rho(qz),$$

as is seen directly by composing the substitutions. In particular

$$C_p C_q = C_{pq}, \quad C_1 = 1, \quad C_q(z_\rho^j) = q^{-j} z_\rho^j.$$

Since q is real and positive, substitution commutes with the reflected conjugation:

$$(C_q f)^\dagger = C_q(f^\dagger).$$

The separate packet labels ρ , local coordinates, multiplicities, and positive-degree jets have all been retained.

On a component let

$$N_\rho f = z_\rho f, \quad U_a|_\rho = a^\rho e^{(\log a)N_\rho}, \quad a > 0, \quad a^\rho = \exp(\rho \log a),$$

with the real logarithm of the original parameter a . These are exactly the jet operators induced by the original scaling $U_a F(x) = F(x/a)$. Multiplication by $a^{\rho+z}$ follows from a change of variables in the original Mellin integral. No centered or normalized scaling has been substituted.

Direct multiplication proves

$$U_a N_\rho U_a^{-1} = N_\rho, \quad C_q N_\rho C_q^{-1} = q^{-1} N_\rho.$$

Conjugating the full exponential gives the exact surviving comparison

$$C_q U_a|_\rho C_q^{-1} = a^\rho \exp\left(\frac{\log a}{q} N_\rho\right) = a^{\rho(1-1/q)} U_{a^{1/q}}|_\rho.$$

Every exponential is its full finite sum through degree $m_\rho - 1$. The factor $a^{\rho(1-1/q)}$ remains part of the formula. This is a relation between two distinct actions on the same actual arithmetic packet. The conjugated operator $C_q U_a C_q^{-1}$ still commutes with N_ρ , because its displayed formula is a polynomial in N_ρ times a scalar. It is C_q itself, not that conjugated arithmetic operator, which scales N_ρ by q^{-1} .

210.8 4. Exact obstruction to a literal simultaneous identification

Let $N = \bigoplus N_\rho$ and $U_a = \bigoplus U_a|_\rho$. Fix $q > 0$, $q \neq 1$, and retain any target vector space W with invertible F and an operator N_D satisfying the exact Deligne-type relation

$$F N_D F^{-1} = q^{-1} N_D.$$

Every linear map $T : A_Z \rightarrow W$ intertwining both proposed operators,

$$T U_a = F T, \quad T N = N_D T,$$

annihilates $N A_Z$. Indeed $F^{-1} T = T U_a^{-1}$, so

$$F N_D F^{-1} T = F T N U_a^{-1} = T U_a N U_a^{-1} = T N = N_D T.$$

The left side is also $q^{-1} N_D T$. Since $1 - q^{-1} \neq 0$, $N_D T = T N = 0$. Hence T factors uniquely through

$$A_Z \twoheadrightarrow A_Z / N A_Z = \bigoplus_{\rho \in Z} \mathbb{C},$$

the actual residue-value observation. An injective such T therefore exists only when every $N_\rho = 0$, which is equivalent to every $m_\rho = 1$.

This proves precisely the obstruction to the **literal simultaneous identification** of original Mellin scaling and the same full jet nilpotent with that pair. It does not forbid other functors or additional actions. There is a concrete surviving quotient map: evaluation at $z = 0$ intertwines U_a with $\text{diag}(a^\rho)$ and sends N to zero. On that quotient the target relation holds with $N_D = 0$, and it imposes no condition on $\Re \rho$. Alternatively, C_q retains all nilpotents and satisfies the target conjugacy relation, with its distinct semidirect interaction with U_a proved above.

210.9 5. Residue Jacobian, adjoint, and trace contraction

Define the actual unit in each component

$$\kappa_{q,\rho}(z) = q^{1-m_\rho} \frac{u_\rho(z)}{u_\rho(qz)}.$$

Changing the local coordinate of integration by $z = qw$ in the residue gives, with its Jacobian retained,

$$\begin{aligned} R_Z(C_q f, C_q h) &= \sum_\rho q \operatorname{Res}_{w=0} \frac{(f^\dagger)_\rho(w) h_\rho(w)}{g_\rho(qw)} dw \\ &= \sum_\rho \operatorname{Res}_{w=0} \frac{(f^\dagger)_\rho(w) \kappa_{q,\rho}(w) h_\rho(w)}{g_\rho(w)} dw. \end{aligned}$$

Thus

$$\boxed{R_Z(C_q f, C_q h) = R_Z(f, M_{\kappa_q} h).}$$

In particular the factor is q^{1-m_ρ} , not q^{-m_ρ} , and the quotient of the full local units remains. The unit relation from reflection proves, without dropping its sign,

$$(\kappa_q^\dagger)_\rho(z) = q^{1-m_\rho} \frac{(-1)^{m_\rho} u_\rho(z)}{(-1)^{m_\rho} u_\rho(qz)} = \kappa_{q,\rho}(z).$$

Put

$$D_q = M_{\kappa_q} C_q^{-1}.$$

Replacing the second $C_q h$ in the residue formula by an arbitrary h proves

$$R_Z(C_q f, h) = R_Z(f, D_q h).$$

Skew-Hermitian symmetry then gives the equally important other-side formula

$$R_Z(D_q f, h) = R_Z(f, C_q h).$$

For example, apply the first formula to (h, f) and take negative complex conjugates; no phase is needed. These are the exact residue adjoint identities.

Retain the original trace contraction

$$J_g = M_{g'} : A_Z \rightarrow A_Z.$$

The actual derivative is $g'_\rho(z) = m_\rho u_\rho(z) z^{m_\rho-1} + u'_\rho(z) z^{m_\rho}$. Modulo its original ideal $(g_\rho) = (z^{m_\rho})$ this gives

$$\begin{aligned} \kappa_{q,\rho}(z) g'_\rho(qz) &\equiv q^{1-m_\rho} \frac{u_\rho(z)}{u_\rho(qz)} m_\rho u_\rho(qz) q^{m_\rho-1} z^{m_\rho-1} \\ &= m_\rho u_\rho(z) z^{m_\rho-1} \equiv g'_\rho(z). \end{aligned}$$

Consequently

$$\boxed{D_q J_g C_q = J_g.}$$

The contracted form is therefore invariant:

$$R_Z(C_q f, J_g C_q h) = R_Z(f, J_g h).$$

Its exact value is

$$R_Z(f, J_g h) = \sum_{\rho \in Z} m_\rho \overline{f_{\iota\rho}(0)} h_\rho(0) = \operatorname{Tr}(M_{f^\dagger h} | A_Z).$$

For the first equality, $g'_\rho/g_\rho = m_\rho/z + u'_\rho/u_\rho$ and the second term is holomorphic. For the second, multiplication by a germ on the basis $1, z, \dots, z^{m_\rho-1}$ is triangular with its constant coefficient on all m_ρ diagonal entries. The radical of this contracted form is exactly NA_Z ; the full residue form is perfect before contraction. C_q is invertible and preserves that radical. No nilpotent or multiplicity has been discarded.

210.10 6. A proved continuous section on the original theta target

We now construct a section of J_Z in the actual space $\mathcal{B}$, not in a substitute polynomial test family. Index the Taylor coordinates by

$$\Lambda = \{(\rho, j) : \rho \in Z, 0 \leq j < m_\rho\}, \quad M = |\Lambda|.$$

Choose fixed real numbers $\alpha < \beta$ and retain the bump

$$\chi(y) = \begin{cases} \exp\left(-\frac{1}{(y-\alpha)(\beta-y)}\right), & \alpha < y < \beta, \\ 0, & \text{otherwise.} \end{cases}$$

It is smooth and all its endpoint derivatives vanish. For $i = (\rho, j)$ let

$$w_i(y) = e^{\rho y} \frac{y^j}{j!}, \quad H_{ik} = \int_{\mathbb{R}} \chi(y) w_i(y) \overline{w_k(y)} dy.$$

The matrix H is invertible. Here is the required independence proof. An identically zero linear combination of the w_i on a nonempty real interval has the form $\sum_{\rho} e^{\rho y} P_{\rho}(y) = 0$ with $\deg P_{\rho} < m_{\rho}$. By analyticity it vanishes everywhere. Fix ρ and apply

$$\prod_{\sigma \in Z, \sigma \neq \rho} (\partial_y - \sigma)^{m_{\sigma}}.$$

All other summands vanish. The remaining equation is

$$e^{\rho y} \prod_{\sigma \neq \rho} (\partial_y + \rho - \sigma)^{m_{\sigma}} P_{\rho}(y) = 0.$$

On polynomials of degree below m_{ρ} , each factor $\partial_y + c$ with $c \neq 0$ is invertible: its inverse is the finite sum

$$c^{-1} \sum_{r=0}^{m_{\rho}-1} (-c^{-1} \partial_y)^r.$$

Thus $P_{\rho} = 0$. Doing this for every ρ proves independence. For any nonzero column v ,

$$v^* H v = \int \chi(y) \left| \sum_i \overline{v_i} w_i(y) \right|^2 dy > 0,$$

because the combination cannot vanish on the whole interval where $\chi > 0$. Hence H is positive definite and invertible.

Define functions in the original positive variable by

$$F_k(x) = \chi(\log x) \sum_{\ell \in \Lambda} \overline{w_{\ell}(\log x)} (H^{-1})_{\ell k}.$$

Each is smooth and supported in $[e^{\alpha}, e^{\beta}]$, with all derivatives zero at its endpoints, so $F_k \in \mathcal{B}$. Direct substitution $y = \log x$ gives

$$\frac{(\mathcal{M}F_k)^{(j)}(\rho)}{j!} = \int \chi(y) w_{(\rho, j)}(y) \sum_{\ell} \overline{w_{\ell}(y)} (H^{-1})_{\ell k} dy = \delta_{(\rho, j), k}.$$

Thus the explicit finite-rank map

$$S : A_Z \rightarrow \mathcal{B}, \quad S\left(\sum_i c_i z_i^{j_i}\right) = \sum_i c_i F_i, \quad J_Z S = 1_{A_Z},$$

is a continuous linear section. The notation in the sum means the specified Taylor coordinates in their separate ρ -components.

For explicit continuity of the observation, choose integers

$$b_- < \min_{\rho \in Z} \Re \rho, \quad b_+ > \max_{\rho \in Z} \Re \rho.$$

For each $i = (\rho, j)$, direct integration of $|\log x|^j$ on the two half-lines proves

$$|(J_Z F)_{\rho, j}| \leq \frac{p_{b_-, 0}(F)}{(\Re \rho - b_-)^{j+1}} + \frac{p_{b_+, 0}(F)}{(b_+ - \Re \rho)^{j+1}}.$$

The $j!$ in the jet definition exactly cancels the $j!$ in those elementary integrals. All constants and original seminorms remain explicit. In particular J_Z and S are continuous, J_Z is surjective, and $\bar{J}_Z$ on Q is surjective. No assertion about closedness of ΘV or completeness of its quotient was needed.

210.11 7. An exact action on the original four-point theta sheaf

Define on $\mathcal{B}$

$$L_q = 1 + S(C_q - 1)J_Z.$$

Then

$$J_Z L_q = C_q J_Z, \quad L_q|_{\ker J_Z} = 1, \quad L_q \Theta = \Theta.$$

The identity $J_Z S = 1$ shows by expansion that

$$L_p L_q = 1 + S(C_p C_q - 1)J_Z = L_{pq}, \quad L_q^{-1} = 1 + S(C_q^{-1} - 1)J_Z.$$

These are exact inverses on the full original function space, not just on the observed packet.

Keep the original four-point upper-set space

$$+ < \eta < \sigma, \quad - < \eta < \sigma,$$

with coefficient sheaf $\mathcal{T}_+ = \mathcal{T}_- = V$, $\mathcal{T}_\eta = \mathcal{B}$, $\mathcal{T}_\sigma = 0$, and restriction maps Θ and $\mathcal{J}\Theta$. Define a sheaf automorphism to be the identity at $+$ and $-$, L_q at η , and the unique map on the zero vector space at σ . This is a sheaf morphism because L_q fixes both ΘV and $\mathcal{J}\Theta V = \Theta V$ pointwise. On derived global sections it is precisely

$$\begin{array}{ccc} V \oplus V & \xrightarrow{\Theta - \mathcal{J}\Theta} & \mathcal{B} \\ \downarrow 1 & & \downarrow L_q \\ V \oplus V & \xrightarrow{\Theta - \mathcal{J}\Theta} & \mathcal{B}. \end{array}$$

The signs and the original two source legs are unchanged.

Consequently L_q descends to an automorphism $\bar{L}_q$ of the exact quotient Q . It induces the identity on degree-zero cohomology and satisfies

$$\bar{J}_Z \bar{L}_q = C_q \bar{J}_Z.$$

Equip Q here with the quotient topology of the original $\mathcal{B}$. Both $\bar{L}_q$ and its inverse are continuous by the quotient universal property. This does not assert that Q is Hausdorff or that ΘV is closed. It is natural for the retained inclusions of nonempty support masks when the same S is used on their common $\mathcal{B}$ stalk. Indeed each $\mathcal{T}_A$ has its original active source legs, this same target, and the corresponding restrictions. The source identities and common L_q commute with every such inclusion. The split reconstruction acts by

$$\tau \mapsto \tau, \quad (A, F) \mapsto (A, L_q F).$$

It fixes $(A, 0)$ and keeps the label A . Thus neither synchronization of masks nor conversion of a supported zero into τ has occurred. At σ the reconstructed support skeleton is fixed.

The action has concrete analytic bounds. In the Taylor coordinate basis C_q is diagonal, so

$$p_{b,k}(L_q F) \leq p_{b,k}(F) + \sum_{\rho \in \mathbb{Z}} \sum_{j=0}^{m_\rho-1} |q^{-j} - 1| p_{b,k}(F_{\rho,j}) |(J_Z F)_{\rho,j}|.$$

Combining this with the preceding observation estimate proves continuity in every original Fréchet seminorm. For $q \geq 1$, all $|q^{-j} - 1| \leq 1$, so the displayed family of bounds is uniform in $q \geq 1$. For its inverse replace these factors by $|q^j - 1|$; it grows at most with the explicitly retained maximum degree $\max_\rho(m_\rho - 1)$. Nothing here bounds the original U_a in terms of $a^{1/2}$: L_q is the new finite-packet grading, and its inverse need not remain bounded as q grows.

The construction is noncanonical in its chosen bump and section. If S' is a second section and $K = S' - S$, then $J_Z K = 0$ and

$$L'_q - L_q = K(C_q - 1)J_Z.$$

Its image is in $\ker J_Z$, it vanishes on $\ker J_Z$, and both choices induce the same C_q on A_Z . This formula records the exact dependence instead of asserting a canonical global arithmetic action.

210.12 8. Compatibility with the original right-adjoint dual map

For the declared diagram category on the four-point space, the original calculation is

$$A_\tau(F) = [F_+ \oplus F_- \xrightarrow{r_+ - r_-} F_\eta], \quad K_\tau(W) = [I_\eta(W) \xrightarrow{(+\text{res}, -\text{res})} I_+(W) \oplus I_-(W)]$$

in degrees 0, 1 and $-1, 0$ respectively. Here $I_x(W)(y) = W$ for $y \leq x$ and zero otherwise. Evaluation gives $\text{Hom}(F, I_x(W)) = \text{Hom}(F_x, W)$; applying this to the two displayed terms proves the right-adjoint identity with differential $\ell \mapsto (\ell r_+, -\ell r_-)$. Therefore

$$H^{-1} R \text{Hom}(\mathcal{T}, K_\tau(\mathcal{L}_1)) = \text{Hom}_E(Q, \mathcal{L}_1),$$

where the original moment line $\mathcal{L}_1$ has the original scaling action a . Its underlying vector space is E ; no action of the new grading on it is being inferred from arithmetic purity.

The original finite-packet morphism is the linear map from the conjugate vector space

$$\iota_Z : \overline{A_Z} \longrightarrow \text{Hom}_E(Q, \mathcal{L}_1), \quad \iota_Z(\bar{f})([F]) = R_Z(f, J_Z F).$$

It is well-defined because $J_Z \Theta = 0$, and injective by the just-proved surjectivity of J_Z and perfection of R_Z . Precomposition with $\bar{L}_q$ has the exact effect

$$\begin{aligned} (\bar{L}_q^* \iota_Z(\bar{f}))([F]) &= R_Z(f, J_Z L_q F) \\ &= R_Z(f, C_q J_Z F) \\ &= R_Z(D_q f, J_Z F). \end{aligned}$$

Thus the diagram into the **same** computed right-adjoint object satisfies

$$\boxed{\bar{L}_q^* \iota_Z(\bar{f}) = \iota_Z(\overline{D_q f}), \quad D_q = M_{\kappa_q} C_q^{-1}.}$$

Every arrow is now calculated on the original theta source and the full actual arithmetic jets. This is not merely a pairing on an unrelated finite algebra. All dual support arrows remain precomposition, and the zero functional at a present mask remains its supported zero functional.

210.13 9. Exact scope of the completed comparison

The new automorphism C_q retains the actual zero ρ , its complete local algebra, and its unit. It provides the conjugacy $N \mapsto q^{-1}N$. Its continuous lift L_q acts on the original theta sheaf and fixes the original relation space ΘV pointwise; its finite-packet effect and dual effect are the explicit diagrams above. These are completed maps with full proofs and analytic seminorm control.

The actual arithmetic scaling remains $U_a = a^\rho e^{(\log a)N}$. It commutes with N and has the exact semidirect relation with C_q . The grading eigenvalues are q^{-j} on the original Taylor coordinates. They do not contain a bound on $\Re \rho$. On simple packets C_q is the identity for every q , while U_a still has eigenvalue a^ρ .

More generally, multiplying C_q on a component by any nonzero scalar c leaves its conjugacy with N unchanged and changes all its eigenvalues to cq^{-j} . The residue formula and its full unit, not that conjugacy alone, state the actual additional information carried by our chosen C_q . Consequently this completed comparison supplies neither a canonical arithmetic Frobenius nor an absolute arithmetic weight estimate. The original tensor-growth calculation over A_τ remains the original problem; the new maps give a precise continuation instead of a false literal identification or an unsupported claim of irrelevance.

211 Completed Mellin-realization calculations on the original theta source

These calculations close two finite algebraic gaps identified by the fully read transcript section U0029–U0040. They use the original theta source, its Fourier convention, its differentiated Gaussian, its complete two-leg support, and the original generator $g = 2\xi$. They do not replace that source by an arbitrary polynomial family. They concern Mellin realization, not the separately assigned homotopy fibre of restriction to σ .

211.1 Retained objects and source equations

Let $E = \mathbb{C}$ and retain

$$V = \{\phi \in \mathcal{S}(\mathbb{R}) : \phi(-x) = \phi(x), \phi(0) = 0, \widehat{\phi}(0) = 0\}, \quad \widehat{\phi}(\xi) = \int_{\mathbb{R}} \phi(x) e^{-2\pi i x \xi} dx,$$

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^k F(x)| < \infty \text{ for every } b \in \mathbb{Z}, k \geq 0\}.$$

Set

$$D = -x\partial_x, \quad \Theta\phi(x) = \sum_{n \in \mathbb{Z} \setminus \{0\}} \phi(nx), \quad JF(x) = x^{-1}F(1/x), \quad \mathcal{M}F(s) = \int_0^\infty F(x) x^s \frac{dx}{x}.$$

The primary Tau Base NOTE.md equations (10)–(14),(21)–(22),(38) and the actual comparison source retain the identities

$$J\Theta = \Theta\mathcal{F}, \quad \mathcal{F}D = (1 - D)\mathcal{F}, \quad \Theta D = D\Theta, \quad \mathcal{M}(DF) = s\mathcal{M}F.$$

The fixed source function is

$$\phi_*(x) = (4\pi^2 x^4 - 6\pi x^2)e^{-\pi x^2}, \quad \widehat{\phi_*} = \phi_*,$$

and

$$b_* = \Theta\phi_*, \quad \mathcal{M}b_* = g, \quad g(s) = 2\xi(s) = s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

The entire function g is not zero. For example, the retained theta-boundary calculation gives $g(0)=1$. The arithmetic quotient is $Q = \mathcal{B}/\Theta V$. The original two-leg complex is

$$C^\bullet = [V \oplus V \xrightarrow{\Theta\phi - J\Theta\psi} \mathcal{B}], \quad C^0 = V \oplus V, \quad C^1 = \mathcal{B}.$$

Its H^0 is the actual Fourier graph V and its H^1 is Q . A single-leg complex has $H^0 = 0$; it is not the same complex.

All sheaf arguments below are stalkwise over $R = \mathcal{O}_{\mathbb{C}, s_0}$, with its original coordinate s , and hence glue. This local analytic ring is an integral domain. A nonzero entire function has a nonzero germ at every point by the identity theorem, even if its value at that point is zero.

211.2 Exact Fourier calculation for the retained theta source

We prove the Fourier self-duality used in the preceding definition, with the original convention and every coefficient. Put $u(x) = e^{-\pi x^2}$. Its integral is one. Indeed, its positive integral I satisfies, by Tonelli's theorem and the polar-coordinate Jacobian,

$$I^2 = \int_{\mathbb{R}^2} e^{-\pi(x^2+y^2)} dx dy = \int_0^{2\pi} \int_0^\infty e^{-\pi r^2} r dr d\vartheta = 2\pi \frac{1}{2\pi} = 1,$$

so $I = 1$.

Differentiation under the Fourier integral is justified by the integrable majorants $(2\pi|x|)^k u(x)$, for each fixed derivative order k . Since $u' = -2\pi x u$, integration by parts gives

$$\begin{aligned} \frac{d}{d\xi} \widehat{u}(\xi) &= \int_{\mathbb{R}} (-2\pi i x) u(x) e^{-2\pi i x \xi} dx \\ &= i \int_{\mathbb{R}} u'(x) e^{-2\pi i x \xi} dx \\ &= i(2\pi i \xi) \widehat{u}(\xi) = -2\pi \xi \widehat{u}(\xi). \end{aligned}$$

The boundary term is zero because $u(x)$ tends to zero at both ends of the real line. The differential equation, together with $\widehat{u}(0) = 1$, gives

$$\widehat{u}(\xi) = e^{-\pi \xi^2}.$$

For every Schwartz function f , the same differentiation and integration by parts prove the typed operator identities

$$\mathcal{F}(xf) = \frac{i}{2\pi} \partial_\xi \widehat{f}, \quad \mathcal{F}(f') = 2\pi i \xi \widehat{f}.$$

The Gaussian derivatives are

$$\begin{aligned} u''(\xi) &= (4\pi^2 \xi^2 - 2\pi) u(\xi), \\ u^{(4)}(\xi) &= (16\pi^4 \xi^4 - 48\pi^3 \xi^2 + 12\pi^2) u(\xi). \end{aligned}$$

Consequently,

$$\begin{aligned} \mathcal{F}(x^2 u)(\xi) &= -\frac{1}{4\pi^2} u''(\xi) = \left(\frac{1}{2\pi} - \xi^2 \right) u(\xi), \\ \mathcal{F}(x^4 u)(\xi) &= \frac{1}{16\pi^4} u^{(4)}(\xi) = \left(\xi^4 - \frac{3}{\pi} \xi^2 + \frac{3}{4\pi^2} \right) u(\xi). \end{aligned}$$

Apply these formulas to the original source $\phi_* = (4\pi^2 x^4 - 6\pi x^2)u$:

$$\begin{aligned}\widehat{\phi_*}(\xi) &= \left[4\pi^2 \left(\xi^4 - \frac{3}{\pi} \xi^2 + \frac{3}{4\pi^2} \right) - 6\pi \left(\frac{1}{2\pi} - \xi^2 \right) \right] u(\xi) \\ &= (4\pi^2 \xi^4 - 12\pi \xi^2 + 3 - 3 + 6\pi \xi^2) u(\xi) \\ &= (4\pi^2 \xi^4 - 6\pi \xi^2) e^{-\pi \xi^2} = \phi_*(\xi).\end{aligned}$$

This establishes the literal equality $\widehat{\phi_*} = \phi_*$. The function is even and Schwartz, $\phi_*(0) = 0$, and $\widehat{\phi_*}(0) = \phi_*(0) = 0$; hence it belongs to the exact source space V .

The same calculation also verifies the source operator expression and the sign of its Fourier intertwiner. Since

$$Du = 2\pi x^2 u, \quad D^2 u = (-4\pi x^2 + 4\pi^2 x^4)u,$$

we have

$$D(D-1)u = (4\pi^2 x^4 - 6\pi x^2)u = \phi_*.$$

For every Schwartz f ,

$$\begin{aligned}\widehat{Df}(\xi) &= -\mathcal{F}(xf')(\xi) = -\frac{i}{2\pi} \partial_\xi (2\pi i \xi \widehat{f}(\xi)) \\ &= \widehat{f}(\xi) + \xi \partial_\xi \widehat{f}(\xi) = (1 - D_\xi) \widehat{f}(\xi).\end{aligned}$$

Here $D_\xi = -\xi \partial_\xi$, with the same sign as the original operator. This proves $\mathcal{F}D = (1 - D)\mathcal{F}$ on its stated Schwartz domain. Moreover, D preserves V : it preserves evenness and the Schwartz class, $(D\phi)(0) = 0$, and

$$\int_{\mathbb{R}} D\phi(x) dx = -[x\phi(x)]_{-\infty}^{\infty} + \int_{\mathbb{R}} \phi(x) dx = 0 \quad (\phi \in V).$$

The boundary term vanishes by Schwartz decay. Thus every $D^m \phi_*$ and every $(1 - D)^m \phi_*$ occurring in the two-leg calculation remains in the original domain.

The Mellin constant can also be obtained directly from the same function. For $\Re s > 0$, substitution $t = \pi x^2$ and $\Gamma(z+1) = z\Gamma(z)$ give

$$\begin{aligned}M_+ \phi_*(s) &= \int_0^\infty (4\pi^2 x^4 - 6\pi x^2) e^{-\pi x^2} x^s \frac{dx}{x} \\ &= \pi^{-s/2} \left(2\Gamma\left(\frac{s}{2} + 2\right) - 3\Gamma\left(\frac{s}{2} + 1\right) \right) \\ &= \pi^{-s/2} \Gamma\left(\frac{s}{2}\right) \left[2\frac{s}{2} \left(\frac{s}{2} + 1\right) - 3\frac{s}{2} \right] \\ &= \frac{1}{2} s(s-1) \pi^{-s/2} \Gamma\left(\frac{s}{2}\right).\end{aligned}$$

The recurrence follows by integration by parts in the defining Gamma integral on this half-plane; its boundary terms vanish at zero and infinity. For $\Re s > 1$, the full nonzero-integer theta sum is absolutely integrable term by term, because

$$\sum_{n \neq 0} \int_0^\infty |\phi_*(nx)| x^{\Re s} \frac{dx}{x} = 2 \sum_{n \geq 1} n^{-\Re s} \int_0^\infty |\phi_*(y)| y^{\Re s} \frac{dy}{y} < \infty.$$

Therefore

$$\begin{aligned}\mathcal{M}\Theta\phi_*(s) &= 2\zeta(s)M_+\phi_*(s) \\ &= s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s) = 2\xi(s) = g(s).\end{aligned}$$

This retains both the factor two from the full integer sum and the factor one half in the source Mellin integral. The source's entire continuation identifies these same functions away from this initial half-plane; no division by g at an arithmetic zero has occurred.

211.3 The raw two-leg syzygy at every source order

For each integer $m \geq 1$, retain the actual functions

$$b_{+,m} = \Theta D^m \phi_* = D^m b_*, \quad b_{-,m} = J \Theta D^m \phi_* = (1 - D)^m b_*.$$

Their Mellin transforms are exactly

$$\mathcal{M}b_{+,m} = s^m g, \quad \mathcal{M}b_{-,m} = (1 - s)^m g.$$

Thus the same source input $D^m \phi_*$ on the two original charts gives these two images. No independent spectral function has been chosen.

Put $a_m(s) = s^m$ and $v_m(s) = (1 - s)^m$. Define

$$\begin{aligned} \delta_m : R^2 &\longrightarrow R \otimes_E \mathcal{B}, & (f, h) &\longmapsto f \otimes b_{+,m} - h \otimes b_{-,m}, \\ \beta : R \otimes_E \mathcal{B} &\longrightarrow R, & f \otimes F &\longmapsto f \mathcal{M}F. \end{aligned}$$

These give the literal commutative comparison

$$\begin{array}{ccc} R^2 & \xrightarrow{\delta_m} & R \otimes_E \mathcal{B} \\ 1 \downarrow & & \downarrow \beta \\ R^2 & \xrightarrow{(f,h) \mapsto g(a_m f - v_m h)} & R. \end{array}$$

First, $b_{+,m}$ and $b_{-,m}$ are E-linearly independent. A relation $cb_{+,m} + db_{-,m} = 0$ gives $g(s)(cs^m + d(1 - s)^m) = 0$. On the nonempty open set on which g does not vanish the polynomial factor vanishes, so that polynomial is identically zero. Evaluation at $s=0$ gives $d=0$; evaluation at $s=1$ gives $c=0$. Tensoring this two-dimensional E-subspace with R is injective because vector spaces split over E . Therefore δ_m is injective.

Here are the exact polynomial coefficients used for its composite:

$$A_m(s) = \sum_{k=0}^{m-1} \binom{m+k-1}{k} s^k, \quad B_m(s) = \frac{1 - A_m(s)(1 - s)^m}{s^m}.$$

The power series $(1 - s)^{-m}$ has coefficients $\binom{m+k-1}{k}$, so its truncation A_m gives a numerator divisible by s^m . Thus B_m is a polynomial and

$$B_m a_m + A_m v_m = 1.$$

The germ g is a non-zero-divisor. Consequently $\beta \delta_m(f, h) = 0$ is equivalent to $a_m f = v_m h$. Set $r = B_m h + A_m f$. Then

$$v_m r = B_m v_m h + A_m v_m f = B_m a_m f + A_m v_m f = f,$$

$$a_m r = B_m a_m h + A_m a_m f = B_m a_m h + A_m v_m h = h.$$

Conversely $(f, h) = (v_m r, a_m r)$ has $a_m f - v_m h = 0$. The parametrization is injective because its two coefficients generate the unit ideal. Hence

$$\boxed{\ker \delta_m = 0, \quad \ker(\beta \delta_m) = R(v_m, a_m).}$$

In particular

$$\boxed{z_m = v_m \otimes b_{+,m} - a_m \otimes b_{-,m} \neq 0, \quad \beta z_m = 0.}$$

This proves the exact all-order extension of A1361's $m=1$ witness.

Its support is not optional. Let $L = \mathcal{P}(\{+, -\})$, with empty mask corresponding to external absence. On the $+$ face δ_m is $f \mapsto f \otimes b_{+,m}$; on the $-$ face it is $h \mapsto -h \otimes b_{-,m}$; on the joint face it is the map above. All maps retain their masks. The raw maps on either singleton face, and their Mellin composites, are injective because $b_{\pm,m}$ and ga_m, gv_m respectively are nonzero. The new syzygy occurs only in the joint face. Its lifted image is

$$(\{+, -\}, z_m) \mapsto (\{+, -\}, 0),$$

not τ . At $m=0$ the two source images coincide, and the raw map already has kernel $R(1,1)$; thus $m=0$ is not falsely included in the new-relation assertion.

This result excludes a quasi-isomorphism of these particular raw complexes: the first H^0 is zero while the second H^0 is R . It says nothing by itself about nonvanishing of the full realized H^1 kernel; that different calculation is given in Section 211.5.

211.4 Operator balancing removes the raw tensor relation, and retains honest joint cycles

Let $A = E[t]$. On $\mathcal{B}$ let t act by D , and on R let t act by multiplication by s . The quotient map

$$\pi_{\text{bal}} : R \otimes_E \mathcal{B} \longrightarrow R \otimes_A \mathcal{B}$$

imposes the R -linear span of the actual relations

$$sh \otimes F - h \otimes DF.$$

These are Mellin-null because $\mathcal{M}(DF) = s\mathcal{M}F$.

For every $j \geq 1$, the exact telescoping identity is

$$h \otimes D^j b_* - h s^j \otimes b_* = \sum_{k=0}^{j-1} \left(h s^k \otimes D^{j-k} b_* - h s^{k+1} \otimes D^{j-k-1} b_* \right).$$

Each summand is the negative of a displayed elementary balancing relation. Applying this identity to all coefficients of the original polynomials t^m and $(1-t)^m$ proves

$$\pi_{\text{bal}}(h \otimes P(D)b_*) = hP(s) \otimes b_* \quad (P \in E[t]).$$

It follows without removing any sign that

$$\pi_{\text{bal}}(z_m) = v_m a_m \otimes b_* - a_m v_m \otimes b_* = 0.$$

More explicitly, with $\Delta_P = 1 \otimes P(D)b_* - P(s) \otimes b_*$,

$$z_m = v_m \Delta_{t^m} - a_m \Delta_{(1-t)^m}.$$

The coefficients of $(1-t)^m$ remain $(-1)^j \binom{m}{j}$.

Balancing is not a reason to erase genuine degree-zero cycles in the original two-leg source. The exact saturated source calculation makes this precise. On the plus leg let t act by D ; on the minus leg let t act by $1 - D$. These are the infinitesimal actions induced by primary (34), since the minus scaling is $aU_{1/a}$. Define

$$\begin{aligned} i_{+,m} : A &\longrightarrow V, & P &\longmapsto P(D)D^m \phi_*, \\ i_{-,m} : A &\longrightarrow V, & Q &\longmapsto Q(1-D)D^m \phi_*. \end{aligned}$$

They are injections. Indeed, Θ applied to the first has Mellin transform $P(s)s^m g$; $J\Theta$ applied to the second has transform $Q(s)(1-s)^m g$, and polynomial multiplication by either nonzero entire function

is injective. Let Ab_* be the cyclic A -submodule of $\mathcal{B}$ generated by b_* . It too is free rank one because $P(D)b_* = 0$ implies $P(s)g(s)=0$ and therefore $P=0$.

The original two-leg differential restricted to these saturated subspaces is therefore exactly

$$C_m^{\text{cyc}} = \left[A^2 \xrightarrow{(P,Q) \mapsto (t^m P - (1-t)^m Q)b_*} Ab_* \right].$$

Fourier supplies the minus term:

$$J\Theta(Q(1-D)D^m\phi_*) = Q(D)(1-D)^m b_*.$$

The same Bezout polynomials show the differential is onto and that its kernel is $A((1-t)^m, t^m)$. Hence

$$\boxed{H^0(C_m^{\text{cyc}}) = A((1-t)^m, t^m), \quad H^1(C_m^{\text{cyc}}) = 0.}$$

This cycle is an actual Fourier-compatible two-leg cycle before Mellin realization. It is not a spurious raw tensor relation.

The A -module R is torsion-free: multiplication by a nonzero polynomial $P(s)$ is injective in the analytic domain R . A torsion-free module over a PID is flat. One direct proof writes it as the directed union of its finitely generated submodules; those submodules are finitely generated torsion-free modules over a PID and hence free, and tensoring commutes with directed colimits. A filtered colimit of exact sequences of modules is exact. Thus R is flat, and tensoring the displayed exact cyclic sequence gives

$$H^0(R \otimes_A C_m^{\text{cyc}}) = R((1-s)^m, s^m), \quad H^1 = 0.$$

No joint H^0 has been lost.

For completeness, its analytic comparison has $\beta_{\text{cyc}}(h \otimes b_*) = hg$ and identity in degree zero:

$$[R^2 \xrightarrow{a_m f - v_m h} Rb_*] \longrightarrow [R^2 \xrightarrow{g(a_m f - v_m h)} R].$$

The degree-one map $\times g$ is injective with cokernel $R/(g)$, and the degree-zero map is identity. Hence there is an exact sequence of these cochain complexes whose quotient is $R/(g)$ concentrated in degree one. The induced map on H^0 is identity on the displayed R -syzygy; the analytic target has $H^1 = R/(g)$. This calculation locates precisely what changes for this saturated cyclic subcomplex.

The cyclic subcomplex is not the full theta complex. Its inclusion is the literal pair $(i_{+,m}, i_{-,m})$ in degree zero and $Ab_* \hookrightarrow \mathcal{B}$ in degree one, and its differential is the restriction just proved. Extending these maps to the corresponding supported faces retains all masks. No equality with the full balanced kernel has been inferred.

211.5 An explicit free submodule in the raw realization kernel

This makes A1427's nonvanishing statement constructive with the actual finite-jet maps.

Let Z be any finite set of actual zeros of g , with their actual positive multiplicities m_ρ . Retain the complete jet space

$$A_Z = \bigoplus_{\rho \in Z} E[z_\rho]/(z_\rho^{m_\rho}), \quad z_\rho = s - \rho,$$

and the primary map

$$J_Z : Q \longrightarrow A_Z, \quad [F] \longmapsto \left(\sum_{j < m_\rho} \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} z_\rho^j \right)_\rho.$$

The source's smooth compactly supported right inverse can be written in its original measure. Fix $0 < R' < R_0$, let

$$\eta(y) = \begin{cases} \exp(-1/(R'^2 - y^2)), & |y| < R', \\ 0, & |y| \geq R', \end{cases}$$

and for $\alpha = (\rho, j)$ put

$$r_\alpha(x) = x^{\bar{\rho}-1} \frac{(\log x)^j}{j!},$$

$$B_{\alpha\beta} = \frac{1}{j!k!} \int_{-R'}^{R'} \eta(y) e^{(\rho+\bar{\sigma}-1)y} y^{j+k} dy \quad (\beta = (\sigma, k)).$$

For a coefficient vector c ,

$$c^* B c = \int_{-R'}^{R'} \eta(y) e^{-y} \left| \sum_{\alpha} \bar{c}_{\alpha} e^{\rho y} \frac{y^j}{j!} \right|^2 dy.$$

The exponential polynomials with distinct exponents and all orders below the retained multiplicities are linearly independent on every open interval. To verify this, a vanishing sum is an entire function of y and vanishes identically. For a selected exponent ρ , applying $\prod_{\sigma \neq \rho} (\partial_y - \sigma)^{m_{\sigma}}$ kills the other blocks. On $e^{\rho y} P_{\rho}(y)$, each factor becomes $(\partial_y + \rho - \sigma)^{m_{\sigma}}$ on the polynomial P_{ρ} ; its constant term is nonzero, and in the degree-ordered polynomial basis its matrix is triangular with nonzero diagonal. Its product is therefore invertible. Thus $P_{\rho} = 0$ for each ρ . Since η is positive on the interval, $c^* B c = 0$ forces $c=0$. Hence B is positive definite and invertible.

For $v \in A_Z$ define

$$F_v(x) = \eta(\log x) \sum_{\beta} (B^{-1}v)_{\beta} r_{\beta}(x).$$

It lies in $C_c^{\infty}((e^{-R_0}, e^{R_0})) \subset \mathcal{B}$. Substituting $x = e^y$ in each Mellin derivative gives $J_Z[F_v] = v$, with exactly the displayed factorials and exponent -1 . Thus

$$s_Z : A_Z \longrightarrow Q, \quad v \longmapsto [F_v]$$

is an explicit E -linear section of J_Z . It is not asserted to be equivariant under scaling; that additional property is neither needed nor inferred.

At each analytic stalk retain

$$\bar{\beta} : R \otimes_E Q \longrightarrow R/(g), \quad h \otimes [F] \longmapsto [h M F], \quad K_{\text{raw}} = \ker \bar{\beta}.$$

Define

$$\boxed{\iota_Z : R \otimes_E A_Z \longrightarrow K_{\text{raw}}, \quad h \otimes v \longmapsto g h \otimes s_Z(v).}$$

The image is in the kernel because its Mellin evaluation is a multiple of g . If $\iota_Z(w) = 0$, applying $1 \otimes J_Z$ gives $g w = 0$ in $R \otimes_E A_Z$. This latter module is free of rank $\sum_{\rho \in Z} m_{\rho}$, and g is a non-zero-divisor. Thus $w=0$. Therefore ι_Z is an injective R -linear map.

This gives an explicit free rank- $\sum_{\rho \in Z} m_{\rho}$ submodule of the raw kernel for every nonempty retained packet Z . The map is natural under stalk restriction for the fixed smooth section. Every derivative direction below each actual multiplicity appears in its domain. In particular the proof does not merely cite existence of a Hamel basis for Q or reduce the packet to its values.

At each original nonempty support mask L , lift the map as

$$(L, w) \longmapsto (L, \iota_Z w),$$

with $\tau \mapsto \tau$. It remains injective, retains its labelled zero, and commutes with the identity transports among the primary nonempty H^1 fibres. The target is the all-support realization-kernel fibre, not an identification with external absence.

Neither this free raw submodule nor the balancing calculation proves that the global balanced kernel is nonzero or zero. They prove the exact raw obstruction and the exact repair of its exhibited operator relation. The surviving full map is

$$\mathcal{O} \otimes_{E[t]} Q \longrightarrow \mathcal{O}/(g),$$

together with its actual kernel and the original strong-Schwartz/quotient topology. It must be connected through the original A_τ and K_τ ; the present calculations have made no replacement of those objects.

211.6 Source pins and transcript locators

The complete primary source was read: Tau_Base_Cohomology_2026-09-12/NOTE.md, SHA-256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3. The canonical route was read completely, SHA-256 a8cdd18817a2c3596778c60a04ef9d76125a03ae5404759835a2bc2b18fa4c74.

The all-order calculation answers A1361 (node c9e551ee-298f-438b-9bdc-2e23c2c0613a), source Section 1, and A1427 (node d7e752ce-cb39-4130-b089-b20333037990), source Section 4, while retaining A1304's actual two-leg source. The smooth section retains A1167 (node 157eecd7f96-4ec5-96bd-6dd376276ea6), source Section 5, with its original measure, factorials, and full jet orders. These are exact transcript UUID locators; line endings of the readable extraction were repaired during the audit without changing message text.

These are written proofs. No Lean session, remote write, numerical zero computation, or independently rerun historical checker is claimed.

212 Exact weighted theta-source constants

This calculation finishes the finite moment reduction left explicit in U0065/A2497 and U0066/A2559 of the retained transcript. It calculates the weighted-source Grams controlling the circle length, and the derivative Grams controlling its Fourier cutoff, on the original theta source. It supplies no asymptotic bound on their growing-degree inverses.

212.1 Original objects and domains

Retain the source's actual finite packet polynomial $h(s) = \prod_{\rho \in Z} (s - \rho)^{m_\rho}$, with the full selected orders, $g = 2\xi$, and its specified inverse Mellin representative $F_h \in \mathcal{B}$, where

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{x>0} x^b |(-x\partial_x)^j F(x)| < \infty \text{ for every } b \in \mathbb{Z}, j \geq 0\}.$$

Write $v_h(s) = \mathcal{M}F_h(s) = g(s)/h(s)$, $\mathcal{M}F(s) = \int_0^\infty F(x)x^s dx/x$, and $D = -x\partial_x$. For $k \geq 1$, set

$$c = k/2, \quad D^{(k)} = \sum_{j=1}^k D_j, \quad \mathcal{V}P = P(D^{(k)})F_h^{\otimes k}, \quad S = \sum_{j=1}^k s_j. \quad (1)$$

The polynomial source of degree at most N is $\mathcal{P}_N$, with the original basis $1, S, \dots, S^N$. Its arithmetic quotient map is the unchanged remainder map $J_N : \mathcal{P}_N \rightarrow E = \mathbb{C}[S]/(\chi_{h,k})$. Its full observation is

$$J^{(k)}\mathcal{V} = \eta_{h,k}J_N, \quad \eta_{h,k}[P] = v_h^{\otimes k}P(A_h^{(k)})1, \quad v_h = j_h(g/h). \quad (2)$$

No coefficient of this unit is changed by the calculations below.

The original half-density coordinates are

$$r = \log x_k, \quad z_i = \log x_i - \log x_k \ (i < k), \quad (3)$$

and

$$(\mathcal{U}_k F)(r, \mathbf{z}) = e^{(kr + \sum_{i < k} z_i)/2} F(e^{r+z_1}, \dots, e^{r+z_{k-1}}, e^r). \quad (4)$$

The coordinate inverse in (3) has determinant one in logarithmic coordinates. Consequently (4) is an isometry from $L^2((0, \infty)^k, d^k x)$ to $L^2(\mathbb{R}, dr; L^2(\mathbb{R}^{k-1}, d\mathbf{z}))$, and $\partial_r \mathcal{U}_k = -\mathcal{U}_k(D^{(k)} - c)$. These statements follow by substitution in the measure and by the chain rule, respectively; for $k = 1$ the relative space is $\mathbb{C}$.

212.2 Weighted lines and exact finite moments

For every real a , define

$$w_a(t) = \frac{|v_h(1/2 + a + it)|^2}{2\pi}, \quad \mu_j(a) = \int_{\mathbb{R}} t^j w_a(t) dt, \quad \mathcal{M}_a(z) = \sum_{j \geq 0} \mu_j(a) \frac{z^j}{j!}. \quad (5)$$

The last expression is a formal series: each coefficient below uses only finitely many of its entries. No analytic convergence assertion about that series is needed.

All the integrals in (5) are finite. Indeed, for any real σ and nonnegative integers b, j , $y^b \partial_y^j (e^{\sigma y} F_h(e^y))$ decays exponentially at both ends. To check this, expand the derivative into finitely many terms $e^{\sigma y} D^l F_h(e^y)$, use a positive integer exponent larger than σ at $+\infty$, and an integer exponent less than σ at $-\infty$ in the definition of $\mathcal{B}$. Any polynomial in y is absorbed by the resulting strict exponential margins. Thus $e^{\sigma y} F_h(e^y)$ is Schwartz. Its Fourier transform with kernel e^{ity} is exactly $v_h(\sigma + it)$, which is therefore Schwartz on that line.

Let

$$m_{k,a} = w_0^{*(k-1)} * w_a, \quad \mu_j^{(k,a)} = j! [z^j] \mathcal{M}_0(z)^{k-1} \mathcal{M}_a(z), \quad (6)$$

where the exponent zero in the case $k = 1$ means the identity for convolution. Expansion of $(t_1 + \dots + t_k)^j$, with Fubini justified by absolute polynomial moments, proves $\mu_j^{(k,a)} = \int t^j m_{k,a}(t) dt$.

Theorem 212.1 (The actual weighted source Gram). For $P, Q \in \mathcal{P}_N$, the original weighted observation is

$$\begin{aligned} M_{k,N}(a)(P, Q) &:= \int_{(0, \infty)^k} x_k^{2a} \overline{\mathcal{V}P(\mathbf{x})} \mathcal{V}Q(\mathbf{x}) d^k x \\ &= \int_{\mathbb{R}} \overline{P(c + a + iu)} Q(c + a + iu) m_{k,a}(u) du. \end{aligned} \quad (7)$$

In the unchanged basis $1, S, \dots, S^N$, its entries are exactly

$$[M_{k,N}(a)]_{b,d} = \sum_{r=0}^b \sum_{s=0}^d \binom{b}{r} \binom{d}{s} (c+a)^{b+d-r-s} (-i)^r i^s (r+s)! [z^{r+s}] \mathcal{M}_0^{k-1} \mathcal{M}_a. \quad (8)$$

In particular these matrices require only $\mu_j(0), \mu_j(a)$ for $0 \leq j \leq 2N$. Their masses are

$$[M_{k,N}(a)]_{0,0} = \mu_0(0)^{k-1} \mu_0(a). \quad (9)$$

Proof. Put $y_j = \log x_j$, use $\sigma_j = 1/2$ for $j < k$ and $\sigma_k = 1/2 + a$, and apply ordinary Fourier Plancherel to $e^{\sum_j \sigma_j y_j} \mathcal{V}P(e^{\mathbf{y}})$. Integration by parts has no boundary term by the estimates just proved. It sends each D_j to multiplication by $s_j = \sigma_j + it_j$. Hence its Fourier transform is

$$P(c + a + i \sum_j t_j) \prod_{j < k} v_h(1/2 + it_j) v_h(1/2 + a + it_k).$$

The factor $(2\pi)^{-k}$ in Plancherel is exactly the product of the $(2\pi)^{-1}$ factors in (5). Expanding the complex inner product and integrating over the sum coordinate proves (7). The binomial formula for each original monomial gives (8), including both phases. Formula (9) is its constant entry. In particular the shift $c+a$ has not been replaced by c , and the sum has not been replaced by an average. $\square$

Each matrix $M_{k,N}(a)$ is positive definite. The entire nonzero Mellin function v_h has isolated zeros on each vertical line, so $w_a > 0$ almost everywhere. For $k \geq 2$, a convolution in (6) is positive at every real sum: for almost every choice of the first $k-1$ variables all factors of its integrand are positive. For $k=1$, the almost-everywhere positivity suffices. A nonzero polynomial has only finitely many zeros on the integration line in (7), so its squared norm is strictly positive.

Let $M = M_{k,N}(0)$. The constants required by A2497 and A2559 are therefore the explicitly defined finite-matrix values

$$\kappa_{a,N} = \lambda_{\max}(M^{-1}(M_{k,N}(a) + M_{k,N}(-a))), \quad a > 0, \quad (10)$$

where eigenvalues are understood in the positive inner product M . In particular there is a fully specified upper value avoiding an additional extreme-eigenvalue calculation:

$$0 < \kappa_{a,N} \leq \mathfrak{k}_{a,N} := \text{Tr}(M^{-1}(M_{k,N}(a) + M_{k,N}(-a))). \quad (11)$$

To prove (11), conjugate by $M^{1/2}$; the resulting matrix is positive, and each eigenvalue is at most the sum of its eigenvalues. The congruence is used to prove the inequality, not to replace the source basis or its metric. With $\kappa_{\pm} = \lambda_{\max}(M^{-1}M_{k,N}(\pm a))$, the same argument gives the individual upper values $\text{Tr}(M^{-1}M_{k,N}(\pm a))$.

212.3 Derivative and Fourier-cutoff Grams, including the cross terms

Write

$$a_h(t) = v_h(1/2 + it)/\sqrt{2\pi}, \quad n(t) = |a'_h(t)|^2, \quad b(t) = \overline{a'_h(t)}a_h(t). \quad (12)$$

All three measures $w_0(t)dt, n(t)dt, b(t)dt$ have finite absolute polynomial moments by the same Schwartz argument. The last is a complex measure; it is not replaced by a positive one. Define

$$\begin{aligned} m_k &= w_0^{*k}, & n_k &= w_0^{*(k-1)} * n, & b_k &= w_0^{*(k-1)} * b, \\ \mathcal{N}(z) &= \sum_{j \geq 0} \int t^j n(t) dt \, z^j / j!, & \mathcal{C}(z) &= \sum_{j \geq 0} \int t^j b(t) dt \, z^j / j!. \end{aligned} \quad (13)$$

Let $p \geq 1$, $R_P(S) = (S - c)^p P(S)$, and let primes on R_P mean polynomial derivatives in the unchanged coordinate S . The derivative Gram in A2497/A2559 is

$$H_{p,N}(P, Q) = \int_{\mathbb{R} \times \mathbb{R}^{k-1}} (1 + r^2) \overline{\partial_r^p \mathcal{U}_k} \mathcal{V} P \, \partial_r^p \mathcal{U}_k \mathcal{V} Q \, dr \, d\mathbf{z}. \quad (14)$$

Theorem 212.2 (Complete derivative Gram). With all polynomials in the following formula evaluated at $c + iu$,

$$\begin{aligned} H_{p,N}(P, Q) &= \int_{\mathbb{R}} (\overline{R_P} R_Q (m_k + n_k) + \overline{R'_P} R'_Q m_k \\ &\quad + i \overline{R_P} R'_Q b_k - i \overline{R'_P} R_Q \overline{b_k})(u) \, du. \end{aligned} \quad (15)$$

Every entry is a finite expression in the moments encoded by $\mathcal{M}_0^k$, $\mathcal{M}_0^{k-1} \mathcal{N}$, and $\mathcal{M}_0^{k-1} \mathcal{C}$, through degree $2(N + p)$.

Proof. The chain rule in (4) gives $\partial_r^p \mathcal{U}_k \mathcal{V} P = (-1)^p \mathcal{U}_k \mathcal{V} R_P$. The two occurrences of $(-1)^p$ cancel in (14). The term without r^2 is (7) at $a = 0$, with polynomial R_P . For the second term return to the independent logarithmic coordinates $y_1, \dots, y_k$; its multiplier is exactly $r = y_k$. For the Fourier kernel $e^{i \sum t_j y_j}$, multiplication by y_k transforms to $-i \partial_{t_k}$. The factor $-i$ cancels against its conjugate in the inner product. After retaining the Plancherel constants in the product of the a_h 's, the differentiated last factor is

$$a'_h(t_k) R_P(c + i \sum_j t_j) + i a_h(t_k) R'_P(c + i \sum_j t_j).$$

Multiplication by its conjugate for P and by the displayed expression for Q gives, respectively, the n_k term, the derivative m_k term, and the cross terms $+i \overline{R_P} R'_Q b_k$ and $-i \overline{R'_P} R_Q \overline{b_k}$. Integrating the other variables gives (15). Expansion in powers of the sum and Fubini prove the stated coefficient products. The largest degree occurs in $\overline{R_P} R_Q$ and is at most $2(N + p)$. $\square$

212.4 A finite choice of comparison parameters and its exact scope

Set

$$\mathfrak{h}_{p,N} = \text{Tr}(M^{-1} H_{p,N}) \geq 0. \quad (16)$$

Both sides in (16) are defined on the original coefficient space. The same positive-matrix argument used for (11) gives $H_{p,N} \preceq \mathfrak{h}_{p,N} M$. Here are the explicit parameters obtained from these completed calculations. For prescribed positive error contributions η_1, η_2 , choose

$$L \geq a^{-1} \log(1 + \mathfrak{k}_{a,N}/\eta_1), \quad (17)$$

and, for the twisted lattice used by all scalar holonomy phases, take an integer

$$J \geq \max \left\{ 2, 1 + \frac{L}{2\pi} \left(\frac{\mathfrak{h}_{p,N}}{(2p-1)\eta_2} \right)^{1/(2p-1)} \right\}. \quad (18)$$

The ordinary lattice can omit the extra one; it has denominator J instead of $J - 1$.

For completeness, the source estimates underlying this parameter choice have direct proofs. Write $\Psi = \mathcal{U}_k \mathcal{V}$ and $\mathcal{C}(s) = \int \Psi(r)^* \Psi(r+s) dr$. Weighted Cauchy–Schwarz gives, for $s > 0$,

$$|v^* \mathcal{C}(s) v| \leq e^{-as} \sqrt{v^* M_{k,N}(-a) v \, v^* M_{k,N}(a) v}.$$

The negative shifts exchange the two weights. Unfolding one period gives the Gram difference as the sum of the nonzero correlations at shifts mL ; holonomy only multiplies each by a unit complex number. Summing the geometric series and using $2\sqrt{xy} \leq x + y$ proves its absolute quadratic-form bound $(M_{k,N}(a) + M_{k,N}(-a))/(e^{aL} - 1)$. This is at most $\eta_1 M$ by (11) and (17).

Integration by parts p times in the retained Fourier transform, then Cauchy–Schwarz with $\int (1 + r^2)^{-1} dr = \pi$, gives $\|\widehat{\Psi} v(u)\|^2 \leq \pi |u|^{-2p} v^* H_{p,N} v$. For the ordinary lattice, summing $|n| > J$ and bounding $\sum_{n>J} n^{-2p} \leq J^{1-2p}/(2p-1)$ gives

$$0 \preceq M(L) - M(L, J) \preceq \frac{1}{2p-1} \left(\frac{L}{2\pi J} \right)^{2p-1} H_{p,N}. \quad (19)$$

The constants arise from π/L in each Fourier coefficient and the two lattice directions; thus the factor in (19) is literal. For phases $0 \leq \theta < 2\pi$, $|n + \theta/(2\pi)| \geq |n| - 1$ for the omitted indices. Repeating the integral bound replaces J by $J - 1$, and (18) makes this at most $\eta_2 M$. With $\eta_1 + \eta_2 < 1$, the resulting finite source Gram lies between $(1 - \eta_1 - \eta_2)M$ and $(1 + \eta_1 + \eta_2)M$.

For this quotient conclusion put $q = \deg \chi_{h,k}$ and take $N \geq q - 1$, so the unchanged remainder map is onto E . Taking the infimum over the unchanged affine sets $\{P : J_N P = v\}$ gives the same inequalities for the canonical quotient Grams. Their sections differ by the original $\ker J_N = \chi_{h,k} \mathcal{P}_{N-q}$,

with $\mathcal{P}_{-1} = 0$, hence by the original theta relations under (1)–(2). At a retained support label that correction maps to its supported zero; it never becomes external absence.

These estimates compute the finite error parameters from the actual one-factor shifted Mellin moments and their full derivative cross terms. They do not bound $\mathfrak{k}_{a,N}$ or $\mathfrak{h}_{p,N}$ uniformly as k, N grow. For the original four endpoints, one may use $N = 2q_k + 2$ in (17)–(18), exactly as in A2497; all smaller polynomial spaces are restrictions of that single source. The inverse M^{-1} and every original mass remain visible, so this result cannot be mistaken for the missing sub-threshold determinant estimate.

Finally, the weighted observations are norms of the already specified representatives, not new maps identifying the arithmetic cohomology with the Boolean stalk. In the primary Tau Base source the cohomology is $A_\tau = R\Gamma(P, -)$, its right adjoint is $K_\tau(W) \simeq S_\eta W[1]$, and its actual top tensor quotient is $Q^{\otimes k}$. Equations (1)–(2) remain the same finite source and full arithmetic observation into that construction. Multiplying the source norm by x_k^{2a} has not been asserted to descend as an endomorphism of $Q^{\otimes k}$.

213 Circle resolvent with all arithmetic jets

U0065/A2470 promised a resolvent derived from theta boundaries. The subsequent A2497 and its retained note calculate the first- and second-order source defects. This note completes the resolvent calculation from those exact defects, including the resonant case. It makes no purity inference from the circle spectrum.

213.1 Original operator and its domain

Fix $k \geq 1$, $L > 0$, $c = k/2$, and the relative Hilbert space $\mathcal{K} = L^2(\mathbb{R}^{k-1})$; for $k = 1$ use $\mathcal{K} = \mathbb{C}$. The scalar holonomy phase is $0 \leq \theta < 2\pi$. Let

$$\mathcal{H} = L^2([0, L]; \mathcal{K}), \quad \mathcal{D} = -\partial_r + c, \quad \text{Dom } \mathcal{D} = \{f \in H^1([0, L]; \mathcal{K}) : f(L) = e^{-i\theta} f(0)\}. \quad (1)$$

The original orthonormal scalar functions are $e_n(r) = L^{-1/2} e^{-i\omega_n r}$, $\omega_n = (2\pi n + \theta)/L$. Fourier series, including $n = 0$, identify (1) with the diagonal

$$\mathcal{D}(e_n \otimes v) = (c + i\omega_n) e_n \otimes v, \quad \sum_n (1 + \omega_n^2) \|f_n\|_{\mathcal{K}}^2 < \infty. \quad (2)$$

In particular (1) is closed and normal: the adjoint of the diagonal has conjugate entries and the same domain. Its spectrum is exactly $\{c + i\omega_n : n \in \mathbb{Z}\}$. To check the last assertion, each listed value has its nonzero eigenvectors, while at any other complex number z the inverse diagonal is bounded and maps onto the stated domain. Its exact operator norm is

$$\|T(z)\| = \delta(z)^{-1}, \quad T(z) = (\mathcal{D} - z)^{-1}, \quad \delta(z) = \min_{n \in \mathbb{Z}} |c + i\omega_n - z| > 0. \quad (3)$$

The minimum exists because the distances tend to infinity. Equality in the norm follows by taking any unit vector in a minimizing mode.

Retain the actual cyclic packet $E = \mathbb{C}[S]/(\chi_{h,k})$, $A = M_S$, and the phase-periodized canonical representative $R : E \rightarrow \mathcal{H}$. Its source is still $P(D_1 + \cdots + D_k)F_h^{\otimes k}$, with $\mathcal{M}F_h = 2\xi/h$, and full arithmetic observation $v_h^{\otimes k} P(A_h^{(k)})1$. Use an admitted finite degree $N \geq \deg \chi_{h,k} - 1$. For this source comparison choose the circle length by the proved formula (17) of `shifted_mellin_source_constants.tex`, with $a = 1$ and $\eta_1 = 1/2$: thus $L \geq \log(1 + 2\mathfrak{k}_{1,N})$. Its phase source Gram is at least one half of the positive original Gram. Periodization is therefore injective on the admitted polynomial

source; composing with the canonical section proves that R is injective. It has values in every twisted Sobolev domain, and the actual theta boundary is

$$B = \mathcal{D}R - RA. \quad (4)$$

It is the scalar-holonomy periodization of the retained source vector $D^{(k)}r_N - r_N A = dK_N^{\text{prim}}$, not the zero vector obtained after applying its arithmetic quotient.

213.2 The resolvent comparison and the complete nonresonant packet

For z outside both spectra, the exact comparison is

$$T(z)R - R(A - z)^{-1} = -T(z)B(A - z)^{-1}. \quad (5)$$

Indeed, (4) says $(\mathcal{D} - z)R = R(A - z) + B$. Multiplying on the left by $T(z)$ and on the right by $(A - z)^{-1}$ gives (5), including its minus sign. All products are defined because E is finite dimensional and $R(E) \subset \text{Dom } \mathcal{D}$.

For a complete primary block $E_\lambda \subset E$, put $N_\lambda = (A - \lambda)|_{E_\lambda}$ and retain its full length r , so $N_\lambda^r = 0$. Restrict (4) to that block. If $\lambda \notin \text{Spec } \mathcal{D}$, it gives $R_\lambda = T(\lambda)R_\lambda N_\lambda + T(\lambda)B_\lambda$. Substitute this expression successively r times. Its last term contains N_λ^r and vanishes, giving the finite formula

$$R_\lambda = \sum_{j=0}^{r-1} T(\lambda)^{j+1} B_\lambda N_\lambda^j. \quad (6)$$

No jet was discarded: all r powers occur. Conversely the right side satisfies (4) on E_λ , by telescoping after multiplication by $\mathcal{D} - \lambda$; the last nilpotent term is zero. It is the unique such solution, because the same iteration applied to a homogeneous solution makes that solution zero. For the original finite coefficient norm, (3) also proves

$$\|R_\lambda\| \leq \sum_{j=0}^{r-1} \delta(\lambda)^{-j-1} \|B_\lambda N_\lambda^j\|. \quad (7)$$

Thus the displayed map is a calculated reconstruction from the retained boundary, not a vanishing assertion.

In particular, for an actual eigenvector $0 \neq v \in E_\lambda$ with $N_\lambda v = 0$,

$$Rv = T(\lambda)Bv, \quad \frac{\|Bv\|}{\|Rv\|} \geq \delta(\lambda) \geq |\Re \lambda - k/2|. \quad (8)$$

The denominator is positive by the injectivity of the canonical source. The first inequality follows either from (3) or directly from (2). Every off-weight primary block is nonresonant, regardless of its imaginary part. Hence making its quotient boundary zero does not make its source boundary zero.

213.3 The resonant block with its full kernel and nilpotents

Suppose $\lambda = c + i\omega_{n_0}$. Let P be the orthogonal projection onto $e_{n_0} \otimes \mathcal{K}$, and write $Q = I - P$. On $Q\mathcal{H}$, the inverse

$$T_Q = (\mathcal{D} - \lambda)^{-1}|_{Q\mathcal{H}} \quad \text{has norm } L/(2\pi). \quad (9)$$

This follows from the nonzero distances $|\omega_n - \omega_{n_0}| = 2\pi|n - n_0|/L$. Projection of (4) and the same nilpotent iteration now yield

$$QR_\lambda = \sum_{j=0}^{r-1} T_Q^{j+1} QB_\lambda N_\lambda^j, \quad PB_\lambda = -PR_\lambda N_\lambda. \quad (10)$$

These are all components of the comparison; (9) has not been used on the resonant mode.

For clarity, write $\chi_{h,k} = (S - \lambda)^r h_\lambda$. The two displayed factors are relatively prime. Choose polynomials a_λ, b_λ with $a_\lambda(S - \lambda)^r + b_\lambda h_\lambda = 1$, and set $\varepsilon_\lambda = [b_\lambda h_\lambda]_{\chi_{h,k}}$. Its residues are one in the λ -local factor and zero in every other primary factor. The Chinese remainder map and its inverse therefore identify $E_\lambda = \varepsilon_\lambda E$ with $\mathbb{C}[S - \lambda]/((S - \lambda)^r)$. The actual embedded increasing power basis is $e_j = \varepsilon_\lambda(S - \lambda)^j$. Thus $N_\lambda e_j = e_{j+1}$ for $j < r - 1$, and $N_\lambda e_{r-1} = 0$. Write $X = PR_\lambda, Y = PB_\lambda$. Equation (10) says exactly

$$Y e_{r-1} = 0, \quad X e_{j+1} = -Y e_j \quad (0 \leq j < r - 1), \quad X e_0 \text{ is free in } P\mathcal{H}. \quad (11)$$

Necessity follows by applying $Y = -X N_\lambda$ to every basis vector. Conversely the values in (11) define a linear map satisfying that equation. Hence (11) proves both sufficiency and the complete freedom, with no assumed semisimplicity. The actual source supplies its particular $X e_0$. A squarefree sampled-value quotient would retain only a further observation of this data; it is not the map in (10)–(11).

213.4 The original Laplacian, including its two boundary terms

Set

$$\mathcal{L} = \mathcal{D}^2 - k\mathcal{D} = \partial_r^2 - k^2/4, \quad A^{\text{lap}} = A^2 - kA, \quad C = (\mathcal{D} - k)B + BA. \quad (12)$$

The domain of $\mathcal{L}$ is exactly

$$\{f \in H^2([0, L]; \mathcal{K}) : f(L) = e^{-i\theta} f(0), f'(L) = e^{-i\theta} f'(0)\},$$

equivalently the Fourier Sobolev domain of order two. Its eigenvalues are exactly $-\omega_n^2 - k^2/4$; the zeroth Fourier index remains included. Applying $\mathcal{D}$ to (4) and subtracting k times (4) proves

$$\mathcal{L}R - RA^{\text{lap}} = C. \quad (13)$$

In particular both terms of C in (12) are necessary. For z outside both relevant spectra, exactly the proof of (5) gives

$$(\mathcal{L} - z)^{-1}R - R(A^{\text{lap}} - z)^{-1} = -(\mathcal{L} - z)^{-1}C(A^{\text{lap}} - z)^{-1}. \quad (14)$$

On E_λ , retain

$$\mu = \lambda^2 - k\lambda, \quad M_\lambda = (2\lambda - k)N_\lambda + N_\lambda^2, \quad M_\lambda^r = 0. \quad (15)$$

If $\mu \notin \text{Spec } \mathcal{L}$, (13) gives the complete finite reconstruction

$$R_\lambda = \sum_{j=0}^{r-1} (\mathcal{L} - \mu)^{-j-1} C_\lambda M_\lambda^j. \quad (16)$$

The proof is the same finite substitution as (6). Formula (15) retains the exceptional coefficient $2\lambda - k$, including the case where it is zero, and retains the N_λ^2 term; it does not replace the original primary block by a simple root.

The linear source maps in (4)–(16) lift at each original support label as $(\ell, v) \mapsto (\ell, fv)$, with $\tau \mapsto \tau$. A source theta boundary has a supported-zero image under the original arithmetic quotient and retains its Hilbert vector in (6) or (10). Its necessary nonvanishing on each nonresonant eigenvector is proved by (8); the resonant boundary can vanish, with its full freedom given by (10)–(11). This resolves the promised resolvent calculation while proving its precise scope: a negative circle Laplacian controls its own resolvent and leaves the displayed arithmetic boundary terms. No bound for the four arithmetic quotient volumes follows by deleting those terms.

214 Exact fluid-cutoff transport into the retained theta complex

This is a completed calculation prompted by A0618, node ba85139d-2899-4a3b-b05e-9f30a7341c82, chain 1146, transcript-segment lines 2698–2818. That answer constructed an admissible cutoff test but left its equivariance and quotient class uncalculated. We calculate the exact scaling morphism and its image in the original theta complex; we do not assert a sign for its arithmetic pairing or replace the original fluid by a self-similar ansatz.

The arithmetic target is the original `Tau_Base_Cohomology_2026-09-12/NOTE.md`, SHA256 d03e71ad18f187bd89880cb8ca6fc9c5d6f260b3de8e8e5702c27db97e7b63c3: equations (10)–(14), (19)–(22), (32)–(45). All spaces and actions below retain those definitions. The factor connecting the early centered test with this target is an explicit invertible multiplication map, not an identification of their coordinates.

214.1 1. Original spaces and the cutoff map

Fix viscosity $\nu > 0$, a time interval I , and a smooth real vector field u on $\mathbb{R}^3 \times I$. Define $e_\theta = (-\sin \theta, \cos \theta, 0)$ and retain the **unaveraged** angular-momentum integral

$$a_u(r, t) = \int_0^{2\pi} r e_\theta \cdot u(r \cos \theta, r \sin \theta, 0, t) d\theta.$$

Let $\chi(r, t)$ be a smooth cutoff whose radial support is compact in $(0, \infty)$, locally uniformly in t . Set

$$D = r\partial_r, \quad b(r, t) = \chi(r, t)a_u(r, t), \quad g(r, t) = (D^2 - \tfrac{1}{4})b(r, t).$$

For every fixed t , $g_t \in C_c^\infty(\mathbb{R}_{>0})$. Define the original centered admissible space

$$\mathcal{T} = \{g \in C_c^\infty(\mathbb{R}_{>0}) : \int_0^\infty g(r)r^{1/2} dr/r = \int_0^\infty g(r)r^{-1/2} dr/r = 0\}.$$

The Mellin transform used in the tau source is $\mathcal{M}h(s) = \int_0^\infty h(r)r^s dr/r$. The support of b_t lies in some $[\alpha, \beta] \subset (0, \infty)$; it and every derivative vanish near both integration endpoints. Therefore, for every complex s ,

$$\mathcal{M}(Db)(s) = [b(r)r^s]_0^\infty - s\mathcal{M}b(s) = -s\mathcal{M}b(s),$$

and a second integration by parts gives

$$\mathcal{M}g(s) = (s^2 - \tfrac{1}{4})\mathcal{M}b(s). \quad (1)$$

At $s = \pm \frac{1}{2}$, this proves both admissibility equations, with all boundary terms zero for the stated support reason. Smooth parameter dependence follows by differentiation under the integral on each common compact support interval.

214.2 2. The explicit map to the original uncentered theta target

Retain the tau source's space

$$\mathcal{B} = \{F \in C^\infty(\mathbb{R}_{>0}) : \sup_{r>0} r^j |(-r\partial_r)^k F(r)| < \infty \text{ for all } j \in \mathbb{Z}, k \geq 0\}.$$

Multiplication defines a linear injection

$$\mathcal{C} : \mathcal{T} \longrightarrow \mathcal{B}, \quad (\mathcal{C}g)(r) = r^{-1/2}g(r). \quad (2)$$

Its image lies in $C_c^\infty \subset \mathcal{B}$, and its inverse on that image is multiplication by $r^{1/2}$. No endpoint extension is used. For $F = \mathcal{C}g$, equation (1) gives the exact entire identity

$$\boxed{\mathcal{M}F(s) = s(s-1)\mathcal{M}b(s - \tfrac{1}{2})}. \quad (3)$$

Thus the early two centered moment cancellations become the uncentered zeros at $s = 0, 1$, through the stated multiplication map.

The test space retains its usual inductive-limit topology over compact support intervals. On each such interval the multiplier $r^{-1/2}$ and all its derivatives are bounded; the product rule therefore bounds every displayed $\mathcal{B}$ seminorm by finitely many test-function seminorms. Thus (2) is continuous into $\mathcal{B}$. The quotient and adjoint calculations below retain the source's algebraic quotient and algebraic dual; they make no assertion that ΘV is closed or that this dual is the continuous dual of a completed quotient.

Retain the actual source spaces V , its Fourier transform with exponent $-2\pi i x \xi$, $\Theta\phi(r) = \sum_{n \neq 0} \phi(nr)$, $JF(r) = r^{-1}F(1/r)$, and

$$\mathbf{A}_\tau(\mathcal{T}) = [V \oplus V \xrightarrow{d} \mathcal{B}], \quad d(\phi, \psi) = \Theta\phi - J\Theta\psi, \quad Q = \mathcal{B}/\Theta V.$$

Formula (2) followed by the quotient map gives a concrete linear map $\mathcal{T} \rightarrow H^1 \mathbf{A}_\tau(\mathcal{T}) = Q$. It does not say that every input class is nonzero. Equation (3), and the full jet formula below, compute its actual finite arithmetic observations without making that assumption.

214.2.1 The early theta background and its exact factor of two

A0598 used $\mathcal{E}\phi(r) = r^{1/2} \sum_{n \geq 1} \phi(nr)$, whereas the retained tau source uses $\Theta\phi(r) = \sum_{n \neq 0} \phi(nr)$. For an even $\phi \in V$, pairing the terms $n, -n$ gives the exact identity

$$\mathcal{C}(\mathcal{E}\phi) = \frac{1}{2}\Theta\phi. \quad (3a)$$

Here multiplication $\mathcal{C}$ extends to the displayed smooth functions by its same formula; this sentence does not assert that the uncut $\mathcal{E}\phi$ belongs to the compactly supported domain $\mathcal{T}$. On every compact positive r -interval the Schwartz bounds permit termwise differentiation of the theta sum, giving $D\Theta\phi = \Theta(D\phi)$. The operator D preserves even Schwartz functions and $\phi(0) = 0$; integration by parts gives $\int_{\mathbb{R}} D\phi = -\int_{\mathbb{R}} \phi = 0$. It therefore preserves V . Direct differentiation of $r^{1/2}h$ gives

$$r^{-1/2}(D^2 - \frac{1}{4})(r^{1/2}h) = (D^2 + D)h.$$

Consequently the uncut background maps to the original theta relation

$$\mathcal{C}(D^2 - \frac{1}{4})\mathcal{E}\phi = \frac{1}{2}\Theta((D^2 + D)\phi) \in \Theta V. \quad (3b)$$

For a compact cutoff χ , the exact image instead is

$$\begin{aligned} \mathcal{C}(D^2 - \frac{1}{4})(\chi\mathcal{E}\phi) &= \frac{1}{2}\chi\Theta((D^2 + D)\phi) + (D\chi)\Theta(D\phi) \\ &\quad + \frac{1}{2}(D^2\chi + D\chi)\Theta\phi. \end{aligned} \quad (3c)$$

The first term still contains its cutoff; membership of the uncut theta image does not erase that factor. Thus (3c) retains all three pieces of the actual early cutoff background in the original Q , without assuming that any one belongs to the relation space.

214.3 3. Constant parabolic scaling, with the same viscosity

For a constant $\lambda > 0$, put

$$u_\lambda(x, t) = \lambda u(\lambda x, \lambda^2 t), \quad p_\lambda(x, t) = \lambda^2 p(\lambda x, \lambda^2 t), \quad f_\lambda(x, t) = \lambda^3 f(\lambda x, \lambda^2 t), \quad I_\lambda = \{t : \lambda^2 t \in I\}.$$

Differentiating each component gives

$$\partial_t u_\lambda = \lambda^3 \partial_t u, \quad (u_\lambda \cdot \nabla) u_\lambda = \lambda^3 (u \cdot \nabla) u, \quad \nabla p_\lambda = \lambda^3 \nabla p, \quad \Delta u_\lambda = \lambda^3 \Delta u, \quad \nabla \cdot u_\lambda = \lambda^2 \nabla \cdot u,$$

where the right sides are evaluated at $(\lambda x, \lambda^2 t)$. Consequently the forced equation $\partial_t u + (u \cdot \nabla)u = -\nabla p + \nu \Delta u + f$ is carried to that same equation with exactly the same ν . This is a map between fields at different coordinates, not an assertion that one fixed solution obeys a self-similarity identity.

Set $\chi_\lambda(r, t) = \chi(\lambda r, \lambda^2 t)$. Substitution in the unaveraged angular integral gives

$$a_{u_\lambda}(r, t) = \int_0^{2\pi} (\lambda r) e_\theta \cdot u(\lambda r \cos \theta, \lambda r \sin \theta, 0, \lambda^2 t) d\theta = a_u(\lambda r, \lambda^2 t).$$

The operator D commutes with $R_\lambda h(r) = h(\lambda r)$. Thus

$$b_\lambda(r, t) = b(\lambda r, \lambda^2 t), \quad g_\lambda(r, t) = g(\lambda r, \lambda^2 t). \quad (4)$$

At corresponding times the theta target satisfies

$$\boxed{F_\lambda = \lambda^{1/2} U_{1/\lambda} F, \quad \mathcal{M}F_\lambda(s) = \lambda^{1/2-s} \mathcal{M}F(s),} \quad (5)$$

where the source's action remains $U_a F(r) = F(r/a)$. Indeed $r^{-1/2} g(\lambda r) = \lambda^{1/2} (\lambda r)^{-1/2} g(\lambda r)$.

Equation (5) lifts to the **original two-leg chain map**

$$(\phi, \psi) \mapsto (\lambda^{1/2} U_{1/\lambda} \phi, \lambda^{-1/2} U_\lambda \psi), \quad F \mapsto \lambda^{1/2} U_{1/\lambda} F. \quad (6)$$

The first leg follows from $\Theta U_a = U_a \Theta$. On the second leg the source identity $U_a J = a J U_{1/a}$ gives $\lambda^{1/2} U_{1/\lambda} J \Theta = \lambda^{-1/2} J \Theta U_\lambda$. Both are therefore precisely the two terms of d , with the original minus sign retained. Each scaling preserves V , since the zero value and zero integral remain zero, and fixes every support mask. It consequently descends to Q . At σ the coefficient map remains the zero map on the zero coefficient space, with the original labelled support skeleton fixed; no class is deleted by this comparison.

214.4 4. Full actual-zero jets and the right-adjoint dual

Let $G(s) = 2\xi(s)$, and retain a finite reflection-stable set Z of actual zeros, with actual orders m_ρ . Write $z_\rho = s - \rho$, $A_Z = \bigoplus_{\rho \in Z} \mathcal{O}_\rho / (G)$, and let N_ρ denote multiplication by z_ρ . The finite observation is the source's map

$$(J_Z F)_\rho = \sum_{j=0}^{m_\rho-1} \frac{(\mathcal{M}F)^{(j)}(\rho)}{j!} z_\rho^j.$$

Equation (3) supplies every coefficient of this polynomial from the original cutoff b . In particular no unproved nonvanishing or simplicity assertion enters its definition. Expanding the exponential multiplier in (5) gives

$$\boxed{(J_Z F_\lambda)_\rho = \lambda^{1/2-\rho} \sum_{k=0}^{m_\rho-1} \frac{(-\log \lambda)^k}{k!} N_\rho^k (J_Z F)_\rho.} \quad (7)$$

Equivalently, coefficient j is

$$\lambda^{1/2-\rho} \sum_{k=0}^j \frac{(-\log \lambda)^k}{k!} \frac{(\mathcal{M}F)^{(j-k)}(\rho)}{(j-k)!}.$$

This retains all nilpotent jets, not only the residue-value eigenline.

The source computes $K_\tau(\mathcal{L}_1) = [I_\eta(\mathcal{L}_1) \rightarrow I_+(\mathcal{L}_1) \oplus I_-(\mathcal{L}_1)]$ in degrees $-1, 0$, with differential $(+\text{res}, -\text{res})$, and $H^{-1} R \text{Hom}(\mathcal{T}, K_\tau(\mathcal{L}_1)) = \text{Hom}(Q, \mathcal{L}_1)$. Thus the retained residue injection evaluates the computed class by

$$\bar{h} \mapsto \ell_h, \quad \ell_h([F]) = \sum_{\rho \in Z} \text{Res}_\rho \frac{h^\dagger(s) \mathcal{M}F(s)}{G(s)} ds, \quad h^\dagger(s) = \overline{h(1-\bar{s})}. \quad (8)$$

For a scaling packet $T_\lambda h(s) = \lambda^{1/2-s} h(s)$ in each local algebra,

$$(T_\lambda h)^\dagger(s) = \lambda^{s-1/2} h^\dagger(s).$$

Multiplying by the multiplier in (5) cancels these two displayed factors exactly. Hence the original residue pairing and its trace contraction are invariant:

$$R_Z(T_\lambda h, T_\lambda k) = R_Z(h, k), \quad R_Z(T_\lambda h, G' T_\lambda k) = R_Z(h, G' k). \quad (9)$$

The derivative multiplier G' commutes with T_λ , since both act by multiplication in the same local algebra. No phase changes the source's raw skew-Hermitian residue orientation; $\mathcal{L}_1$ has not been replaced by a different coefficient line. In particular (9) concerns the explicitly displayed transport $T_\lambda = \lambda^{1/2} U_{1/\lambda}$. The original uncentered action still has $R_Z(U_a h, U_a k) = a R_Z(h, k)$; here its factor $a = 1/\lambda$ cancels the two real scalar factors $\lambda^{1/2}$ carried by the two inputs.

214.5 5. The unchanged source Weil scalar is invariant under this transport

Retain exactly

$$(g_1 * g_2)(x) = \int_0^\infty g_1(y) g_2(x/y) dy/y, \quad g^*(x) = \overline{g(x^{-1})}.$$

Then

$$(g * g^*)(x) = \int_0^\infty g(y) \overline{g(y/x)} dy/y.$$

For $g_\lambda = R_\lambda g$, substitute $v = \lambda y$ to obtain

$$(g_\lambda * g_\lambda^*)(x) = \int_0^\infty g(v) \overline{g(v/x)} dv/v = (g * g^*)(x). \quad (10)$$

This is equality of the entire test function, before any arithmetic functional is applied. In particular it retains every prime term and the complete archimedean subtraction in

$$W_p(f) = (\log p) \sum_{m \geq 1} p^{-m/2} (f(p^m) + f(p^{-m})),$$

$$W_{\mathbb{R}}(f) = (\log 4\pi + \gamma) f(1) + \int_1^\infty (f(x) + f(x^{-1}) - 2x^{-1/2} f(1)) \frac{x^{1/2}}{x - x^{-1}} \frac{dx}{x}.$$

Therefore the source scalar $\sum_v W_v(g * g^*)$, whose required sign in A0618 is nonpositive under RH, is unchanged by (4) at corresponding times. No estimate, omitted boundary term, discarded prime or replacement norm proves this: equation (10) does.

214.6 6. Time-dependent concentration and its exact extra force

Let $\lambda(t) > 0$ and $s(t) \in I$ be smooth. Define

$$u^\#(x, t) = \lambda(t) u(\lambda(t)x, s(t)), \quad p^\#(x, t) = \lambda(t)^2 p(\lambda(t)x, s(t)),$$

and transport χ by the same arguments. Equations (4)–(10) still hold instantaneously with source time $s(t)$. They do not by themselves claim a fluid-equation intertwiner for this varying parameter.

Write $X = \lambda(t)x$ and $\mathcal{N}(u, p) = (u \cdot \nabla_X)u + \nabla_X p - \nu \Delta_X u$. Direct differentiation, using the original equation $\partial_s u + \mathcal{N}(u, p) = f$, yields the complete transformed force

$$\begin{aligned} & \partial_t u^\# + (u^\# \cdot \nabla_x) u^\# + \nabla_x p^\# - \nu \Delta_x u^\# \\ &= \lambda s' f(X, s) + (\lambda^3 - \lambda s') \mathcal{N}(u, p)(X, s) \\ &+ \frac{\lambda'}{\lambda} (u^\# + x \cdot \nabla_x u^\#). \end{aligned} \quad (11)$$

Indeed $\partial_t u^\# = (\lambda'/\lambda)(u^\# + x \cdot \nabla_x u^\#) + \lambda s' \partial_s u$, whereas each nonlinear, pressure and viscosity term carries λ^3 . This proves (11) term by term. Divergence is $\lambda^2 \nabla_X \cdot u$, so incompressibility is retained. If $s' = \lambda^2$, the middle term cancels and the remaining force is

$$\lambda^3 f(X, s) + \frac{\lambda'}{\lambda}(u^\# + x \cdot \nabla_x u^\#). \quad (12)$$

The second summand is a calculated force contribution; its endpoint regularity cannot be inferred from the original force's regularity.

For the test and theta amplitude, direct differentiation gives

$$\begin{aligned} \partial_t g^\# &= \frac{\lambda'}{\lambda} Dg^\# + s' R_\lambda \partial_s g, \\ \partial_t F^\# &= \frac{\lambda'}{\lambda} (D + \tfrac{1}{2}) F^\# + s' \lambda^{1/2} U_{1/\lambda} \partial_s F. \end{aligned} \quad (13)$$

Writing w for the Mellin variable in this sentence, to distinguish it from the source-time function $s(t)$, the first transformed generator is exactly $(\lambda'/\lambda)(\frac{1}{2} - w)$; on the ρ -jet it is $(\lambda'/\lambda)((\frac{1}{2} - \rho)I - N_\rho)$. Equation (10) shows at each time that the transported Weil scalar equals the source scalar at $s(t)$. Thus parameter variation in λ alone contributes zero to that scalar, whereas changes in the actual source profile or a cutoff not transported by this formula need their own calculation.

214.7 Proven scope

We have completed the exact transport of A0618's cutoff construction into the original A_τ complex, Q , the full actual-zero jets and the retained right-adjoint dual. Pure transported parabolic concentration preserves the entire autocorrelation and the source Weil scalar; this does not rule out effects from the actual NS solution's changing anisotropic profile, interactions or cutoff. The explicit extra force in (11)–(12) shows why a time-dependent coordinate transport cannot be called a new smooth-forced solution without calculating that term. Neither a vanished supported quotient kernel nor a global weight estimate has been assumed.

215 Finished calculations on the retained physical and arithmetic formulas

These calculations use the objects and constants displayed in A0656 and A0706. They close bounded algebraic omissions. They do not identify the modular surface, the physical wedge, or the fluid/gravity expansion with the later split-base cohomology by assumption. The source coordinates below are LF coordinates in the pinned transcript segment.

215.1 1. The modular scattering coefficient retains every zero multiplicity

A0656, lines 2964–3096, displays

$$S(k) = \pi^{-2ik} \frac{\Gamma(\frac{1}{2} + ik)}{\Gamma(\frac{1}{2} - ik)} \frac{\zeta(1 + 2ik)}{\zeta(1 - 2ik)}, \quad E_* = \frac{\hbar^2}{2mR^2} > 0, \quad \mathcal{E}(k) = E_*(k^2 + \tfrac{1}{4}).$$

Take any nontrivial zeta zero in the specified lower half-plane, with its actual multiplicity:

$$\rho = a - i\gamma, \quad 0 < a < 1, \quad \gamma > 0, \quad q = \text{ord}_{s=\rho} \zeta(s) \geq 1.$$

Solving the denominator equation exactly gives

$$k_\rho = \frac{\gamma}{2} - \frac{i(1-a)}{2}, \quad 1 - 2ik_\rho = \rho, \quad 1 + 2ik_\rho = 2 - \rho, \quad \frac{1}{2} - ik_\rho = \frac{\rho}{2}, \quad \frac{1}{2} + ik_\rho = 1 - \frac{\rho}{2}.$$

Both Gamma arguments have positive real part. Gamma is finite and nonzero there. Also $\Re(2 - \rho) = 2 - a > 1$, where the absolutely convergent Euler product is nonzero. Consequently the analytic numerator

$$N(k) = \pi^{-2ik} \frac{\Gamma(\frac{1}{2} + ik)}{\Gamma(\frac{1}{2} - ik)} \zeta(1 + 2ik)$$

is nonzero at k_ρ . Taylor expansion at the actual zero gives

$$\zeta(1 - 2ik) = \frac{\zeta^{(q)}(\rho)}{q!} (-2i)^q (k - k_\rho)^q + O((k - k_\rho)^{q+1}).$$

Thus the pole order is exactly q , and its leading Laurent coefficient is exactly

$$a_{-q} = \frac{q! N(k_\rho)}{(-2i)^q \zeta^{(q)}(\rho)} \neq 0.$$

The map to energy has derivative $2E_* k_\rho \neq 0$, so it is locally invertible at this pole. The energy-plane pole has the same order and leading coefficient

$$b_{-q} = a_{-q} (2E_* k_\rho)^q.$$

Direct squaring, without removing either real correction, gives

$$\mathcal{E}_\rho = E_* \left[\frac{\gamma^2}{4} - \frac{(1-a)^2}{4} + \frac{1}{4} \right] - i \frac{E_* \gamma (1-a)}{2}.$$

Let $\sum_{j=1}^q b_{-j} (\mathcal{E} - \mathcal{E}_\rho)^{-j}$ be the complete principal part. The positively oriented local contour contribution with the explicitly specified convention $(2\pi i)^{-1} \oint e^{-i\mathcal{E}t/\hbar} \mathfrak{S}(k(\mathcal{E})) d\mathcal{E}$ equals

$$e^{-i\mathcal{E}_\rho t/\hbar} \sum_{j=1}^q \frac{b_{-j}}{(j-1)!} \left(-\frac{it}{\hbar} \right)^{j-1}.$$

Indeed, expand the exponential in powers of $\mathcal{E} - \mathcal{E}_\rho$; its coefficient of power $j - 1$ is the displayed factor, which is exactly the residue paired with the order- j pole. A lower-half-plane contour used in a global inverse transform may carry a different overall orientation; the convention above fixes this sign and makes no unproved contour deformation. Every multiple zero contributes the complete polynomial of degree $q - 1$, with nonzero top coefficient, multiplying the decaying exponential. Its exponential amplitude factor is

$$\exp \left[-\frac{E_* \gamma (1-a)t}{2\hbar} \right].$$

The source's simple-pole width $\Gamma_\rho = E_* \gamma (1-a)$ is therefore retained, and the previously undisplayed multiplicities are now explicit. This calculation concerns the principal part of the continued scattering coefficient. It does not assert a complete time-domain expansion for every wavepacket, or convert poles of a continued coefficient into nonreal eigenvalues of a self-adjoint Hamiltonian. Those claims require a specified inversion contour, packet class, and bounds on the remaining integral.

215.2 2. Channel redistribution is exact and need not be positive

A0656, lines 3104–3137, uses a Hilbert space $\mathcal{H}$, a unitary $U : \mathcal{H} \rightarrow \mathcal{H}$, and an orthogonal projection $P = P^* = P^2$. For every $\psi \in \mathcal{H}$,

$$\langle \psi, (U^*PU - P)\psi \rangle = \langle U\psi, PU\psi \rangle - \langle \psi, P\psi \rangle = \|PU\psi\|^2 - \|P\psi\|^2.$$

Moreover,

$$\frac{1}{2}U^*[2P - I, U] = \frac{1}{2}U^*((2P - I)U - U(2P - I)) = U^*PU - P.$$

No domain issue occurs: both operators are bounded. Unitarity does not imply positivity of this operator. In $\mathbb{C}^2$ with its usual inner product, take

$$P = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad U = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Then

$$U^*PU - P = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}.$$

The two coordinate unit vectors have expectations -1 and $+1$. This retains the precise useful interpretation of a change in the selected observable. Any use of this identity to prove an arithmetic positivity statement still requires the actual arithmetic subspace and pairing; the identity by itself supplies no such sign.

215.3 3. Equal marginal histories leave a phase family even after cross-energy measurement

A0706, lines 3835–3901, displays a thermofield vector and the partial-trace map. Work on the exact countable energy eigenbasis appearing there. Put

$$p_n = \frac{e^{-\beta E_n}}{Z(\beta)}, \quad \rho_\beta = \sum_n p_n |n\rangle\langle n|, \quad \sum_n p_n = 1.$$

For every real phase sequence $\theta = (\theta_n)$, the norm-convergent vector

$$|\Psi_\theta\rangle = \sum_n \sqrt{p_n} e^{i\theta_n} |n\rangle_L |n\rangle_R$$

has norm one because its summands are mutually orthogonal. In the partial trace of $|\Psi_\theta\rangle\langle\Psi_\theta|$, the right basis inner product is $\langle m|n\rangle = \delta_{mn}$; hence both marginal density operators are exactly ρ_β . The product density $\rho_\beta \otimes \rho_\beta$ has the same marginals. This proves the source's many-to-one statement.

When $\sum_n p_n E_n^2 < \infty$, diagonal summation gives

$$\langle H_L H_R \rangle_{\Psi_\theta} = \sum_n p_n E_n^2, \quad \langle \delta H_L \delta H_R \rangle_{\Psi_\theta} = \sum_n p_n E_n^2 - \left(\sum_n p_n E_n \right)^2.$$

This value is independent of all phases. It is zero in the product state after centering because the expectation factors. Thus the particular cross-energy observable in A0706 distinguishes the displayed product state from a nonzero-variance thermofield vector, but it does not recover the phase pattern inside the entire pure-state family.

An explicit bounded cross observable that does retain this missing phase is

$$O_{mn} = (|m\rangle\langle n|)_L \otimes (|m\rangle\langle n|)_R, \quad m \neq n.$$

Direct action on the series gives

$$\langle \Psi_\theta | O_{mn} | \Psi_\theta \rangle = \sqrt{p_m p_n} e^{i(\theta_n - \theta_m)}.$$

Its Hermitian real and imaginary parts measure respectively the cosine and sine of this relative phase, with the exact factor $\sqrt{p_m p_n}$. This is a concrete continuation beyond the source's single cross-energy observable.

For completeness, partial trace after arbitrary local unitary driving obeys

$$\text{Tr}_R[(U_L \otimes U_R)\rho(U_L^* \otimes U_R^*)] = U_L(\text{Tr}_R \rho)U_L^*.$$

To prove it, pair both sides with any bounded A_L ; cyclicity of the trace replaces $(A_L \otimes I)$ by $(U_L^* A_L U_L \otimes I)$, and the defining property of partial trace gives equality of all such expectations. The same argument applies on the right. Therefore equal initial marginals give equal histories for the same specified local unitary drives. This is an obstruction to reconstructing the joint state from those histories alone. It does not obstruct a reconstruction that includes the displayed cross observables, a joint evolution law, or an independently specified joint state.

215.4 4. The arithmetic occupation map, modular clock, and trace-class boundary

A0706, lines 3903–3980, gives the BC Hamiltonian

$$H|n\rangle = E_* \log n |n\rangle, \quad E_* > 0.$$

Let $\mathfrak{P}$ denote the primes. The bosonic Fock occupation basis over $\ell^2(\mathfrak{P})$ is indexed by sequences $m = (m_p)_{p \in \mathfrak{P}}$ of nonnegative integers of finite total sum. Such a sequence has finite support. Unique factorization is a bijection

$$n \longleftrightarrow (v_p(n))_{p \in \mathfrak{P}}, \quad (m_p)_p \longmapsto \prod_p p^{m_p}.$$

Sending one orthonormal basis to the other gives a surjective isometry $\mathcal{U}$, hence a unitary. On its full diagonal-operator domain,

$$\mathcal{U}H\mathcal{U}^* = \sum_p E_* \log p N_p.$$

The equality of domains is explicit: a Fock coefficient sequence c_m belongs to this domain exactly when

$$\sum_m \left(\sum_p E_* m_p \log p \right)^2 |c_m|^2 < \infty,$$

which is the image of $\sum_n (E_* \log n)^2 |c_n|^2 < \infty$. Thus this is an operator equality, including its domain, rather than a formal equality of symbols.

Write $\sigma = \beta E_*$. The positive trace is

$$\text{Tr}(e^{-\beta H}) = \sum_{n \geq 1} n^{-\sigma}.$$

It is finite exactly when $\sigma > 1$, by comparison with $\int_1^\infty x^{-\sigma} dx$; for $\sigma \leq 0$ the terms do not even tend to zero. For any finite prime set F , summing the independent geometric occupation series gives

$$\sum_{\text{supp}(m) \subset F} \prod_{p \in F} p^{-\sigma m_p} = \prod_{p \in F} (1 - p^{-\sigma})^{-1} \quad (\sigma > 0).$$

Increasing F through all primes and using nonnegative monotone sums recovers $\sum_n n^{-\sigma}$. Hence the full Gibbs density and doubled vector exist in the displayed Hilbert-space representation exactly for $\beta E_* > 1$. In that range,

$$|\text{TFD}_\beta\rangle = \zeta(\beta E_*)^{-1/2} \sum_{n \geq 1} n^{-\beta E_*/2} |n\rangle_L |n\rangle_R,$$

and its prime factors are exactly those displayed in A0706. Every energy moment used in the preceding calculation is finite because $\sum_n n^{-\sigma} (\log n)^j < \infty$ for every fixed nonnegative integer j and $\sigma > 1$, as follows from the same integral comparison after $x = e^y$.

The frequency dictionary is $\omega_p = E_* \log p / \hbar$. Substitution into the source's thermal-coefficient match gives

$$\beta E_* \log p = \frac{2\pi c \omega_p}{a} \iff \beta = \frac{2\pi c}{\hbar a}.$$

No prime-dependent choice remains. Combining this equality with the actual trace-class domain yields the precise domain of this global vector correspondence:

$$0 < a < \frac{2\pi c E_*}{\hbar}.$$

At the upper endpoint, $\beta E_* = 1$, the vector normalization diverges through the harmonic series, although every individual prime's geometric factor is finite. This is an omitted global boundary in the retained response. It is a limitation of this trace-class arithmetic representation, not a theorem that an arbitrary Rindler observer lacks a KMS state.

The modular sign and proper clock also agree exactly with the source convention. On the thermofield representation the modular operator for the left algebra is

$$\Delta = \rho_\beta \otimes \rho_\beta^{-1}.$$

For a bounded left observable, the convention used in A0706 gives

$$\Delta^{-is} (A \otimes I) \Delta^{is} = (e^{i\beta s H} A e^{-i\beta s H}) \otimes I.$$

The scalar partition factors cancel. Physical Heisenberg time is $\alpha_t(A) = e^{itH/\hbar} A e^{-itH/\hbar}$, so $t = \beta \hbar s = 2\pi c s / a$, exactly the source relation $s = a\tau / (2\pi c)$. This proves a thermal representation and clock correspondence. It does not construct a spatial observable net, a relativistic stress tensor, or a cooling generator.

215.5 5. The force pullback has a real terminal-control issue

A0706, lines 3660–3697, constructs a one-form through the actual preterminal fluid flow:

$$A_t = -(\Phi_t^{-1})^* \int_0^t \Phi_s^* f_s ds, \quad h_{00} = -2v^j A_j.$$

Pulling back by Φ_t , differentiating, and using the chain rule for a transported one-form gives

$$\Phi_t^*[(\partial_t + \mathcal{L}_v)A_t] = -\Phi_t^* f_t, \quad \partial_t A_i + v^j \partial_j A_i + A_j \partial_i v^j = -f_i.$$

Therefore the boundary-force expression is exactly

$$\frac{1}{2} \partial_i h_{00} - \partial_t A_i + v^j (\partial_i A_j - \partial_j A_i) = -\partial_t A_i - v^j \partial_j A_i - A_j \partial_i v^j = f_i.$$

In Lagrangian coordinates the full derivative factor is

$$A_t(\Phi_t(x)) = -D\Phi_t(x)^{-T} \int_0^t D\Phi_s(x)^T f_s(\Phi_s(x)) ds.$$

This identifies exactly what must be computed on the source's actual flow, rather than silently inferring terminal regularity from f .

The general implication from terminal-flat forcing to smooth coefficients is false even among smooth preterminal forced incompressible NS solutions. The following explicit comparison tests that implication without replacing the source's finite-energy field. Retain arbitrary viscosity $\nu > 0$, source time $0 \leq t < 1$, and put

$$u = 1 - t, \quad g(t) = e^{-1/u^2}, \quad v(t, x) = \left(-\frac{x_1}{u}, \frac{x_2}{u}, 0 \right), \quad p(t, x) = g(t)x_1 - \frac{x_2^2}{u^2}, \quad f = g(t) dx^1.$$

The force extends smoothly by zero to $t = 1$, with all terminal time derivatives zero: every derivative is a polynomial in u^{-1} times e^{-1/u^2} , which tends to zero. The velocity has divergence $-1/u + 1/u = 0$ and zero Laplacian. Its first material-acceleration component is zero and its second is $2x_2/u^2$; adding $\nabla p = (g(t), -2x_2/u^2, 0)$ gives exactly f . Thus

$$\partial_t v + v \cdot \nabla v - \nu \Delta v + \nabla p = (g(t), 0, 0)$$

for every retained $\nu > 0$.

The flow and pulled-back force are

$$\Phi_t(x) = (ux_1, u^{-1}x_2, x_3), \quad \Phi_s^* f_s = (1-s)g(s) dx^1.$$

Writing $I(t) = \int_0^t (1-s)g(s) ds$, the prescribed construction yields

$$A_t = -\frac{I(t)}{u} dx^1, \quad h_{00} = -\frac{2I(t)x_1}{u^2}.$$

Here $I(t)$ tends to the strictly positive finite number $\int_0^1 (1-s)e^{-1/(1-s)^2} ds$, so these coefficients do not extend smoothly to the endpoint. This example is not compactly supported and does not have finite total kinetic energy; it therefore does not settle the actual NS manuscript's terminal behavior. It proves exactly that the displayed preterminal force-map identity alone cannot make that inference. The strongest continuation remains evaluating its full flow derivatives and the gravitational corrections on the actual retained NS profile.

216 Exact source-viscosity and cutoff-clock morphism

The retained A0656 states a viscosity-one NS stage (LF2866). A0706 displays cutoff viscosity r_c (LF3571–3577) and later the coordinate embedding $\tau = t$ with unchanged spatial coordinates (LF3611–3627). The retained response does not display the equation-preserving conversion between those parameters. The linked full research package was not acquired by this bounded worker; this finding is about the retained response.

Keep the original source viscosity $\nu_s > 0$, source coordinates (t, x) , and the complete forced source equations

$$\partial_t u_i + u^j \partial_j u_i - \nu_s \Delta u_i + \partial_i p = f_i, \quad \partial_i u^i = 0.$$

Keep the target cutoff parameter $r_c > 0$ and its coordinates (τ, x) . Set

$$b = \frac{r_c}{\nu_s}, \quad t = b\tau, \quad v_i(\tau, x) = b u_i(b\tau, x),$$

$$P(\tau, x) = b^2 p(b\tau, x), \quad f_i^{\text{cut}}(\tau, x) = b^2 f_i(b\tau, x).$$

Here b has the time-coordinate conversion units required by the displayed equations; no equality of source and cutoff clocks is presumed. The map on points is

$$j_c^{\nu_s, r_c} : (t, x) \mapsto \left(\tau = \frac{\nu_s}{r_c} t, r = r_c, x \right).$$

Direct differentiation gives

$$\partial_\tau v_i = b^2 \partial_t u_i, \quad v^j \partial_j v_i = b^2 u^j \partial_j u_i, \quad r_c \Delta v_i = r_c b \Delta u_i = b^2 \nu_s \Delta u_i, \quad \partial_i P = b^2 \partial_i p.$$

All right-hand source fields are evaluated at $(b\tau, x)$. Consequently

$$\partial_\tau v_i + v^j \partial_j v_i - r_c \Delta v_i + \partial_i P = f_i^{\text{cut}}, \quad \partial_i v^i = b \partial_i u^i = 0.$$

The map is invertible: $\tau = t/b$, $u_i(t, x) = b^{-1} v_i(t/b, x)$, $p(t, x) = b^{-2} P(t/b, x)$, and $f_i(t, x) = b^{-2} f_i^{\text{cut}}(t/b, x)$. This is an exact bijection between the displayed forced-equation data, with the original viscosity retained. It is not a modification of the source solution.

The source's cutoff proper clock is $dt_c = \sqrt{r_c} d\tau/c$. With origins chosen at source $t = 0$, the same morphism gives

$$t_c = \frac{\nu_s}{c\sqrt{r_c}} t.$$

The original source endpoint ($t = 1, x = 0$) is therefore sent, under this particular same-spatial-coordinate map, to

$$\left(\tau = \frac{\nu_s}{r_c}, r = r_c, x = 0 \right), \quad t_c = \frac{\nu_s}{c\sqrt{r_c}}.$$

The simple identification $\tau = t$, $v = u$, $P = p$, and unchanged spatial coordinates intertwines these equations only in the parameter-matching case $r_c = \nu_s$: otherwise the target residual differs by $(\nu_s - r_c) \Delta u_i$. One may instead use a different explicitly typed spatial-coordinate conversion, but it must be written and its action on the source support, wavelengths, force, and norms must be carried through.

For this exact map, the source spatial support and wave numbers at corresponding times are unchanged, whereas

$$\int |v(\tau, x)|^2 dx = b^2 \int |u(b\tau, x)|^2 dx,$$

$$\int_{\tau_0}^{\tau_1} \int |\nabla v|^2 dx d\tau = b \int_{b\tau_0}^{b\tau_1} \int |\nabla u|^2 dx dt.$$

These follow from the pointwise factor b in v and the exact change $dt = b d\tau$. The displayed Brown–York coefficient therefore becomes

$$[\mathfrak{B}_2(v, P)]_{\tau\tau} = \frac{c^4 b^2}{16\pi G_5 \sqrt{r_c}} |u(b\tau, x)|^2.$$

Finally, this change of clock does not remove the actual higher-derivative problem. At the corresponding source Fourier wave number k , the magnitude ratio of the displayed correction $-\frac{3}{2}r_c^2 \Delta^2 v_i$ to $-r_c \Delta v_i$ remains exactly $\frac{3}{2}r_c |k|^2$. Its growth must still be calculated on the source’s actual decreasing wavelengths.

217 Complete mathematical continuation ledger

This volume preserves the complete passage audits, including their historical repairs and exact scope statements. The separate proof volume contains the newly completed calculations. Long coverage tables have been expanded into labelled row entries without dropping cells.

218 Overview

219 Mathematical continuation audit of the original tau-base programme

This audit concerns the complete published conversation at <https://chatgpt.com/share/6aa6bc6e-98cc-83eb-9343-e811c26d6631>. It evaluates calculations and their exact scope. The starting mathematical object for continuation is the construction explicitly accepted at U0046: the original split cohomology over the absolute base b_τ , with its actual pushforward A_τ , right adjoint K_τ , theta source, full finite jets and tensor operations.

The public source was fully recovered and its ordering verified. All 67 user turns and 148 readable assistant prose records were read in five contiguous segments. The complete 5,350-node source, including other assistant and tool records, is retained separately. The share redacts 2,600 tool payloads; the audit does not claim to recover those hidden contents. Source-file proofs are checked against separately retained files, rather than inferred from redacted tool responses.

The transcript contains historical scope substitutions and unfinished calculations, but it also contains substantial later repairs. In particular, the early generic comparison, selected Jordan model, and finite-field illustration precede the accepted tau-base construction. The later source must not be used to suggest that it already existed when those earlier replies were written. Conversely, once A1523 constructs the actual tau-base model and U0046 accepts it, that model is the object every subsequent continuation must preserve.

The main accepted programme locators are:

- U0043, node d908924e-830b-46ad-8d9c-f2b78a536989: the request to use tau as the absolute base, rather than merely repeat the finite-field result in split notation.
- A1523, node b670b6c0-a774-4398-b978-9c9779fca379: the original absolute base, $A_\tau = R\Gamma(P, -)$, separate derived restriction to σ , supported Q , computed K_τ , finite residue arrow and tensor pushforward.
- U0046, node 0af0ed52-c7ab-45fb-85a5-1911193398cb: explicit acceptance of that context and instruction to continue using the resulting objects.
- A1694, node 1fa0ebbc-f569-40c1-b7ac-b523da19a5f0: the actual continuous theta retraction and global representative section, including its nonzero scaling cocycle and complete boundary-pairing expression.
